CHAMBERS'S

INFORMATION FOR THE PEOPLE.

A POPULAR ENCYCLOPÆDIA.

FIFTEENTH AMERICAN EDITION,

WITH

NUMEROUS ADDITIONS AND MORE THAN FIVE HUNDRED ENGRAVINGS.

VOL. I.

PHILADELPHIA:
PUBLISHED BY JAS. B. SMITH & CO.,
NO. 610 CHESTNUT STREET
1859.

PREFACE

TO THE AMERICAN EDITION.

The following was intended by its accomplished authors, Messrs. William and Robert Chambers, of Edinburgh, to form a complete *Popular Cyclopædia*, or book of general *Information for the People.* It is the first attempt to place a considerable work of the character of an encyclopædia within the reach of all classes of the people. The plan on which the work was formed was to select only the subjects on which it is important for the people generally to be informed. The minutiæ of biography and topography, scientific technicalities, and other matters required only for occasional reference, are omitted; and thus what usually fills up the greater part of an encyclopædia is at once dismissed. There remains for the full accomplishment of the plan, "a series of articles on the most important branches of science, physical, mathematical and moral, natural history, political history, geography and literature." This furnishes such a course of reading, as, if studied and received into the mind, will make a well-informed man. The portions of a large and costly encyclopædia, which have been omitted, are such as do not form any part of the standing knowledge of any person whatever, besides those for whom it may have a technical, professional, or local interest. "It will be understood, then, that the 'Information for the People' is not meant as an encyclopædia unfailing in reference for all departments of human knowledge, but as an encyclopædia including such knowledge only as tends to improve every mind possessing it—such knowledge as expands, liberates, and fertilizes—with the addition of only a very few articles of which the interest and value are of a more limited nature. The ruling object has been to give what may be expected to prove the means of *self-education* to all such classes of society as are debarred from the receipt of knowledge in more favourable circumstances."

CHAMBERS'S

INFORMATION FOR THE PEOPLE.

ASTRONOMY.

ASTRONOMY (from the Greek, *astron*, a star, and *nomos*, a law) is, comprehensively, that science which explains the nature and motions of the bodies filling infinite space, including our own globe, in its character of a planet or member of the solar system. The science may be divided into two departments—1. *Descriptive Astronomy*, or an account of the systems of bodies occupying space; 2. *Mechanical Astronomy*, or an explanation of the physical laws which have produced and which sustain the arrangements of the heavenly bodies, and of all the various results of the arrangement and relations of these bodies. *Uranography* is a subordinate department of the science, presenting an account of the arrangements which have been made by astronomers for delineating the starry heavens, and working the many mathematical problems of which they are the subject.

DESCRIPTIVE ASTRONOMY.

The early ideas of mankind respecting the objects described by astronomy, proceeded upon appearances which the uninstructed eye placed before them, and were far from being true. It was supposed that the earth was, as it seems, a fixed plane, or, at the most, a fixed sphere, with an outer sphere, forming the heavens, revolving around it once in the twenty-four hours. Even philosophers deemed the earth the central and most important object in the system, and regarded the heavenly bodies, the sun, moon, planets, and stars, as comparatively small objects, fixed in the different crystal spheres, each of which observed its own laws of revolution, according to the apparent motions of the bodies fixed in it. It was not till after much study and investigation that even the most enlightened minds arrived at a knowledge of the truth; nor was it for some time longer that the idea of the earth not being in the centre of the system, or any thing but a small and subordinate part of it, was generally admitted. There is no room here to trace all the steps by which the truth was ascertained, or to argue the uninstructed mind out of all its first and erroneous impressions. But it may be hoped that when the actual constitution of the heavens has been described, it will be possible to form some notion of how the objects in their real character and real arrangements come to appear as they do to our eyes.

The field contemplated by the astronomer is no less than INFINITE SPACE. So, at least, he may well presume space to be, seeing that every fresh power which he adds to his telescope allows him to penetrate into remoter regions of it, and still there is no end. In this space, systems, consisting of suns and revolving planets, and other systems again, consisting of a numberless series of such lesser systems, are suspended by the influence of gravitation, operating from one to another, yet each body at such a distance from another, as, though the mind of man can in some instances measure, it can in none conceive. We begin with what is usually called the Solar System—that is, the particular solar system to which our earth belongs.

THE SOLAR SYSTEM.

The solar system, so named from *sol* (Latin), the sun, consists of the sun in the centre, twenty-nine planets, and an unknown number of bodies named comets. The word planet is from the Greek, *planao*, to wander, because the few such bodies known to the ancients were chiefly remarkable in their eyes on account of their constantly shifting their places with reference to the other luminaries of the sky. Comets are so named from *coma* (Latin), a head of hair, because they seem to consist of one bright spot, and a long brush streaming from behind it.

Planets.—Eleven of the planets are called *primary*, because they move directly around the sun, and eighteen *secondary*, because they move round primary planets. The secondary planets are also denominated satellites, from *satelles* (Latin), originally signifying a life-guardsman, but, by a wider application, one who follows and serves another. Only four of the primary planets have satellites.

The primary planets are Mercury, Venus, the Earth, Mars, Vesta, Ceres, Pallas, Juno, Jupiter, Saturn, and Herschel, or Uranus. Most of these names are derived from the fabulous divinities of ancient Greece. The Earth has one satellite, the Moon; Jupiter has four; Saturn, seven; and Uranus is supposed to have six.

The planets move round the sun on nearly one level or plane, corresponding with the centre of his body, and in one direction, from west to east. The secondary planets, in like manner, move in planes round the centres of their primaries, and in the same direction, from west to east. These are denominated revolutionary motions; and it is to be observed that they are double in the case of the satellites, which have at once a revolution round the primary, and a revolution, in company with the primary, round the sun. The path described by a plane in its revolution is called its *orbit*.

Each planet, secondary as well as primary, and the sun also, has a motion in its own body, like that of a bobbin upon a spindle. An imaginary line, forming, as it were the spindle of the sun or planet, is denominated the *axis* and the two extremities of the axis are called the *poles*. The axes of the sun and planets are all nearly at a right angle with the plane of the revolutionary movements. The motion on the axis is called the rotatory motion, from *rota*, the Latin for a wheel. The sun, the primary planets, and the satellites, with the doubtful exception of two attending on Uranus, move on their axes in the same direction as the revolutionary movements, from west to east.

The Sun is a sphere or globe, of 882,000 miles in diameter, or 1,384,472 times the bulk of the earth, moving round its axis in 25 days. When viewed through a telescope, the surface appears intensely bright and luminous, as if giving out both heat and light to the surrounding planets. But on this surface there occasionally appear dark spots, generally surrounded with a border of less dark appearance; some of which spots have been calculated to be no less than 45,000 miles in breadth, or nearly twice as much as the circumference of the earth. The region of the sun's body on which the spots appear, is confined to a broad space engirdling his centre. They are sometimes observed to come into sight at his western limb, to pass across his body in the course of twelve or thirteen days, and then disappear. They are sometimes observed to contract with great rapidity, and disappear like something melted and absorbed into a burning fluid. Upon the bright parts of the sun's body there are also sometimes observed streaks of unusual brightness, as if produced by the ridges of an agitated and luminous fluid. It has been surmised, that the sun is a dark body, enveloped in an atmosphere calculated for giving out heat and light, and that the spots are produced by slight breaks or openings in that atmosphere, showing the dark mass within. Though so much larger than the earth, the matter of the sun is of only about a third of the density or compactness of that of our planet, or little more than the density of water.

The sun is surrounded to a great distance by a faint light, or luminous matter of extreme thinness, shaped like a lens or magnifying-glass, the body of the sun being in the centre, and the luminous matter extending in the plane of the planetary revolutions, till it terminates in a point. At particular seasons, and in favourable states of the atmosphere, it may be observed, before sunrise or after sunset, in the form of a cone pointing obliquely above the place where the sun is either about to appear or which he has just left. It is termed the *Zodiacal Light*.

The Solar System.

Mercury, the nearest planet to the sun, is a globe of about 3140 miles in diameter, rotating on its axis in 24 hours and 5½ minutes, and revolving round the central luminary, at a distance of 37,000,000 of miles, in 88 days. From the earth it can only be seen occasionally in the morning or evening, as it never rises before, or sets after the sun, at a greater distance of time than 1 hour and 50 minutes. It appears to the naked eye as a small and brilliant star, but when observed through a telescope, is horned like the moon, because we only see a part of the surface which the sun is illuminating. Mountains of great height have been observed on the surface of this planet, particularly in its lower or southern hemisphere. One has been calculated at 10¾ miles in height, being about eight times higher, in proportion to the bulk of the planet, than the loftiest mountains upon earth. The matter of Mercury is of much greater density than that of the earth, equalling lead in weight; so that a human being placed upon its surface would be so strongly drawn towards the ground as scarcely to be able to crawl.

Venus is a globe of about 7800 miles in diameter, or nearly the size of the earth, rotating on its axis in 23 hours, 21 minutes, and 19 seconds, and revolving round the sun, at the distance of 68,000,000 of miles in 225 days. Like Mercury, it is visible to an observer on the earth only in the morning and evening, but for a greater space of time before sunrise and after sunset. It appears to us the most brilliant and beautiful of all the planetary and stellar bodies, occasionally giving so much light as to produce a sensible shadow. Observed through a telescope, it appears horned, on account of our seeing only a part of its luminous surface. The illuminated part of Venus occasionally presents slight spots. It has been ascertained that its surface is very unequal, the greatest mountains being in the southern hemisphere, as in the case of both Mercury and the Earth. The higher mountains in Venus range between 10 and 22 miles in altitude. The planet is also enveloped in an atmosphere like that by which animal and vegetable life is supported on earth and it has consequently a twilight. Venus performs its revolution round the sun in 225 days. Mercury and Venus have been termed the Inferior Planets, as being placed within the orbit of the Earth.

The Earth, the third planet in order, and one of the smaller size, though not the smallest, is important to us, as the theatre on which our race have been placed to "live, move, and have their being." It is 7902 miles in mean diameter, rotating on its axis in 24 hours, at a mean distance of 95,000,000 of miles from the sun, round which it revolves in 365 days, 5 hours, 56 minutes, and 57 seconds. As a planet viewed from another of the planets, suppose the moon, "it would present a pretty, variegated, and sometimes a mottled appearance. The distinction between its seas, oceans, continents, and islands, would be clearly marked: they would appear like brighter and darker spots upon its disc. The continents would appear bright, and the ocean of a darker hue because water absorbs the greater part of the solar light that falls upon it. The level plains (excepting, perhaps, such regions as the Arabian deserts of sand) would appear of a somewhat darker colour than the more elevated and mountainous regions, as we find to be the case on the surface of the moon. The islands would appear like small bright specks on the darker surface of the ocean; and the lakes and mediterranean seas like darker spots or broad streaks intersecting the bright parts, or the land. By its revolution round its axis, successive portions of the surface would be brought into view, and present a different aspect from the parts which preceded."*

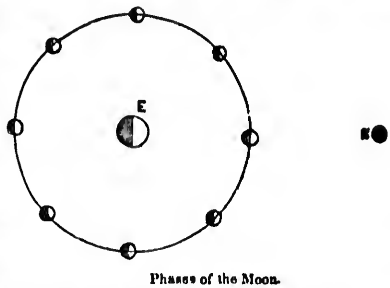
The form of the earth, and probably that of every other planet, is not strictly spherical, but spheroidal; that is, flattened a little at the poles, or extremities of the axis. The diameter of the earth at the axis is 26 miles less than in the cross direction. This peculiarity of the form is a consequence of the rotatory motion, as will be afterwards explained.

The earth is attended by one satellite, the *Moon*, which is a globe of 2160 miles in diameter, and consequently about a 49th part of the bulk of the earth, revolving round its primary in 27 days, 7 hours, 43 minutes, and 11 seconds, at the distance of 240,000 miles. The moon is 400 times nearer the earth than the sun is; but, its diameter being at the same time 400 times less than that of the sun, it appears to us of about the same size. The moon rotates on her axis in exactly the same time as she revolves round the earth. She consequently presents at all times the same part of her surface towards the earth.

Telescopic appearance of the Moon.

Inspected through a telescope, her surface appears of unequal brightness, and extremely rugged. The dark parts, however, are not seas, as has been supposed, but more like the beds of seas, or great alluvial plains. No appearance of water, or of clouds, or of an atmosphere, has been detected. The surface presents numerous mountains, some of them about a mile and three quarters in height, as has been ascertained by measurement of the shadows which they cast on the neighbouring surface. The tops of the mountains of the moon are generally shaped like a cup or basin, with a small eminence rising from the centre, like many volcanic hills on the earth. It has hence been surmised that the moon is in a *volcanic state*, as the earth appears to have been for many ages before the creation of man, and that it is perhaps undergoing processes calculated to make it a fit scene for animal and vegetable life.

