sufficiently so that the sun has passed its zenith before significant amounts of NO<sub>2</sub> are created, photodissociation of NO<sub>2</sub> will be diminished and less ozone will accumulate on that date. At moderately high [HC]/[NO<sub>X</sub>] ratios (usually greater than about 5 to 8:1), the greater availability of organic radicals means that all of these radicals are not consumed as rapidly in reactions with NO, and more reactions between the radicals and NO<sub>2</sub> are able to occur. Thus, the amount of ozone formed and accumulated begins to become limited by the availability of NO<sub>X</sub>, and becomes less sensitive to additional organic precursors. At very high [HC]/[NO<sub>X</sub>] ratios (greater than about 20 to 30:1), ozone cannot accumulate because either the ozone is consumed by reaction with hydrocarbons or radicalradical termination reactions occur which reduce oxygen atom and, hence, ultimate ozone concentration.

Identification of the nitrogen-containing products in atmospheric reactions has been under investigation for a number of years.<sup>28-30</sup> In general, the most important gaseous nitrogen-containing products in the NO<sub>X</sub>-organic system are nitric acid and PAN. As noted, reactions of NO and NO<sub>2</sub> with free radicals produce, in addition to nitrous, nitric, and peroxynitric acids, a variety of organic nitrogen-containing species (Table 6-1). There currently exist important areas of uncertainty with regard to the formation of nitrogencontaining products in atmospheric reactions. The extent of 1.1.1.1.1.1.1 141