The moon, turning on its axis once in a little more than 27 days, presents every part of its surface in succession to the sun in that time, as the earth does in 24 hours. The *day* of the moon is consequently nearly a fortnight long, and its *nights* of the same duration. The light of the sun, falling upon the moon, is partly absorbed into its body; but a small portion is reflected or thrown back, and becomes what we call *moonlight*. The illuminated part, from which we derive moonlight, is at all times increasing or diminishing in our eyes, as the moon proceeds in her revolution around our globe. When the satellite is at the greatest distance from the sun, we, being between the two, see the whole of the illuminated surface,



Phases of the Moon.

which we accordingly term *full moon*. As the moon advances in her course, the luminous side is gradually averted from us, and the moon is said to wane. At length, when the satellite has got between the earth and the sun, the luminous side is entirely lost sight of. The moon is then said to *change*. Proceeding in her revolution, she soon turns a bright edge towards us, which we call the *new moon*. This gradually increases in breadth, till a moiety of the circle is quite filled up; it is then said to be *half moon*. The luminary, when on the increase from *new* to *half*, is termed a crescent, from *crescens*, Latin for increasing; and this word has been applied to other objects of the same shape—for instance, to a curved line of buildings.

In the early days of the new moon, we usually see the dark part of the body faintly illuminated, an appearance termed the *old moon in the new moon's arms*. This faint illumination is produced by the reflection of the sun's light from the earth, or what the inhabitants of the moon, if there were any, might be supposed to consider as moonlight. The earth, which occupies one invariable place in the sky of the moon, with a surface thirteen times larger than the apparent size of the moon in our eyes, is then *at the full*, shining with great lustre on the sunless side of its satellite, and receiving back a small portion of its own reflected light. The light, then, which makes the dark part of the moon visible to us, may be said to perform three journeys, first from the sun to the earth, then from the earth to the moon, and finally from the moon back to the earth, before our eyes are enabled to perceive this object.

* Dick's Celestial Scenery, 135.

Mars, the fourth of the primary planets, is a globe of 4189 miles in diameter, or little more than a half of that of the earth; consequently, the bulk of this planet is only about a 5th of that of our globe. It performs a rotation on its axis in 24 hours, 39 minutes, and $21\frac{1}{3}$ seconds, and revolves round the sun, at a distance of 142,000,000 of miles, in 686 days, 22 hours, and 18 seconds. Mars appears to the naked eye of a red colour; from which circumstance it was, probably, that the ancients bestowed upon it the name of the god of war. Inspected through a telescope, it is found to be occasionally marked by large spots and dull streaks, of various forms, and by an unusual brightness at the poles. As the bright polar parts sometimes project from the circular outline of the planet, it has been conjectured that these are masses of snow, similar to those which beset the poles of the earth.

Vesta, Ceres, Pallas, and *Juno* are four small globes, revolving between the orbits of Mars and Jupiter, in paths near and crossing each other, and which are not only much more elliptical than the paths of the other planets, but also rise and sink much further from the plane of the general planetary revolutions.

Vesta is of a bulk only 1-15,000th part of the bulk of the earth, with a surface not exceeding that of the kingdom of Spain. It revolves round the sun in 3 years, 66 days, and four hours, at a mean distance of 225,500,000 miles. Though the smallest of all the planets, it gives a very brilliant light, insomuch that it can be seen by the naked eye.

Juno is 1425 miles in diameter, and presents, when inspected through the telescope, a white and well-defined appearance. Its orbit is the most eccentric of all the planetary orbits, being 253,000,000 of miles from the sun at the greatest, and only 126,000,000, or less than one-half, at the least distance. In the half of the course nearest to the sun, the motion of the planet is, by virtue of a natural law afterwards to be explained, more than twice as rapid as in the other part.

Ceres has been variously represented as of 1624 and 160 miles in diameter. The astronomer who calculated its diameter at 1624 miles, at the same time believed himself to have ascertained that it has a dense atmosphere, extending 675 miles from its surface. It is of a reddish colour, and appears about the size of a star of the eighth magnitude. Ceres revolves round the sun, at a distance of 260,000,000 of miles, in four years, 7 months, and 10 days.

Pallas has been represented as of 2099 miles in diameter, with an atmosphere extending 468 miles above its surface. Another astronomer has allowed it a diameter of only 80 miles. It revolves round the sun, at a mean distance of 266,000,000 of miles, in 4 years, 7 months, and 11 days. However unimportant it may appear beside the larger planets, it has a peculiar interest in the eyes of astronomers, on account of its orbit having a greater inclination to the plane of the ecliptic than those of all the larger planets put together.

These four planets, which are sometimes called *asteroids*, have only recently become known to mankind. Ceres was discovered at Palermo in Sicily, on the 1st of January, 1801, by M. Piazzi, who gave it this name in honour of the tutelary goddess of his native country. Pallas was discovered at Bremen, in Lower Saxony, on the 28th of March, 1802, by Dr. Olbers. Juno was discovered by Mr. Harding, at the observatory of Lilienthal, near Bremen, on the 1st of September, 1804. Vesta was discovered on the 29th of March, 1807, by the same astronomer who had discovered Pallas.

Jupiter is the largest of all the planets. Its diameter is nearly eleven times that of the earth, or 89,170 miles, and its volume or mass is consequently 1281 times that of our globe. The density of Jupiter is only a fourth of that of the earth, or about the lightness of water; and a human being, if transferred to it, would be able to leap with ease over a pretty large house. It performs a rotation on its axis in 9 hours, 55 minutes, and 33 seconds, or about two-fifths of our day. It revolves round the sun, at a distance of 490,000,000 of miles, in 4330 days, 14 hours, and 39 minutes, or nearly twelve of our years. Viewed through a telescope, Jupiter appears surrounded by dark lines, or belts, which occasionally shift, melt into each other, or separate, but sometimes are observed with little variation for several months. These belts are generally near the equator of the planet, and of a broad and straight form; but they have been observed over his whole surface, and of a lighter, narrower, and more streaky and wavy appearance. It is supposed that the dark parts are lines of the body of the planet, seen through openings in a bright cloudy atmosphere.

Jupiter is attended by four satellites, which revolve round it, in the same manner as the moon round our globe, keeping, like it, one face invariably presented to their primary. They are of about the same size, or a little larger diameter than our moon; the first having a diameter of 2508, the second of 2068, the third of 3377, and the fourth of 2890 miles. The first revolves round the primary planet in 1 day, 18 hours, 28 minutes; the second in 3 days, 13 hours, 14 minutes; the third in 7 days, 3 hours, 43 minutes; and the fourth in 16 days, 16 hours, 32 minutes. These satellites frequently eclipse the sun to Jupiter; they are also eclipsed by the primary planet, but never all at the same time, so that his dark side is never altogether without moonlight.

The satellites of Jupiter were discovered by Galileo, being among the first results of the invention of the telescope. They have been of great use in several astronomical calculations of importance, particularly in suggesting the theory of the gradual propogation of light. It having been observed that their eclipses always took place sooner than was to be expected when the earth was near Jupiter, and later when it was at the greatest distance, an astronomer solved the difficulty by supposing that light required some time to travel—a conjecture which was afterwards confirmed by other observations.

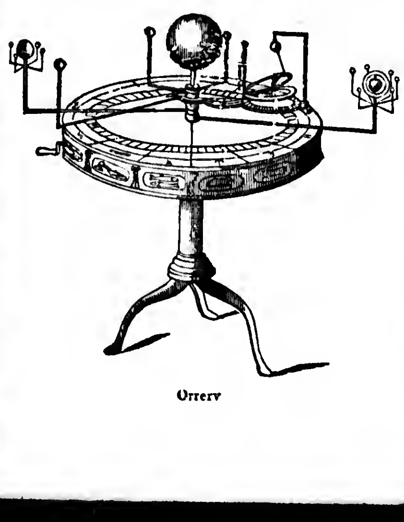
Saturn, seen through a telescope, is the most remarkable of all the planets, being surrounded by a ring, and attended by seven satellites. In bulk this is the second of the planets, being 79,042 miles in diameter, or about 995 times the volume of the earth. Its surface appears slightly marked by belts like those of Jupiter. It performs a rotation on its axis in 10 hours, 16 minutes, and revolves round the sun, at a distance of 900,000,000 of miles, in 10,746 days, 19 hours, 16 minutes, or about $29\frac{1}{2}$ of our years. At such a distance from the sun, that luminary must be diminished to one-eightieth of the size he bears in our eyes, and the heat and light in the same proportion. The matter of Saturn is one-eighth of the density of our earth.

The ring of Saturn surrounds the body of the planet in the plane of its equator. It is thin like the rim of a spinning-wheel, and is always seen with its edge presented more or less directly towards us. It is luminous with the sun's light, and casts a shadow on the surface of the planet, the shadow of which is also sometimes seen falling on part of the ring. The distance of the inner edge from the planet is calculated at about 19,000 miles; its entire breadth from the inner to the outer edge is 28,538; the thickness is not more than 100. In certain positions of the planet, we can see its surface at a considerable angle, and the openings or loops which it forms on the sides of the planet. At other times we see its dark side, or only its edge. From observations made upon it in favourable circumstances, it is found to be apparently divided near the outer edge by a dark line of nearly 1800 miles in breadth, as if it were divided into two concentric rings. From other appearances, it has been surmised to have other divisions, or to be a collection of several concentric rings. It is also occasionally marked by small spots. The ring of Saturn rotates on its own plane in 10 hours, 32 minutes, 15 seconds, and a part of a second, being about the same time with the rotation of the planet.

The seven satellites of Saturn revolve around it, on the exterior of the ring, and almost all of them in nearly the same plane. They are so small as not to be visible without a powerful telescope. The two inner ones are very near to the outer edge of the ring, and can only be discerned when that object is presented so exactly edgeways as to be almost invisible. They have then been seen passing like two small bright beads along the minute thread of light formed by the edge of the ring. The three next satellites are also very small; the sixth is larger, and placed at a great interval from the rest. The seventh is the largest; it is about the size of the planet Mars, and is situated at nearly thrice the distance of the sixth, or about 2,300,000 miles from the body of Saturn. The revolutions of these satellites range from 1 to 79 days; and it has been ascertained of some of them that, according to the usual law of secondary planets, their rotations on their axes and their revolutions round their primary are performed in the same time, so that, like our moon, they always present the same face to the centre of their system. The orbit of the seventh satellite is much inclined to the plane of Saturn's equator.

Uranus, or *Herschel*, the remotest planet known in the solar system, is a globe of 35,112 miles in diameter, rotating on its axis in 7 hours, and performing a revolution round the sun, at a distance of 1,800,000,000 of miles, in 84 of our years. It was discovered, on the 13th of March, 1781, by Sir William Herschel, at Bath. The sun to this remote planet must appear only a 400th part of the size which he bears in our eyes. Two satellites are known, and other four are suspected, to attend upon Uranus. The two which have been observed circulate round their primary in orbits almost perpendicular to the ecliptic, and are further supposed to move in a direction contrary to that of all the other planetary motions—namely, from east to west.

Some idea may be obtained of the comparative size of the principal objects of the solar system, by supposing a globe of two feet diameter, placed in the centre of a level plain, to represent the sun; a grain of mustard-seed, placed on the circumference of a circle 164 feet in diameter, for Mercury; a pea, on a circle of 284 feet, for Venus; another pea, on a circle of 430 feet, for the Earth; a large pin's head, on a circle of 654 feet, for Mars; four minute grains of sand, in circles of from 1000 to 1200 feet, for Vesta, Ceres, Pallas, and Juno; a moderate sized orange, on a circle of nearly half a mile in diameter, for Jupiter; a small orange, on a circle four-fifths of a mile in diameter, for Saturn; and a small plum or full-sized cherry, on a circle of a mile and a half in diameter, for Uranus. It is calculated that the united mass of the whole of the planets is not above a 600th part of the mass of the sun. The sun and planets are represented, with an approximation to correctness, in philosophical toys termed orreries, of which the appearance is conveyed in the preceding engraving.



Orrery

COMETS.

Comets are light vapoury bodies, which move round the sun in orbits much less circular than those of the planets. Their orbits, in other words, are very long ellipses or ovals, having the sun near one of the ends. Comets usually have two parts, a body or nucleus, and a tail; but some have a body only. The body appears as a thin vapoury luminous mass, of globular form; it is so thin, that, in some cases, the stars have been seen through it. The tail is a lighter or thinner luminous vapour surrounding the body, and streaming far out from it, in one direction. A vacant space has been observed between the body and the enveloping matter of the tail; and it is equally remarkable that the tail has in some instances appeared less bright along the middle, immediately behind the nucleus, as if it were a stream which that nucleus had in some measure parted into two.

In ignorant ages, the sudden appearance of a comet in the sky never failed to occasion great alarm, both on account of its threatening appearance, and because it was considered as a sign that war, pestilence, or famine, was about to afflict mankind. Knowledge has dispelled all such fancies; but yet we are not well acquainted with the nature of comets.

Out of the great multitude—certainly not less than 1000—which are supposed to exist, about 150 have been made the subject of scientific observation. Instead of revolving, like the planets, nearly on the plane of the sun's equator, it is found that they approach his body from all parts of surrounding space. At first, they are seen slowly advancing, with a comparatively faint appearance. As they approach the sun, the motion becomes quicker, and at length they pass round him with very great rapidity, and at a comparatively small distance from his body. The comet of 1680 approached within one-sixth of his diameter. After passing, they are seen to emerge from his rays, with an immense increase to their former brilliancy and to the length of their tails. Their motion then becomes gradually slower, and their brilliancy diminishes, and at length they are lost in distance. It has been ascertained that their movement round the sun is in accordance with the same law which regulates the planetary movements, being always the quicker the nearer to his body, and the slower the more distant. In the remote parts of space their motions must be extremely slow.

Three comets have been observed to return, and their periods of revolution have been calculated. The most remarkable of these is one usually denominated Halley's Comet, from the astronomer who first calculated its period. It revolves round the sun in about seventy-five years, its last appearance being at the close of 1835. Another, called Enke's Comet, from Professor Enke of Berlin, has been found to revolve once in 1207 days, or 3⅓ years; but, in this case, the revolving body is found, at each successive approach to the sun, to be a little earlier than on the previous occasion, showing that its orbit is gradually lessening, so that it may be expected ultimately to fall into the sun. This fact has suggested that some part of that space through which the comet passes, must be occupied by a matter presenting some resistance to the movement of any denser body; and it is supposed that this matter may prove to be the same which has been described as constituting the zodiacal sight. It is called a *resisting medium*; and future observations upon it are expected to be attended with results of a most important nature, seeing that, if there be such a matter extending beyond the orbit of the earth, that planet, in whose welfare we are so much interested, will be exposed to the same ultimate fate with Enke's Comet.

The third, named Beila's Comet, from M. Beila of Josephstadt, revolves round the sun in 6¾ years. It is very small, and has no tail. In 1832, this comet passed through the earth's path about a month before the arrival of our planet at the same point. If the earth had been a month earlier at that point, or the comet a month later in crossing it, the two bodies would have been brought together, and the earth, in all probability, would have instantly become unfit for the existence of the human family. Comets are often affected in their motions by the attraction of the planets. Jupiter, in particular, has been described by an astronomer as a perpetual stumbling-block in their way. In 1770, a comet got entangled amidst the satellites of that planet, and was thereby thrown out of its usual course, while the motions of the satellites were not in the least affected.

Comets often pass unobserved, in consequence of the part of the heavens in which they move being then under daylight. During a total eclipse of the sun, which happened sixty years before Christ, a large comet, not formerly seen, became visible, near the body of the obscured luminary. On many occasions, their smallness and distance render them visible only by the aid of the telescope. On other occasions, they are of vast size. The comet now called Halley's, at its appearance in 1456, covered a sixth part of the visible extent of the heavens, and was likened to a Turkish scymitar. That of 1680, which was observed by Sir Isaac Newton, had a tail calculated to be 123,000,000 of miles in length, a space greater than the distance of the earth from the sun. There was a comet in 1744, which had six tails, spread out like a fan across a large space in the heavens. The tails of comets usually stretch in the direction opposite to the sun, both in advancing and retiring, and with a slight wave at the outer extremity, as if that part experienced some resistance.

THE STARS.

The idea at which astronomers have arrived respecting the stars, is, that they are all of them suns, resembling our own, but diminished to the appearance of mere specks of light by the great distance at which they are placed. As a necessary consequence to this supposition, it may be presumed that they are centres of light and heat to systems of revolving planets, each of which may be further presumed to be the theatre of forms of beings, bearing some analogy to those which exist upon earth.

The stars, seen by the naked eye on a clear night, are not above a thousand in number. This, allowing a like number for the half of the sky not seen, gives about two thousand in all of visible stars. These are of different degrees of brilliancy, probably in the main in proportion to their respective distances from our system, but also perhaps in some measure in proportion to their respective actual sizes. Astronomers class the stars under different *magnitudes*, not with regard to apparent size, for none of them present a measurable disc, but with a regard to the various quantities of light flowing round them: thus, there are stars of the first magnitude, the second magnitude, and so on. Only six or seven varieties of magnitude are within our natural vision; but with the telescope vast numbers of more distant stars are brought into view; and the magnitudes are now extended by astronomers to at least sixteen.

The stars are at a distance from our system so very great, that the mind can form no idea of it. The brilliant one called Sirius or the Dog-star, which is supposed to be the nearest, but merely because it is the most luminous, has been reckoned by tolerably clear calculation to give only 1-20,000,000th part of the light of the sun hence, supposing it to be of the same size, and every other way alike, it should be distant from our earth not less than 1,960,000,000,000,000,000 miles. An attempt has been made to calculate the distance of Sirius by a trigonometrical problem. It may be readily supposed that the position of a spectator upon the earth with respect to celestial objects must vary considerably at different parts of the year: for instance, on the 21st of June, he must be in exactly the opposite part of the orbit from what he was on the 21st of December—indeed, no less than 190,000,000 of miles from it, or twice the distance of the earth from the sun. This change of position with relation to celestial objects is called *parallax*. Now, it has been found that Sirius is so distant, that an angle formed between it and the two extremities of the earth's orbit is too small to be appreciated. Were it so much as one second, or the 3600th part of a degree, it could be appreciated by the nice instruments we now possess; but it is not even this. It is hence concluded that Sirius must be at least 19,200,000,000 of miles distant, however much more! Supposing this to be its distance, its light would take three years to reach us, though travelling, as it does, at the rate of 192,000 miles in a second of time!

It is ascertained beyond doubt, that some stars, at one time visible, and registered by ancient astronomers, are not now to be seen; while many instances are on record of stars which have come into sight for a time, and then gradually vanished. A large star suddenly became visible 125 years before Christ, and attracted the attention of Hipparchus, who was thereby induced to draw up a catalogue of stars, the first ever made. In the year 389, a star blazed forth in the constellation Aquila,* and after remaining for three weeks as bright as the planet Venus, disappeared. A star appeared in the region of the heavens between Cepheus and Cassiopeia, in the years 945, 1264, and 1572, and is supposed to be one which comes within our sight once every three hundred and nineteen years, or thereby. At its last appearance, it was very attentively observed by the celebrated Danish astronomer Tycho Brahe, who published a volume respecting it. Its appearance was so sudden, that in returning from his laboratory to his dwelling-house, he found a group of country people gazing at it, and was satisfied it had not been in that quarter of the sky half an hour before. It was then as bright as Sirius, and continued till it surpassed Jupiter when brightest, and was visible at mid-day. It disappeared entirely about eighteen months after being first observed. Another bright star appeared, in the constellation Serpentarius, in October 1604, and remained for a year. It is mentioned by contemporary writers, that at the birth of Charles II. in 1630, a large star, never before observed, appeared in the day-time, as if to mark something extraordinary in the fortunes of the child that day ushered into existence. Other instances have been noticed in still more recent times; but, upon the whole, this is a point in which astronomical observation is defective. It seems, however, to be clearly ascertained, that some, if not all of the stars, have periodical motions throughout space, some more rapid than others. In several of the instances where the period is short, there is no want of positive knowledge. It has been ascertained, for instance, that the star Omicron, in Cetus, has a periodical movement occupying

* It may be stated here, in anticipation of more particular explanations to be given afterwards that the starry heavens are by astronomers mapped out into a series of constellations, or assemblages of stars, each of which bears the name of some figure or other object, as *Aquila* the Eagle, *Cetus* the Whale, *Castor and Pollux*, twin demigods of the Greek mythology, &c. Each particular star in a constellation, in the order of its magnitude, is distinguished by a letter of the Greek alphabet and, when these are exhausted, with a number.

334 days. It is seen as bright as a star of the second magnitude for about a fortnight: then gradually diminishes for three months, till it becomes invisible, in which state it remains for five months, when it again becomes visible, and gradually increases till it regains its former brightness, more or less—for it does not always reach the same degree of lustre. The star Algol, in the constellation Perseus, continues visible during a period of sixty-two hours, when it suddenly loses its splendour, and from a star of the second magnitude is reduced, in three hours and a half, to the fourth; after which it begins to increase, and in three hours and a half resumes its former size There are eleven other stars which exhibit analogous phenomena, some of them at intervals of five hundred years, to which we may look forward without any danger of mistake. Astronomers have not yet made sufficiently extensive observations to settle whether our own sun have any motion through space; but that it has such a motion, has been surmised without any apparent reference to this branch of inquiry.

Another variety in the nature of these luminaries is their being in some instances, not *single* stars, as they appear to the naked eye, but a group of two or more, evidently, from their motions, forming one system. The star Castor, one of the twins, is found, when much magnified, to consist of two stars, of between the third and fourth magnitude, within five seconds (a very small space) of each other. Sir William Herschel made observations upon more than 500 stars of this kind, where the distance is not more than half a minute (also a very small space); and to this list a foreign astronomer has added five times that number. Nor is there reason to suppose that, in *all* these instances, one of the stars is at a great distance behind the other, and that they are only brought together by the accident of our position. Many of the double stars no doubt are thus accidentally brought together; but of a great number it has been fully ascertained that they are each a system, with a reciprocal relation to each other. They are therefore called *Binary Stars.* It is generally observed that they move round each other within a certain time, and in elliptical orbits; the revolution of Castor, for instance, is supposed to be accomplished in 334 years; of ξ of Ursa Major, in 58¼ years; of 70 Ophiunci in 78 years. In fact, there is the same variety in this branch of the starry system as in its other departments, and the revolutions of the few binary stars that have been accurately surveyed range from forty-three to twelve hundred years. Several of these duplicate stars have made a revolution since they were first observed, and are now advancing in their second period. One, ζ Hercules, was seen double, in 1782, by Sir William Herschel; in 1795, it was hardly distinguishable to be double; in 1802, it was double no longer, the one being eclipsed by the other, though a small part of one was still jutting out at the side of the other; astronomers are now watching to observe them once more become separate. Whether one of these stars serves to the other as a sun, or whether both are suns, or whether the organized life with which they are probably stored, be of a kind which can endure a perpetual light and heat thrown from the one to the other—or in what other manner these immense worlds are put to use—it would be vain to inquire. One remarkable peculiarity in them is, the variety of tints apparent in the light emitted by a considerable number of them; but no accurate account has yet been given of the reason of this wonderful difference of colour in the stars.

Perhaps the most magnificent of all the starry phenomena is the *Milky Way.* This, as is generally known, is a broad belt, of whitish lustre, which stretches round the whole sky, being parted into two streaks for a large part of the circuit. The ancients formed the mean idea of this light, that it was the milk spilt by the nurse of Mercury, one of the deities; and hence its name. When examined by a telescope, it is found to consist entirely of stars, "scattered by millions," as Sir John Herschel beautifully describes them, "like glittering dust, on the black ground of the general heavens." The average magnitude of these stars is about the tenth or the eleventh, and hence their invisibility to the naked eye. It is a very remarkable circumstance, that, though the stars of the larger magnitudes are scattered with considerable equality over the whole heavens, there is a notable clustering of the smaller ones towards the body of this ring. Sir William Herschel, by gauging, as it were, the depth of our starry system in this and other parts, arrived at what he believed to be an approximation to the figure of the system itself—namely, an elongated cake-shaped mass, parting flat-wise into two at one particular part of the exterior (where the Milky Way is double), and in which our solar system was placed somewhat nearer the one extremity than the other. Where the distance between two stars is so great as we have seen, and we can suppose the distance between all the rest to be no less, what must be the entire extent of this star-system, composed as it is of millions of millions of distinct bodies!

NEBULÆ.

Within the bounds of what has here been called the star-system, great numbers of bodies have been discovered, which, from their cloud-like appearance, are called *Nebulæ.* There is one of magnificent appearance in the girdle of the constellation Andromeda, and another still more splendid in the sword-hilt of Orion, both visible to the naked eye. Some of these objects are of most irregular form, stretching like a fragment of semi-pellucid membrane over the sky, with patches of brighter matter scattered irregularly throughout their extent. In others, the bright patches are of greater intensity, so as to have the decided appearance of *gatherings* of the matter towards a particular point. Others there are, in which these bright parts seem nearly disengaged from the surrounding thin matter, or only bedded on a slight background composed of it. In a fourth class, we see detached masses, approaching more or less to a spherical form, and with various measures of comparative brightness towards the centre, until they resemble a star with only a slight *bur* around it. It is a new and startling surmise of astronomers, that these are examples of a series of states in which nebulous matter exists, during a process forming it into solar systems more or less analogous to our own—belated portions, so to speak, of the same soft and diffused material, which, countless ages ago, was condensed into the defined bodies forming the remainder of our star-system!

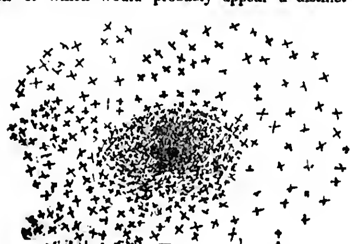
There is much, it must be owned, to support this hypothesis, startling as it is. The physical laws known to operate in our own solar system are in perfect harmony with it. It has been shown that such matter, in agglomerating, would necessarily assume a spherical form, just as a drop of dew takes that shape on the point of a thorn, namely, by the law of attraction. Particles of any fluid matter, flowing towards a centre, will, unless in the extraordinary circumstances of their meeting in a direct line (circumstances which scarcely ever occur), form a whirl or vortex. The meeting of two currents of the ocean forming a whirlpool, or of two currents of air forming a whirlwind, or even such a trivial and familiar phenomenon as the sinking of water through a funnel, are examples of the working of this law of matter. Hence, then, a rotatory motion would be an almost unavoidable result of the agglomeration of a mass of nebulous matter. In this we can, of course, see the origin of such a motion as that which our sun is known to have upon his axis.

And not only are the formation and movements of suns to be thus accounted for, but it has been shown that the same laws will explain how a whole planetary system may have been made up. As the process of condensation in a nebular mass proceeds, the whirling motion must always become more rapid, just as a sling, when the string is allowed to wind up round our finger, flies always the faster as the string shortens. While the rotatory motion is thus increasing, the centrifugal force may become too great to permit the outer and probably softer portion to adhere to the mass; and this outer and softer portion will therefore be left off as a ring surrounding the principal mass at a little distance. Other portions may thus be successively detached, till a considerable number of rings will be left encircling the central mass. Only if the matter of these rings be of a uniform character, can it be expected that they should continue as rings. Almost necessarily, there will be inequalities in their composition, causing them to break up into pieces, each of which, by virtue of gravity, will then collapse into a sphere. A sphere, thus formed, must needs retain the same revolutionary motion as the ring of which it once formed a part, and at the same time it must acquire a rotatory motion in the same direction. Thus we have a set of primary planets, the bodies of which have only to undergo the same processes as the central mass, in order to throw off satellites. The two rings which surround Saturn appear an example of two exterior portions of that planet as yet not advanced from the intermediate state, but which may in time become additions to the number of his satellites. The zodiacal light may also be a residue, of extreme thinness, of the matter of which our system was formed.

It might be supposed that this hypothesis, ingenious as it is, could scarcely be stretched to account for the formation of solar systems in which there are two suns revolving round each other. But this difficulty is easily overcome. It has been shown that the nebulous matter, in certain cases, may assume that arrangement. On the surface of a flowing stream, in which slight repulsions of water from the banks produce little eddies, how common is it to see two of those miniature whirlpools come within each other's influence, and then go on wheeling round each other: *precisely in that manner* do the two suns of a binary star carry on their revolutions, and from circumstances of a similar nature, though upon so much greater a scale, may these revolutions have originated.

REMOTE STAR-SYSTEMS.

Our own star-system, inconceivably vast as it is, is but an item of the heavenly inventory. Far beyond its bounds, the telescope of Herschel has descried similar systems in great numbers, each hanging in some tolerably defined shape in the vast empyrean, and each capable of being resolved, not exactly into stars, though these are in some instances visible, but into what has been expressly called *star-dust*, a collection of small brilliant particles, each of which would probably appear a distinct sun



Remote Star System.

under a stronger power of artificial vision. Observations have been made upon these star-systems chiefly in the direction of the thinner parts of our own system, where the sky is clearest of our own stars, and where of course they are most distinct from other and nearer objects. But even in these limited fields of the sky very great numbers have been seen—between 1000 and 2000 in the northern hemisphere alone—a number, we must recollect, exceeding that of all the ordinarily visible stars in the same moiety of the heavens.

They are of various forms, but in general, as has been said, tolerably well defined, and therefore differing entirely from the irregularly diffused matter of our nebulæ. Many appear as spherical clusters, with a crowding of the star-dust towards the centre: of this kind there is a brilliant example in the constellation Hercules. It has been remarked, that in the worlds about the centre of such clusters, the visible heavens must be inconceivably brilliant, though they will have no appearances resembling our milky way. There is another spherical class, in which the external parts are the most brilliant: in these cases, the visible heavens of a world near the centre will probably be almost entirely composed of milky way. From our earth these annular clusters are presented in various points of view, some so nearly edgewise, that we can barely see the long line of thin matter in the centre. There is one of most peculiar form, namely, an oval, with a regularly formed space of more brilliant matter extending across it in something like the form of a dumb-bell!! Surprising to relate, there are more than one bearing a strong resemblance to the form which has been presumed as that of our own star-system, namely, a flattened mass, with a brilliant annular exterior, parting flatwise into two at one part! In the *Magellanic clouds*, a nebulous object in the southern hemisphere, there is one remote star-system (30 Doradûs), described by Sir John Herschel as "consisting of a number of loops united in a kind of unclear centre or knot, *like a bunch of ribbons disposed in what is called a true lover's knot!*" "We are," says an astronomer who possesses eloquence worthy of his noble science, "lost in mute astonishment at these endless diversities of character and form. But in the apparent aim of things near and around us, we may perhaps discern some purpose which such variety will also serve. It seems the object or result of known material arrangements, to evoke every variety of creature, the condition of whose being can be made productive of a degree of durability; and perhaps it is one end of this wonderful evolution of firmaments of all orders, that there too th law of variety may prevail, and room be found for unfold ing the whole riches of the Almighty."*

The vast general distance of these clusters, their distinctness from our own system, and their relative distances, have been determined by the comparative powers of the telescopes employed in observing them. Some of them are distant from us many thousands of times the distance of Sirius, the nearest of our own stars. The astronomer last quoted speaks of the telescope representing us as in the centre of a sphere, whose circumference is 35,000 times as far from us as that star, "and beyond whose circuit, infinity, boundless infinity, stretches unfathomed for ever."

URANOGRAPHY.

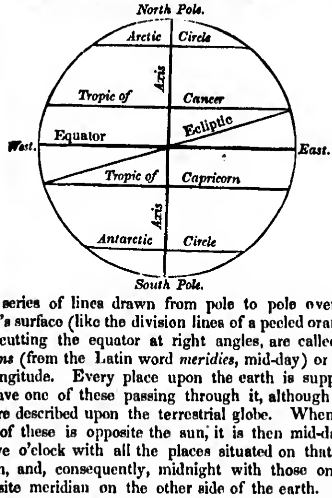
Under this term (delineation of the heavens) may be comprehended all those arrangements which have been made by astronomers for artificial representation of the heavens, and for the working of the many mathematical problems of which the heavenly bodies are the subject.

The stars, as they appear in their places on the apparent concave sphere of the heavens, are represented in proper arrangement on the *celestial globe*, which is expressly designed as a miniature of that sphere, but bearing also the fanciful figures assigned to the constellations

* Views of the Architecture of the Heavens, by J. P. Nichol, LL.D. 1837.

and the lines necessary for the working of various problems. It is required that, in the first place, we give a brief description of the terrestrial globe, or similar miniature representation of the earth.

Astronomers, for the convenience of their science, have supposed certain lines to pass through and around the globe. One, passing through the centre, between north and south, is called the *axis* of the globe, from a Greek word signifying axle. The two extremities are called the *poles*, from the Greek word *polos*, signifying a pivot. A line girding the globe in the middle is styled the *equator;* all to the north and south of which are respectively called the northern and southern hemispheres. The circuit of the earth, both in its girth between east and west, and between north and south, is divided into 360 parts, called degrees. At the distance of twenty-three and a half nearly of these degrees from the equator, in both directions, are two parallel lines called the *tropics*, and at the same distance from each pole is a parallel circle, styled in the one case the *arctic*, and in the other the *antarctic* circle. The space between the tropics is called the *torrid zone*, because the sun, being always vertical in some part of that space, produces a greater degree of heat than what is felt elsewhere. The spaces between the tropics and the arctic and antarctic circles are called the *temperate*, and the spaces within these latter circles the *frigid zones*. Lastly, a line which cuts the equator obliquely, touching upon opposite points of the tropics, is called the *ecliptic*. The ecliptic and equator are called greater circles, because they cut the earth at the thickest parts; the others are called lesser circles.



A series of lines drawn from pole to pole over the earth's surface (like the division lines of a peeled orange), and cutting the equator at right angles, are called *meridians* (from the Latin word *meridies*, mid-day) or lines of longitude. Every place upon the earth is supposed to have one of these passing through it, although only 24 are described upon the terrestrial globe. When any one of these is opposite the sun, it is then mid-day or twelve o'clock with all the places situated on that meridian, and, consequently, midnight with those on the opposite meridian on the other side of the earth. The exact situation of a place upon the earth's surface, or its latitude and longitude, is determined by means of these circles. They are all divided, as already hinted, into 360 parts, which parts are called *degrees;* these degrees again into 60 equal parts, called *minutes*; the minute into 60 others, called *seconds*, and so on. They are all indicated by certain signs placed behind the figure, and near the top of it—thus, 8° 5′ 7″ is 8 degrees, 5 minutes, 7 seconds. A degree is 60 geographical miles, or about 69 English statute miles; a minute is the 60th part of that; and so on. The *latitude* of a place is its distance measured in that manner from the equator. If it lies north of that line, it is in north latitude; if south of it, in south latitude. There being only 360 degrees in the circumference of the earth, and the distance from the equator to either of the poles being only a fourth part of it, a place can never have more than 90 degrees of north or south latitude. The *longitude* of a place is the distance of its meridian from another, which is called the first meridian. The first meridian is quite arbitrary, and it is a matter of indifference through what point we draw it, provided it be settled and well known which one we adopt, so as to prevent mistakes. Foreigners fixed upon the principal observatories of their respective countries. In Germany, the island of Ferro is generally adopted; in France, the observatory of Paris; and in England, that of Greenwich. Longitude is reckoned either east or west of the first meridian; and 180 is therefore the utmost degree of longitude. Some geographers, however, reckon longitude all the way round the globe. From the shape of the earth, which is flat at the poles, the degrees of longitude decrease as we approach these in either direction. In order to measure latitude, each globe is furnished with a brass meridian circle, on which the degrees are marked. Longitude is measured by a similarly graduated circle, termed the artificial horizon, in which the globe is suspended.

The other great circle, called the Ecliptic, is divided into twelve parts, called signs, which bear the name of the constellations through which this circle passes in the heavens, as shall be afterwards explained. There are other smaller circles which run round the earth, parallel to the equator; these are called *parallels of latitude*, because, being everywhere at the same distance from the equator, the latitude of every point contained in any one of them is the same.

The celestial globe, representing that apparent outer sphere, the sky, in the centre of which the earth seems suspended, is marked by lines similar to those upon the terrestrial globe, each line upon the latter being supposed to have a corresponding line opposite to it in the heavens. Thus, the celestial sphere is divided into the same number of degrees as the terrestrial. The celestial poles correspond to those parts of the heavens to which the terrestrial poles always point. The celestial equator corresponds also to the terrestrial, and is, like it, everywhere 90 degrees distant from the poles. The equator of the earth thus lies directly under that of the heavens: the ecliptic does exactly the same, and cuts the former also at an angle of 23 degrees, 28 minutes.

The place where the ecliptic cuts the equator at the vernal equinox, is called the first point of Aries; and from this point the distance of all celestial bodies eastward and westward of it is measured. This is called their *right ascension*, and corresponds to the terrestrial longitude. Their latitude is determined by their distance from the equator, and is called their *declination*. The declination of the sun or other heavenly body is therefore called north or south declination, according to its proximity to the north or south pole of the heavens. Hence it follows, that when the sun's declination is 10 degrees north, he is vertical at a place whose latitude is 10 degrees north. But the right ascensions do not so correspond with the longitudes, simply because the first point of the constellation Aries does not correspond to the first meridian (Greenwich); and because the longitudes are not measured quite round as the right ascensions are.

The sun, which is always in the ecliptic, has, of course, no latitude, but he passes through all the degrees of longitude in a year. When any other celestial object has the same longitude as the sun, it is said to be in *conjunction* with him; and when the difference of longitude amounts to 180 degrees, half the circle of the heavens, it is said to be in *opposition* to him. Both these terms are comprehended in that of *syzygy*, which, when applied to any celestial object, means that it is either in conjunction or opposition to him. What is called an *equinoctial colure*, is a great circle supposed to be drawn through the pole of the ecliptic and the points where it intersects the equator. The *solstitial colure* is a similar circle, which passes through the solstitial points at right angles to it

The former colure is a secondary to the ecliptic, and the latter a secondary to both it and the equator. The equinoctial points are Aries and Libra, where the ecliptic cuts the equator. The solstitial points are Cancer and Capricorn; and when the sun is in either of them, he is at his farthest distance above or below the equator.

Allusion has already been made to the constellations, or fanciful figures, marked on celestial globes, to aid in distinguishing the position of the stars. The earliest astronomers seem to have adopted the idea of thus mapping out the starry heavens, being no doubt at first led to do so by the slight resemblances borne by various groups of stars to familiar terrestrial objects. Thus, a group in the northern part of the sky bears some resemblance to an ancient wain, or to a plough—as also to the hinder part of an animal, with its tail extended. Hence, it has been variously called *the Plough*, *Ursa Major*, or the Greater Bear, and *Charles's Wain*—the last term being in honour of the illustrious French king Charlemagne. (In ordinary globes, Ursa Major is alone marked.) Another group, in the southern heavens, conveys the idea of a man's figure, and has been called Orion, from an early Greek semi-divine hero of that name. Some of the

Constellation Orion.

names of the constellations were conferred by Chaldean observers several hundred years before o r era: others have been given within the last few ages. Particular stars of large magnitude also bear particular names, generally Arabic, having been affixed by Arabian astronomers, as Aldebaran, Dubhe, Alioth, &c. Arcturus and the group of small stars called the Pleiades, are alluded to in the book of Job, which is well known to be one of the earliest of the scriptural compositions, and probably not less than 3000 years old.

Twelve of the constellations are placed in that part of the heavens which is opposite to the ecliptic in the terrestrial globe; that is to say, the plane of the planetary motions, if extended to the stars, would strike the part occupied by these constellations. This part of the celestial globe is called the *Zodiac*, and these are named the Zodiacal Constellations, or, more commonly, the *Signs of the Zodiac*. The zodiac is a zone or belt, extending eight or ten degrees on each side of the ecliptic. It is divided into twelve parts, each of thirty degrees, called the signs of the zodiac. The names of the signs, and the days in which the sun enters them, are as follow:—*Spring signs*—Aries, the Ram, 21st of March; Taurus, the Bull, 19th of April; Gemini, the Twins, 20th of May. *Summer signs*—Cancer, the Crab, 21st of June; Leo, the Lion, 22d of July; Virgo, the Virgin, 22d of August. These are called northern signs, being north of the equator *Autumnal signs*—Libra, the Balance, 23d of September, Scorpio, the Scorpion, 23d of October; Sagittarius, the Archer, 22d of November. *Winter Signs*—Capricornus the Goat, 21st of December; Aquarius, the Water-bearer 20th of January; Pisces, the Fishes, 19th of February These are called southern signs. Within the zodiac are performed the revolutions of all the principal planets.

MECHANICAL ASTRONOMY.

It is the province of Mechanical Astronomy to explain the physical laws which have produced, and which sustain, the arrangements of the bodies occupying space, as well as all the various results of the arrangement and relations of those bodies.

It may in the first place be proper to explain what is meant by a *physical law*. In the operations of nature, certain results are invariably observed to take place as a consequence of certain circumstances. This has suggested to the mind of man, that there is an *order* in all things, by virtue of which they are regulated to the best general purposes, the authorship of the *order* being no doubt the same as the authorship of matter itself, that is to say, referable to the Divine Being. Any particular regulation which we find imposed upon matter, we term a law of matter, or a physical law.

LAWS OF ATTRACTION AND MOTION.

We have first to consider the laws by virtue of which *particles and masses of matter attract each other*, as far as these are concerned in the province of Mechanical Astronomy.

Particles of matter, when brought close together, or within insensible distances, have a tendency to cohere, or stick together, and this operates in all cases, unless there be opposing influences of superior force. It is termed the *attraction of cohesion*.

Particles of matter have also a tendency to move or be drawn towards each other. This is called the *attraction of gravitation*, because it is what the weight or gravity of an object depends upon.

Under the influence of the attraction of cohesion, particles of fluid matter, when suspended at a proper distance from other objects, arrange themselves round a centre, and take a globular form. The dew-drop, suspended from the point of a thorn or blade of grass, is a familiar example of matter thus acting. If two such drops are brought close together, they will unite; a new and common centre will be instantly established for both, and they will resolve themselves into a new mass equally globular as before.

Under the influence of the law of gravitation, when any two masses of matter are brought to a proper distance from each other, they will, if there be no sufficient obstacle, rush together, and then remain in union.

We may see this law operating if we take two fragments of cork, no matter how small, and set them afloat on the surface of a cup of water. If kept a considerable way apart, the impediments to their mutual attraction are too strong, and they therefore do not meet. But, if brought within a short distance of each other, we shall observe them begin mutually to exercise an influence over each other, and immediately they will rush together, and so remain.

Material laws are equally ready to act on a large as a small scale, and on a small as upon a large one. The same attraction of cohesion, which causes the tear drawn from our eye by sympathetic feeling to be round, produced the spherical form of the vast orbs which people space. These, being originally fluid masses, gathered themselves round a centre, by the irresistible force of the law of the attraction of cohesion. So are the planets restrained in their position regard. the central luminary, by the force of the same law of gravitation which causes an apple dropping from a tree to fall upon the ground, or two tea-stalks floating in our evening cup to go together, and range themselves as closely side by side as possible.

We have next to consider the laws which regulate the *motion* of masses of matter.

A mass of matter set in motion upon the surface of the earth, or within the compass of the atmosphere, invariably comes sooner or later to a stop. If we roll a ball along the surface, it goes briskly for a while, then slowly, and finally it stops and remains at rest. What causes it to stop is the resistance it meets with from the roughness of the ground, and the opposing fluid (atmosphere) in which it moves. It is precisely when as much force has acted in opposition to its motion, as was exerted in setting it agoing, that it comes to a pause. Were it not, however, for this opposing force, the ball, once set in motion, would travel on and on for ever.

Just so the orbs of space, once set in motion, go on and on perpetually, there being nothing whatever to oppose their progress. This applies as well to their spinning or rotatory motion on their axes, as to their progress along their orbits. If a top were set a-spinning on a smooth marble tablet, underneath the exhausted receiver of an air-pump, it would be found to keep in motion for a far longer space of time than in any ordinary circumstances, for then there would be comparatively little air to give resistance to its rotation, and the chief opposition would lie in its friction against the tablet. Could the air be entirely drawn away, and the top be made to spin in a state of suspension, it would be in precisely the same circumstance as an orb revolving on its axis in space, and in that case it would never stop as long as all the circumstances remained unaltered.

But the orbitual revolutions of planets are circular—why should they be so? Because these orbs are under the influence of both the law of attraction and the laws of motion. Assuming the nebular hypothesis to be true, the impulse which they originally obtained tended to throw them off in a direct line into space, in the plane of the ecliptic. But the law of attraction prevented this result, and caused them to assume a circular course round the parent orb. They were propelled by the one cause (the centrifugal or centre-quitting force), but restrained by another (the centripetal or centre-seeking force, that is to say, attraction), and they therefore settled into paths where the two forces balanced each other.

To explain. If we take any circular body, say a common grinding-stone, and, having first put a few pieces of clay upon its rim, cause it to revolve quickly in a horizontal manner, it will be found that the pieces of clay, one after another, fly off in straight lines from the rim. The cause of this is, that each particular part of the rim of the grinding-stone, at every instant of its revolution, is describing a straight-forward movement, and has itself, from the revolutionary motion, a tendency to go straight on, and is only kept in its place by being fixed to the rest of the stone. Every bit of clay that flies off receives, at the instant of its parting, the force of the straight-forward impulse which at that moment affected the part of the rim where it rested; and hence its going off in a straight line. It is to be observed, however, that the earth immediately begins to act upon the flying piece of clay, and draws it downwards to itself in a bending line, its last movements being in fact a part of a circle. This is the power of attraction, which, in this case, is exercised in much greater force by the earth than by the grinding-stone; were the grinding-stone the sole mass of matter near by, and the opposing force of the atmosphere withdrawn, we should see the clay begin to fly round the stone in a circular course.

And this naturally brings us to consider the comparative powers of attraction exercised by different objects. A large mass has a much greater power of attraction than a small one. When two of unequal bulk are brought near each other, we shall only be sensible, perhaps, of the large one drawing the small one to it, and see no attractive power in the small one whatever. In reality, each mass, however small in comparison, exercises a certain degree of attractive power; and this power will depend expressly upon its relative bulk and density, according to fixed regulations of the nicest kind.

One great and important law presides over the attraction which one mass exercises over another. This relates to the *distance* between the two masses. We shall suppose two globes of unequal size. When the small one is removed to as great a distance from the large one as there is space between the surface of the large one and its centre (that is to say, the distance of a semi-diameter of the large one), the attractive force is diminished one-half. When it is removed to twice that distance, or two semi-diameters, the attraction is diminished to a fourth. When it is removed to the distance of three semi-diameters, the force is lessened to a ninth; to four semi-diameters, a sixteenth; to five, a twenty-fifth, and so on; the diminution being always as the squares of the amount of semi-diameters of distance, or these sums multiplied by themselves. The moon is distant from the earth sixty of the earth's semi-diameters; consequently, the attractive power exercised by the earth over the moon is only a 3600th part of what it would exercise at its surface.

In the revolution, then, of a planet round the sun, and of a satellite round a planet, there are various forces at work, all of them in the nicest proportion to each other, and to the mass of each body. There is first the amount of motion resulting from the original impulse; then the amount of attraction exercised by the central and larger over the smaller orb—the one pulling outwards and the other pulling inwards, but both in union attended with the result of a circular or revolutionary motion.

Gravity has not the same force at all parts of the earth's surface. At the equator, the centrifugal force produced by the rotating motion is greatest; it declines in both directions towards the poles. In proportion as the centrifugal force is greater, the attractive power of the mass of the earth is less, for the first of these forces is directly counteractive of the other. There is of course least attractive power at the equator; and bodies are there drawn with less force towards the centre of the earth than would be found to be the case elsewhere. Yet this difference is not great, for even at the equator the attractive force is 288 times that of the centrifugal. Neither does the difference tell in the weighing of objects, for in that case two equivalents are used, and if a certain object is lighter, so also is the weight put into the opposite scale. The difference was first detected, in consequence of pendulum clocks being found to go slower as they were brought towards tropical latitudes. It was ascertained that the pendulum of a clock which went right at London, required to be one-eighth of an inch shorter (by which means its motion was accelerated) when it was placed upon the equator. This effect, however, is not altogether owing to the increase of centrifugal force, but partly also to the greater distance of the equator from the centre. And it was from a speculation as to the slower movements of pendulums at the equator, that Sir Isaac Newton first conceived the idea of the spheroidal form of the earth, which he ascertained to be of less diameter at the poles than at the equator, as 229 is to 230, or by twenty-six miles.

The orbits of the planets, it has been already seen, are not strictly circles, but rather ellipses, the sun being in each case placed in one of the *foci*, that is, the centre of one end of the ellipse. How should this circumstance affect the revolutionary motion? It might be supposed that, when the planet came to the part of its course where it is nearest to the sun, the attractive force would be greater, and that some derangement might take place. But this is not the case. At that part of the course the planet moves faster than elsewhere, and thus baffles the greater attractive force. This phenomena is particularly apparent in comets, which have so eccentric an orbit. These bodies move with inconceivably greater speed when near the sun than in the remote parts of their orbits.

It was a discovery of the German astronomer Kepler, in the seventeenth century, that, notwithstanding the increased speed, a revolving orb goes over exactly the same amount of its circuit as when it moves more slowly. Suppose a multitude of lines radiating from the sun, at equal distances from each other, the orb would be found to cross from one to another of these, in exactly the same time when it was *farthest* from the sun as when it was *nearest*. In scientific language, it describes equal areas in equal times.

Another discovery of Kepler established that there is a relation between the times respectively required by the planets for their revolutions, and their various distances from the sun. At a first glance, we are struck by the fact that the periods of revolution increase more than in proportion to the distances. For example, the period of Mercury is about 88 days, and that of the Earth 365, being in proportion as 1 to 4.15 (or about 4 1-7th), while their distances, respectively 37,000,000 and 95,000,000 of miles, are in the less proportion of 1 to 2.56 (or a little more than 2½); and a similar remark holds good in every instance. If we take the squares of the distances, we arrive at nothing satisfactory, for it considerably exceeds the proportion of the periods. If, however, we take the squares of the periods of two planets, we find they are in exactly the same proportion to each other as the *cubes* of the mean distances. Some may find a difficulty in understanding the nature of this calculation; but its ingenuity and its results form one of the highest boasts of astronomical science. "When we contemplate," says Sir John Herschel, "the constituents of the planetary system from the point of view which this relation affords us, it is no longer mere analogy which strikes us—no longer a general resemblance among them, as individuals independent of each other, and circulating about the sun, each according to its own peculiar nature, and connected with it by its own peculiar tie. The resemblance is now perceived to be a true *family* likeness; they are bound up in one chain—interwoven in one web of mutual relation and harmonious agreement—subjected to one pervading influence, which extends from the centre to the farthest limits of that great system, of which all of them, the earth included, must henceforth be regarded as members."*

The solar system, though composed of many different masses distant from each other, is to be considered with respect to other masses as *one mass*, having a centre of gravity, by which its position with respect to other masses is regulated. The nearest stars no doubt exercise the force of gravitation upon it, so as to keep it in its position; and it also acts in the same way upon them. It is therefore not strictly correct to speak of the solar system or any part of it as *suspended* in space, for that term implies a hanging from a fixed point. It is in reality kept at its place by attractive influences exerted all round it by other masses. In like manner, we are to suppose our star-cluster as poised by the same forces in the midst of other clusters; and these again poised by others—an idea which leads us on and on through the fields of infinity, till the mind loses itself in an effort beyond its finite powers, and pauses contented to wonder and adore!

* Treatise on Astronomy, 183.

DIURNAL AND ANNUAL MOTION OF THE EARTH.

The earth is to be considered as a globe of nearly 8000 miles in diameter, performing a rotatory motion on its axis once every twenty-four hours. This motion is at the rate of 1042 miles an hour to places at the equator, but only 644 miles at London, and a gradually diminishing amount in places nearer to the poles.

From the situation of the earth with respect to the sun, it necessarily follows that only one-half of its surface should be exposed at a time to the light and heat diffused from that body. This is the case with all the planets. When any one part of the earth is presented to the sun, it is day at that part, and all the other heavenly objects are lost in the blaze of the great luminary. When, on the contrary, any part is averted from the sun, it is dark at that part, and the light of the stars is allowed to tell upon our organs. Each part is thus brought once every twenty-four hours towards the sun; in short, this is the cause of what we familiarly know as day and night.

There is a minute difference between the *civil* or *legal day* and what is called the *sidereal day*. The entire orb of the earth in reality revolves in 23 hours, 56 minutes, 4 seconds, or 3 minutes, 56 seconds, less than 24 hours. This is called a sidereal day, because the earth is then in the same relation to the stars as it was the day before. The fixed stars are so immensely distant from our earth, that its whole orbit is in respect to them but a point; so that no sensible difference is produced by its revolving round the sun. But the sun being much nearer us, any movement made by the earth can be appreciated. The time which elapses from the sun's being on the meridian of any place to its returning to the same spot next day, is exactly 24 hours, and is called an astronomical day. The natural day would always be the same as the sidereal day, if the earth had no other motion than that upon its axis. But in the same time that it has performed one of its daily revolutions eastward, it has also advanced about a degree westward, or in the opposite direction, which is the course it takes round the sun; so that, before the sun can shine exactly upon the same meridian, the earth must make up as it were its lee-way, and this it does in 3 minutes, 56 seconds, the difference of time between a natural and sidereal day. If the earth, then, had no other than its diurnal motion, we should have 366 days in the year.

When any spot on earth comes directly opposite to the sun, it is noon at that spot, and at every place in the same longitude. At the same moment, it is an hour before noon at the meridian of longitude fifteen degrees to the west of the same spot, and an hour earlier for every fifteen degrees farther to the west; because, as the earth moves from west to east, it requires so much time to bring those places to the same point, namely, opposite to the sun. In like manner, it is an hour after noon for every fifteen degrees to the eastward of the spot where it is noon, because at those places the sun has already been for so many hours past meridian. Thus the hour of the day varies in every part of the globe where the longitude or meridian line is different. When it is twelve o'clock noon with us in any particular part in Britain, it will be twelve o'clock at midnight in a corresponding point on the opposite side of the globe, near New South Wales; and the intermediate hours, sooner or later, will all lie in the countries between these two points, exactly according to their position or degrees of longitude.

The earth is at a mean distance of 95,000,000 of miles from the sun, and performs its revolution round him in a sidereal year, which is 365 days, 6 hours, 9 minutes, 11 seconds, mean solar time. The earth travels at the rate of 68,000 miles per hour. Its orbit is, as already stated, not a circle, but an ellipse, the sun being situated in one of the foci, that is, not in the centre, but near one of the ends of the oval-shaped figure. Neither does the earth go round the sun in an upright or perpendicular position; its axis is slanting or oblique. The degree of obliquity is 23 degrees 28 minutes. The points at which the ecliptic cuts the equator, are called *nodes:* the period of time at which it does this, *equinoxes* (a Latin term, signifying equal nights, for the days and nights are then of equal length all over the world). In consequence of this obliquity, during one part of the earth's course, the north pole is turned towards the sun, and the south is dark; and during another part of its course, the south pole is turned to the sun, and the north is dark: and this is the cause of the difference of seasons, which will be better understood by referring to the annexed figure.

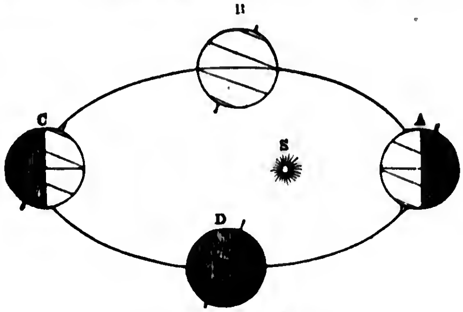


Illustration of the Seasons.

THE SEASONS.

Let S represent the sun, and A B C D the earth at various places of its annual circuit; when the earth is at B or D, these are the periods of the equinox, when the line of the equator intersects or cuts through the line of the ecliptic. At this period, one-half of the globe is illuminated from pole to pole, or there is over all the earth an equal day and night of twelve hours. But when the earth has proceeded to A, the pole or axis still keeping the same position, or pointing to one particular place in the starry heavens, it will be turned more directly from the sun; a greater proportion of his rays will shine on any particular spot of the southern half of the globe, and the period of day, or sunlight, will exceed that of darkness by the proportion of the light and shade parted in the circle of the earth. It will be observed, also, that within the circle of the south pole, the sun will shine continually as the earth revolves on its axis, or, in short, to the inhabitants of that part of the globe the sun will never set for several months. When the earth has proceeded on to D, one-half of its annual course is finished, or this is the spring equinox, or equal day and night. At C, again, the earth has arrived at our longest day in summer, when the axis is turned to the sun, and the regions around the pole are in the light for a greater period, while darkness, or night, prevails for a less. It will be seen, too, that now the pole and circle around it revolve in perpetual light; or to the inhabitants of that region, the sun never sets for some months, but they have one continued and uninterrupted day. At the other, or south pole, the same changes take place, only matters are reversed—there it is summer while we have winter, and the winter of the north pole is the summer of the south. In the middle regions of the earth, or around the equator, the sun's place does not suffer a very great change; and, accordingly, there the heat is nearly of the same intensity all the year through; and the length of their days and nights is nearly equal, or nearly the same as at the periods of the equinoxes. But the orbit in which the earth travels round the sun is not an exact circle; it is, as we have already mentioned, an ellipse, and the sun is placed near one end of it, as at the small circle and letter S. In consequence of this circumstance, the sun is much nearer us at one period of the year than another, and this happens in our winter; accordingly, the sun appears about one-thirtieth part larger in January than in June. But in proportion as the earth approaches in her orbit to the sun, her motion is quickened, and she passes over the winter half year in nearly eight days' less time than the summer. It is principally from this circumstance, as well as the shorter period of the day, that although the sun be nearer us in winter, and consequently his power of imparting heat greater, yet the actual quantity imparted is, on the whole, much less in the one season than the other. We have said that the north pole of the earth always points to a particular spot in the heavens; this is not, strictly speaking, correct; the pole or axis makes a circle round the centre of the axis of the ecliptic in a long period of years, and it is this motion that gives rise to the precession of the equinoxes, which will be afterwards described under that title.

ABERRATION OF LIGHT.

Although the most convincing proof of the earth's orbitual motion is not to be found in any circumstance of which the senses can take immediate cognisance, but is afforded by the full development of the planetary system, there is, however, one direct proof of it in a phenomenon discovered by Bradley, an illustrious astronomer. It is called the aberration of light, and is manifested by a small difference between the apparent and true places of a star, occasioned by the motion of light combined with that of the earth in its orbit. Vision, it is well known, arises from rays of light proceeding from any object, and entering the eye; and we see the object in the direction in which the rays have come. If both the body giving forth light and that one which receives it be at rest, the former will be seen in its true place, at least in so far as aberration is concerned; but let either of the bodies move, and this will not be the case. In order to render this plain, suppose a shower of hail to fall perpendicularly upon a number of tubes—say the pipes of an organ; if the organ remain stationary, the hailstones will descend sheer from the top to the bottom, without any deviation right or left; but move the organ in any direction, and they will strike the side opposite to the direction in which the motion is made. Now, it is just in this way that the eye misses the perpendicular ray, and, meeting an oblique one, receives an impression that the star lies in that direction. The object thus appears displaced, and the amount of displacement is *aberration.* The earth travels at the rate of about nineteen miles per second, and therefore is every instant changing its direction. Time is also occupied by light in traversing space, which it does at the amazing rate of 192,000 miles per second; so that also requires to be calculated for by astronomers. The effect of aberration is to make a star apparently describe a small ellipse in the heavens, in the centre of which it would be seen if the earth were motionless. The reader must carefully distinguish between aberration and refraction; their effects are the same—namely, to displace the ray projecting object—but they proceed from very different causes. Besides these corrections which astronomers have to make in their calculations, there is another, resulting from what is called parallax, which may be as well introduced in this place.

PARALLAX.

The word parallax, in its general signification, denotes change of place; but in astronomical books it has a conventional meaning, and implies the difference of apparent positions of any heavenly luminary when viewed from the surface of the earth and from its centre. The centre of the earth is the general station to which all astronomical observations are referred; the situation of a heavenly body, observed from the surface of the earth, is called the apparent place; and that at which it would be seen from the imaginary place of observation at the centre of the earth, the true or mean place. Hence the altitudes of the heavenly bodies are depressed by parallax, which is greatest at the horizon, and decreases as the altitude of the object increases. This may be rendered very plain, by supposing that two persons placed individually at the end of a straight line, look at a candle removed at, say, 100 yards distant from them. It is evident that the burning body will appear to be projected upon the wall of an apartment, or any other background, at very different positions to each of the spectators. The angle which this difference of position makes is similar to parallax. The farther they remove from the light, allowing them still to remain at the same distance from each other, the more obtuse the angle would become, and the less the parallax. Thus, the fixed stars, being so far removed from us, when viewed from any two positions upon the earth's surface, are seen at the same place upon the celestial sphere, and hence have no perceptible parallax. It is different, however, with the luminaries belonging to our system; and by this means astronomers have been enabled to estimate the quantity of space which separates us from them. For a complete account of the means by which this is accomplished, we must refer the reader to more elaborate treatises than the present. A general and correct enough idea of it may be formed from the familiar example we have given. In the same manner, suppose two observers, one in the northern the other in the southern hemisphere, at stations on the same meridian, observe on the same day the meridian altitudes of the sun's centre. "Having thence derived the apparent zenith distances," says Sir J. Herschel, whose language would be deprived of clearness were it abridged, "and cleared them of the effects of refraction, if the distance of the sun were equal to that of the fixed stars, the sum of the zenith distances thus found would be precisely equal to the sum of the latitudes north and south of the places of observation; for the sum in question would then be equal to the meridional distance of the stations across the equator. But the effect of the parallax being in both cases to increase the apparent zenith distances, their observed sum will be greater than the sum of the latitudes by the whole amount of the two parallaxes. This angle, then, is obtained by subducting the sum of the latitudes from that of the zenith distance; and this once determined, the horizontal parallax is easily found, by dividing the angle so determined by the sum of the signs of the two latitudes." It may be observed, that the angles are determined by means of very nice instruments. The parallax thus obtained is called the *daily* or geocentric, in contradistinction to the annual or heliocentric, by which, in general, is understood the difference of place of a heavenly body, as seen from the earth and from the sun; in particular, however, it denotes the angle formed by two lines from the ends of the diameter of the earth's orbit to a fixed star, which, as we have already observed, from the immense distance of the latter, is inappreciable. Some idea of the importance of parallax may be obtained from the fact, that before the sun's was determined, the distance of that luminary from us was not estimated at within 13,000,000 of miles of its true amount. Its parallax is, of course, a very minute quantity, only 8″ 6.

OF SOLAR, SIDEREAL, AND ANOMALISTIC YEARS

There are three different periods at which the sun may, in different senses, be said to return to the same position—when he returns to the same equinox at which he was before; when he returns to the same point in his orbit, or the ecliptic; and when, being in perigee (least distance from the earth), or apogee (farthest distance from the earth), he comes back to either again; or, which is the same thing, when, having been at a given distance from any of these points, he returns to the same point with respect to them. Each of these may be said to be a completion of the revolution of the sun (strictly speaking, it is a revolution of our own earth round him), and a revolution thus performed is called *a year*. The first and shortest is the equinoctial, solar, or tropical year; for his time of returning from tropic to tropic, they being situations holding the same relation to the equinox for the time being, is obviously the same as that from equinox to equinox. The value of this year is 365 days, 5 hours, 49 minutes, nearly. But although the earth has thus returned to the same equinox, it has not made the entire circuit of its orbit, but must travel a little further to arrive at the same point it was in a year before. This arises from a backward movement of the equinoctial point. (See "Precession of the Equinoxes.") The second is the sidereal year, which consists, as we said before, of 365 days, 6 hours, 9 minutes, 9 seconds, 6, reckoned in mean solar time, or *a day more*, reckoned in sidereal time. Here, then, there is a remarkable difference between solar and sidereal time, which requires explanation. If the reader will recollect what was said with regard to a solar and sidereal *day*, the discrepancy between the times of the years will become apparent. In the course of twelve months, all the little daily deficiencies, as it were, amount to twenty-four hours, which constitutes the difference between the two years. The sun's apparent *annual* motion among the stars is performed contrary to the apparent *diurnal* motion of the sun and stars; hence the stars gain every day three minutes, fifty-six seconds on the sun, which makes them rise that portion of time earlier every day. In the course of a year, the sun will fall behind the stars a whole circumference of the heavens, or one revolution, which deficiency he must make up to complete the number of days in a year. It is evident, then, that the sun apparently, or the earth really, turns 366 times round upon its axis; and had it no other motion, there would be as many days in a year. After the earth or sun has completed a sidereal year, before it can finish an anomalistic year, it must describe a farther arc of 11″ 8 to arrive at its original position in perihelion, the latter having moved forward to that amount. In so doing it occupies 4′ 39″ 7, which must be added to the sidereal period, making the anomalistic year 365 days, 6 hours, 13 minutes, 49 seconds, 3, in length. All these periods have their uses in astronomy; but the one in which mankind are most particularly interested is the tropical year, or that on which the seasons depend, and which is a compound phenomenon, depending chiefly and directly on the annual revolution of the earth round the sun, but subordinately also, and indirectly, on its rotation round its own axis.

MEASUREMENT OF TIME.

Although the sidereal day, from its uniformity, is well adapted for astronomical purposes, yet it is scarcely sufficiently marked for the ordinary wants of life. No person but an astronomer ever attends to the culmination of a star; on this account the diurnal return of the sun to the same meridian has been universally adopted as the measure of time; and this is called a *civil day*. Most nations reckon the beginning of their day from midnight, but astronomers count from noon to noon. The day thus determined is called the astronomical or solar day, and, being regulated by the true motion of the sun, the time which is measured by it is called true or apparent time. Two causes conspire to render astronomical days unequal; first, the variable velocity of the sun in his orbit, and, second, the obliquity of the ecliptic. A mean astronomical day, which is independent of any causes of inequality, has been obtained by astronomers introducing into the system two imaginary suns. These two fictitious bodies are supposed to move uniformly, the first in the ecliptic, the second in the equator, and as the circles are both equal, the actual motion of each of the bodies is equal. To those desirous of studying this part of the subject, we would recommend a perusal of the article *Astronomy* in the seventh edition of the Encyclopædia Britannica, page 778, where it is well illustrated. The correction or equation, by which apparent time is reduced to mean time, is technically called the *equation of time*. There are only four days in the year when the apparent and mean time are the same, and the equator of time nothing. In the interval between the first and second of these, that is, December 24th and April 15th, and, again, in that between the third and fourth, that is, June 15th and September 1st, the apparent is always later than the mean time, or the clock is before the sun; in the other intervals which complete the year, the reverse is the case, and the clock is after the sun. The greatest difference between solar and true time amounts to between fifteen and sixteen minutes. Tables of equation are constructed for the purpose of correcting the differences.

THE MOON.

Next to the sun, the moon is to the inhabitants of the earth the most remarkable and important of all the heavenly bodies. The mean horizontal parallax of the moon is 57′ 48″; and her mean distance from the earth 236,847 miles. Like the sun, the moon advances in the heavens in a motion contrary to that of the stars. Notwithstanding the vast distance she is from us, it is little more than one-fourth of the sun's diameter, and the globe of that magnificent luminary would nearly *twice* include the whole orbit of the moon! It has various motions; as a secondary planet, it revolves round the earth, which is its primary. Along with the latter, it revolves round the sun, and it has a rotatory motion upon its own axis. Owing to the sun's apparent movement in the heavens being in the same direction with that of the moon, only slower, the latter has to make up for that slowness in the same way as we have mentioned with regard to the earth and the time it takes constitutes the difference between the sidereal and synodic month or lunation. The sidereal month is 27 days, 7 hours, 43 minutes, 11 seconds, 5, in which time the moon performs a complete revolution round her primary; and the other is 29 days, 12 hours, 44 minutes, 2 seconds, 87, the time which elapses between two new moons, or two conjunctions of the sun with the moon. It happens that its revolution upon its axis is performed in the same time as its revolution round the earth, so that the same side of her orb is always presented to the latter planet. Although the moon's rotation on her axis is uniform, her motion in her orbit is not so, and we are by this means enabled at times to obtain a peep of the equatorial portions of her eastern and western sides. Her axis, also, is not perpendicular to her orbit, and a small part of each of her poles alternately become visible. These phenomena are known by the name of *librations* of the moon, and they are of two distinct kinds, the result of different causes.

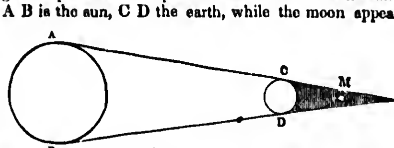
The wisdom and beneficence of the Deity are strikingly displayed in the economy of moonlight, as distributed to our globe during various seasons of the year. The remarkable phenomenon of the *harvest* moon is familiar to every one. During the time that our satellite is full, and for a few days before and after, in all about a week, there is less difference between the time of her rising on any two successive nights, than when she is full in any other month of the year. By this means, an immediate supply of light is obtained after sunset, so beneficial for gathering in the fruits of the seasons. To conceive of this phenomenon, it must be recollected that the moon is always opposite to the sun when she is full; that she is full in the signs Pisces and Aries, these being the signs opposite to Virgo and Libra, which the sun passes through in September and October, our harvest months. Thus, although, whenever the moon enters the two former signs (and she does so twelve times in a year), the same circumstance takes place with regard to the time of her rising; yet it is not observed on these other occasions, just because she is not *full* at the time. The reason of there being little difference in the time at which she rises on several consecutive nights, is, that at these periods her orbit is nearly parallel with the horizon. The harvest moons are as regular in south latitude as with us in north latitude, only they happen at different periods of the year.

ECLIPSES.

Eclipses are caused by the positions of the earth and moon with respect to each other and to the sun. An eclipse of the sun takes place when the moon is between the sun and earth; and an eclipse of the moon is the result of the earth being between the sun and moon. In other terms, the shadow of the earth cast upon the moon causes a lunar eclipse, and that of the moon upon the earth causes a solar eclipse.

The following figure explains an eclipse of the sun A B is the sun, M the moon, and C D the earth. The

shadow of the moon falls upon a part of the earth's surface; and there, accordingly, the sun appears in eclipse, the body of the moon being placed between. Another diagram represents an eclipse of the moon. In this instance, A B is the sun, C D the earth, while the moon appears



as a small circle M involved in the shadow thrown by the earth.

The places of the earth's orbit and the moon's do not exactly coincide, but cross or intersect each other; and the consequence is, that, in general, the moon, when she is in conjunction with the sun, either passes on one side or the other, and therefore does not intercept the sun's rays, or produce an eclipse. An eclipse of this kind can only take place when the earth and moon are in conjunction in that part of their orbits which cross each other (called the nodes), because it is then only that they are both in a right line with the sun. If the orbit of the moon were parallel to that of the earth, an eclipse would happen every month. Partial eclipses, again, are caused when the moon, in passing the earth, is not directly in a line with the sun, but a little on either side; the consequence of which is, the edge of one side of the moon only dips into the sun's disc. When the sun is eclipsed, the total darkness is confined to one particular part of the earth, but the lunar eclipses can be seen from every part of the earth, when the moon is above the horizon; and both circumstances prove that the earth is a good deal larger than the moon. The moon arrives very nearly at the same situation with respect to the earth, after making 223 revolutions, which are performed in eighteen years, of 365 days, 15 hours, 7 minutes, and 43 seconds, each; so that, after a period of about eighteen years, the series of eclipses recommences nearly in the same order, a circumstance observed by the ancients. The mean number of eclipses which occur in a year is about four, and there are sometimes as many as seven. There must necessarily be two solar eclipses, but it is possible that there may not be even one lunar. A remarkable eclipse, called an annular (or circular) solar eclipse, happens when the moon being in conjunction with the sun, the edge of the latter appears for a few minutes as a narrow ring of light encircling all round the dark disc of the moon. A great solar eclipse, visible in England, will take place in March 15, 1858, and a still more remarkable one, when the whole disc will be nearly covered, in August 19, 1887.

THE SATELLITES.

The earth, we have seen, is attended in her annual circuit round the sun by one satellite, the moon, which revolves round her as a centre. Strictly speaking, both move round a common centre of gravity in an elliptic orbit, the regularity of which is disturbed by their mutual attractions, so that it is undulated or waved, thus, ———. The number of undulations in a whole revolution is, however, only thirteen, so that the deviation from the ellipse is exceedingly trifling. Jupiter, Saturn, and Uranus, are all attended by satellites, as we have seen; and they form, as it were, each of the primaries with its attendant moons, a sort of miniature system, entirely similar in the laws by which they are governed to the great system to which they all belong, where the sun may be termed the primary planet, and the primary planets the satellites. Their orbits are circles or ellipses of small eccentricity, the primary occupying one focus. Of these systems, that of which Jupiter forms the head, has been studied with the greatest attention. The discovery of Jupiter's satellites by Galileo, was one of the first fruits of the invention of the telescope, and forms a remarkable era in the history of astronomy. From it resulted a solution of the great problem of the longitude, and the grand discovery of the aberration of light. It also established completely the Copernican system, and confirmed the laws of Kepler. The satellites of Jupiter revolve from west to east like our moon, but they are much less in comparison with their primary than it, whilst their orbits are of smaller dimensions, and less inclined to the ecliptic of their primary than that of our satellite. The largest of them is about 3377 miles, and the least about 2068 miles in diameter. The satellites of Saturn have been much less studied, and have fewer peculiarities. Those of Uranus, however, are remarkable, insomuch as their orbits are nearly perpendicular to the ecliptic, and in these orbits they are supposed to have a retrograde motion—that is, from *east* to *west*, instead of from *west* to *east*, like the other planetary bodies. No satisfactory cause for this departure (if it be one) from the general rule can be given. It is by accurate observation of the satellites that the densities of the planets, or their weight as proportioned to their bulks, have been ascertained; as also, by watching their frequent eclipses, that the velocity with which light travels from the heavenly bodies to the earth has been brought within our calculation.

PERTURBATIONS.

The name of *perturbations* has been applied to those inequalities in the lunar and planetary motions, which arise from the universality of attraction. Thus, not only does the sun attract the earth, and the earth the moon, but the latter attracts the preceding, and both are again influenced in their movements by the great centre of the system to which they belong. Not only is this the case, but every individual planet in the system attracts, and is attracted by, all the rest, although certainly in a very trifling degree when compared with that exercised by the sun over the whole of them. But in those miniature systems, such as the moon and earth, Jupiter and his satellites, &c., the perturbations thus arising, though insensible in short intervals, become apparent when accumulated, and derange the elliptic motions and relations. The calculation of the effects of these disturbing forces is famous in the history of analysis, under the name of *The Problem of the Three Bodies*. It is so worded, because the Sun, Moon, and Earth, and the Sun, Jupiter, and Saturn, form each separately a system little influenced by the rest. Any thing like an attempt to exhibit the method by which these nice calculations are made, is impossible in this place: of its difficulty, some idea may be formed, when we consider, what is apparent to every one, that the bodies under investigation are continually shifting their relative distances from each other, and altering the intensity of the disturbing force, which evidently must materially increase the abstruseness of the calculation. One of the principal effects produced on our globe by this play of gravitation is called

THE PRECESSION OF THE EQUINOXES.

The equinoctial points, we have already explained, are Aries and Libra, where the ecliptic cuts the equator. They are also termed nodes, and the line which joins the two is called the line of the nodes. The longitudes of the stars, as has been also observed, are counted on the ecliptic from the vernal equinox Aries. Now, if the line of the nodes is invariable, the longitude of the stars will of course remain the same from age to age. But, on comparing the actual state of the heavens with the recorded observations of ancient astronomers, it is perceived that the longitudes of the stars have considerably increased; so that, to explain the circumstance, we must either suppose that the whole firmament has moved in the order of the zodiacal signs, or else that the equinoctial points have gone backwards, or retrograded westward; since these points depend entirely upon the motion of the earth, which was far more likely to be disturbed by some cause or other, than that the countless multitude of stars should have a motion relative to these points. Accordingly, the phenomenon has been explained, by attributing to them a retrograde motion from *east* to *west*, in consequence of which the sun arrives at them sooner than if they had remained at rest. Hence the equinoxes, spring and autumn, and the other seasons, happen before he has completed an entire circuit. This motion, however, is extremely slow, amounting only to a degree in about seventy-six years; so that the equinoctial points will take nearly 26,000 years to make an entire revolution of the heavens. This motion was known in very ancient times, and its discovery is ascribed to Hipparchus, who lived about 140 years before Christ. The consequence of this retrograde movement is, that the sun's place amongst the zodiacal signs, at any season of the year, is greatly different from what it formerly was. The vernal equinox now happens in the constellation Pisces; the summer solstice in Gemini; the autumn equinox in Virgo; and the winter solstice in Sagittarius. Astro nomers, however, still count the signs from the vernal equinox, which always corresponds to the intersection of the ecliptic with the equator; and on this account it is necessary carefully to distinguish between them.

The cause of precession is to be found in the combined action of the sun and moon upon the protuberant mass of matter accumulated at the earth's equator, the attraction of the planets being scarcely sensible. The attracting force of the sun and moon upon this shell of matter is of a twofold character; one is parallel to the equator, and the other perpendicular to it. The tendency of the latter force is to diminish the angle which the plane of the equator makes with the ecliptic; and were it not for the rotatory motion of the earth, the planes would soon coincide; but by this motion the planes remain constant to each other. The effect produced by the action of the force in question is, however, that the plane of the equator is constantly, though slowly, shifting its place in the manner we have described.

NUTATION.

The action of the sun and moon in producing precession is various, at different periods of the year, according to the relative distance of the earth from them. Twice a year, the effect of the sun in producing it is nothing; and twice a year, namely, at the solstices, it is at maximum. On no two successive days is it alike, and, consequently, the precession of the equinoctial points must be unequal, and the obliquity of the ecliptic subject to a half-yearly variation; for the sun's force, which changes the obliquity, is variable, while the rotation of the earth, which counteracts it, is constant. By this means, the plane of the equator is subject to an irregular motion, which is technically called the *solar nutation*. Its amount, however, is so exceedingly small, as not to be appreciable by observation. That resulting from the moon's action, however, is sufficiently so, as to have been discovered by Bradley before theory had indicated its existence. Its period depends upon the revolution of the moon's nodes, which is performed in $18\frac{2}{3}$ years, and in about that period of time the axis of the world describes a small circle in the heavens, about eighteen seconds in diameter, contrary to the order of the signs. This apparent vibratory motion is denominated the nutation of the earth's axis. The two phenomena of precession and nutation are intimately connected, or rather are constituent parts of the same phenomenon, and dependent upon the same cause, as noticed above under Precession. It is impossible here to enter more minutely into the subject, or explain it more in detail. For an admirable account of it, we refer the reader to Herschel's Treatise on Astronomy, p. 333. We also would direct the inquirer to the same admirable work, for further information upon the subject of perturbations, comprising all the complicated varieties of motion. In general, they may be said to arise from the play of attractions kept up by the whole of the planets amongst themselves, they with the sun, and the sun with them; the distances of the bodies from each other, which are always varying; and the masses of matter, and the shape of the bodies, which are invariable. In concluding this part of our subject, we may remark, that it is by means of the perturbations of those planets which have no satellites, that astronomers have arrived at a knowledge of their masses. Every planet produces an amount of perturbation in the motions of any other, proportioned to its *mass*, and to the degree of advantage or *purchase* which its situation in the system gives it over their movements.

[WORKS ON ASTRONOMY.

Of the various treatises on Astronomy, which may be read with pleasure by those who wish to pursue the study in detail, we shall mention a few which are easily obtainable in this country. The two books of Dr. Dick, entitled, "*Celestial Scenery*" and "*The Sidereal Heavens*," are written in a delightful style, and imbody the recent discoveries in this interesting and important science. The work of Whewell on Astronomy and General Physics, is of the same popular character. Professor Kendall's work, entitled, "*Uranography: or, A Description of the Heavens, designed for Schools and Academies, accompanied by an Atlas of the Heavens, showing the Places of the principal Stars, Clusters, and Nebulæ*," is an excellent manual for practical purposes. It was prepared particularly for the use of the students at the Observatory of the Philadelphia High School, where the author is a professor. It is chiefly a translation from the admirable German original of J. J. von Littrow, Director of the Vienna Observatory, and the maps which accompany it are copied from Littrow's "*Atlas of the Starry Heavens.*" By adding the discoveries of Struve and Mædler, the new atlas is greatly improved. By the use of this atlas, the student may easily make himself familiar with the names and positions of the several constellations; and a proper degree of attention to the comparison of the atlas with the stars themselves, will enable one who wishes to make a particular study of this science, to fix in his mind the map of the heavens as firmly as almost every intelligent person has in his mind the general figure of the earth's surface. Although few persons make a study of astronomy as *amateurs*, there are many who would be delighted with so much knowledge of the subject gleaned from the atlas, as would enable them to recognise the most remarkable and conspicuous of the heavenly bodies. To such persons the atlas is invaluable.

Among the older treatises of Astronomy, that of Ferguson has always been most popular, on account of that plain, sensible, Franklin-like style which distinguishes the self-taught author. Dr. Gregory's "*Astronomy*," and the "*Astronomical Lectures*" of Dr. John Keill, are excellent for the elementary parts, though superseded in a great measure by recent discoveries and improvements. The great works of Lalande, Delambre, Newton, and Laplace, are of course intended only for the use of the most accomplished mathematicians, who make astronomy their favourite pursuit.—*Am. Ed.*]

GEOLOGY.

Basalt.—The Giants' Causeway.

Section I.—EXPLANATIONS—ORDER OF ROCKS.

Geology (from the Greek, *ge*,* the earth, and *logos*, discourse) may be defined as the science which describes the solid materials of the earth, the order in which they are arranged, the causes which have effected that arrangement, and the organic remains which are found in them. The investigations of the science are, in present circumstances, limited to the external crust of the earth.

The solid parts of this crust consist of a variety of substances, to which, whether they be hard or soft, the term *rock* is applied. Rocks are distinguished both by peculiarities in their constitution, and peculiarities in their form and arrangement.

At some places the surface of the earth is found to consist of a hard rock of crystalline or glassy texture, generally called granite, though subject to a considerable number of varieties. Granite is never, except in peculiar circumstances, found in the form of a layer, whether thick or thin, but generally in large irregular-shaped masses; and no other kind of rock, except in equally rare and peculiar circumstances, is ever found beneath it.

At other places the earth's immediate surface is found composed of some one of certain kinds of rock not less hard in texture than granite, and also of a crystalline consistence, but always found *in layers or beds*, generally of great thickness.

At other places we find, near the surface of the earth, rocks of a comparatively soft, and not of a crystalline consistence, forming also layers or beds, of greater or less thickness.

In some places, rock of a very hard kind is found, not exactly like any of the above, deposited in irregular forms, and often with the appearance of having penetrated through gaps forcibly made in other rocks.

Finally, throughout the first three classes of rocks, but particularly the first two, there are thin *veins* of diverse substances, including minerals.

Rocks of the first class are denominated Plutonic (from Pluto, the god of the infernal regions amongst the ancients), as supposed to have been formed at great depths in the earth, the matter having been originally in a hot and soft state, and afterwards cooled and crystallized slowly, under such enormous pressure as prevented the contained gases from expanding. The term *unstratified* is also applied to this class of rocks.

Rocks of the second and third classes are called Aqueous, as composed of matter deposited by water. Those of the second class are more specially named *Metamorphoric* (from the Greek, *metamorphosis*, a transformation), as supposed to have undergone a remarkable change in the course of their formation. It is supposed that the matter of these rocks, derived from rocks of the granitic kind, and suspended in vast oceans, was, when deposited, subjected to a great heat from below, which gave it in its reconsolidation much of that crystalline texture which it had in its plutonic form.

Rocks of the fourth class are denominated Volcanic, as being evidently composed of lavas, or masses of fire-melted rocky matter, which have been sent upwards by volcanoes.

Rocks of the second and third classes are likewise called *Stratified Rocks*, as being invariably found in strata or layers. Rocks of the first and fourth classes, as wanting this peculiarity, are distinguished as *Unstratified Rocks*.

The plutonic, and some of the lower metamorphoric rocks, have been also called *Primary*, or *Primitive Rocks*, as either the first formed of all, or formed very early. The upper metamorphoric rocks have in like manner been called the *Transition Series*, as forming a kind of link between the primary and those which follow, and partaking of the characters of both. Of the remainder of the aqueous rocks, a considerable number, being the lower portion, are sometimes called the *Secondary Rocks*, while the upper are named *Tertiary*. *Igneous Rock* is also a various name for the volcanic kind.

When rocks of various classes are seen at or near the same place, it is found that those of the second (except in the extraordinary circumstances alluded to) lie above those of the first; and those of the third above those of the second and first classes. Special kinds of aqueous rock are also found in a certain order above one another —much in the same way as if we were to place a book of many volumes on its side, having previously arranged the volumes according to their numbers, in which case the second would be above the first, the third above the second, and so on. Rocks are thus said to observe an *order of superposition*—the volcanic kind alone observing no order.

In some of the upper metamorphoric rocks, and in all those of the secondary and tertiary series, remains of plants and animals are found, showing that when these rocks were formed, the earth had become a scene of vegetable and animal life. The rocks containing these *organic remains*, or *fossils*, are called Fossiliferous; and the remaining rocks, from their containing no such relics, are called Non-fossiliferous.

Above the harder rocks, there are generally layers of clayey and earthy matter, topped by what is called the vegetable soil.

The principal rocks, exclusive of the volcanic, are ranged in the order indicated in the table at the end of this section, descending from the highest to the lowest.

Whatever rock, then, appears on or near the surface, if it be not of the volcanic kind, we may form from it some notion of what rocks are, and are not, below. If, for instance, we anywhere find one of the rocks of the tertiary series, we may deem it almost certain that rocks of the secondary, transition, and primary series, would be found in succession downwards, if we could dig to the proper depth. If we find rocks of the secondary series, it is equally likely that transition and primary rocks are below, and so on. The same conclusions may be formed respecting special kinds of rock of the various classes: if, for instance, we find at the surface a particular member of the secondary series, we may know that certain others of the same series are below. What alone prevents this rule from being of constant application, is the fact, that in no place does every member of the whole

* The g is pronounced hard, and the e as in gem.

series of known rocks exist. Everywhere some are wanting, in France, for example, transition rocks are in many places wanting. The rule, nevertheless, is certain with respect to the rocks which do exist at any place.

The order of supraposition enables us to conclude with greater certainty as to the absence of all rocks higher in the list than that which we find at the surface. If we find secondary rocks at the surface, we may be certain that none of the tertiary are there; if transition, none of the secondary or tertiary; if primary, none of the transition, secondary, or tertiary.

SECTION II.—CAUSES OF ARRANGEMENT.

The whole science of geology rests on certain natural laws, which are supposed, or have been ascertained, to be in constant operation, though not always, perhaps, with equally powerful effects. They chiefly resolve themselves into what have been called *Degrading and Elevating Causes.*

DEGRADING CAUSES.

The degrading causes are those which refer to the dissolving and wearing away of the elevated parts of the earth's surface, and the carrying of these parts down into lower levels. The *dissolving* is brought about by certain chemical and mechanical laws, and the *carrying down into low levels* is, in the main, a result of the law of gravitation. Considering that the solid parts of the earth are in their very nature liable to the operation of these laws, it appears quite unavoidable that land should be degraded. It is only, however, of late years that the degradation of land has attracted any attention. The immense scale on which it is constantly taking place was first explained in a satisfactory manner by Mr. Charles Lyell, in his "Principles of Geology," published in 1830.

The causes of the degradation of elevated land may be considered under three heads—*meteoric*, or those connected with the atmosphere; *fluviatile*, or those depending on rivers; and *oceanic*, or those in which the sea is the immediate agent.

The operation of the atmosphere and its vapoury contents upon the land proceeds in two ways, chemical and mechanical. There is a tendency in the hardest rock to absorb oxygen and carbonic acid from the atmosphere, and to be by that union dissolved. And this is a union which is always taking place, though in some places with more conspicuous effects than elsewhere. If the soil on any hill of volcanic rock be examined, we shall first find a fine powdery earth, then a mixture of earth and splinters of rock; next splinters alone, graduating into the hard rock below: such may be considered as an exhibition of the gradual process by which a hard rock is dissolved into powder or earth under the action of the atmosphere. In Jamaica, this dissolution of volcanic rock has taken place to a great depth. In granite, which is considered the hardest of all rocks, one of the component substances (felspar) has a great tendency to be decomposed, and hence even this rock is sometimes found to have been reduced to gravel or powder to a considerable depth. A hollow way, blasted through granite, was found by a geologist to have been in six years pulverized to the depth of three inches. These are solely *chemical* phenomena. Again, water perforates into minute fissures in rocks. When a frost arrives, the water swells, and dislodges parts of the rock, which are precipitated into the lower level. Or it may meet some clayey veins or strata, hitherto sufficient to keep various masses together. These veins or strata, being gradually softened by the water, lose their power of cementing the masses. The upper then fall away or slide into a lower level. A *slide* of rock from the Ruffiberg, in Switzerland, in 1806, filled the bottom of the vale below, destroying many villages, and causing the loss of 800 lives. The impulse of wind and rain on the surface of rock is also of great efficacy in pulverizing and wearing it down, sharp parts being rounded, and soft parts hollowed. In Sweden there are some large detached masses of granite, containing perforations produced by this cause, some so very large as to admit of a horse and cart passing through them. These effects may be considered as chiefly *mechanical.* As surely, then, as any part of the earth's crust is elevated into the atmosphere, just as certainly is it liable to be worn down and carried into a lower level.

When water collects into channels and follows its well-known tendency to find the lowest level to which it has access, it becomes a mechanical instrument of still greater force for wearing down the land. In its smallest rills, as it descends the mountain side, it cuts into the soil, and carries off whatever particles it can disengage. When gathered into brooks, its operations are still more powerful. When one of these is placed amongst mountains, every heavy shower swells it into an impetuous river, by which large quantities of detached rock and soil are brought down. In the upper parts of the courses of almost all rivers, the greater speed of descent makes up for the smaller volume of water, as far as the power of bringing down stones and soil is concerned. Again in the lower part of the course, the smaller speed is sometimes compensated by the unevenness of the course; in which case, the water is incessantly driven from one projection of the banks against another, and by that means wears away a great quantity of solid matter. Many facts have been collected to prove the great efficacy of rivers in wearing down the land. The Nerbuddah, a river of India, has scooped out a channel in basaltic rock, 100 feet deep. The river Moselle has worn a channel in solid rock to the depth of 600 feet. Messrs. Sedgwick and Murchison give an account of gorges scooped out in beds of the rock called conglomerate, in the valleys of the Eastern Alps, 600 or 700 feet deep. A stream of lava, which was vomited from Ætna in 1603, happened to flow across the channel of the river Simeto. Since that time the stream has cut a passage through the compact rock to the depth of between 40 and 50 feet, and to the breadth of between 50 and several hundred feet. The cataract of Niagara, in North America, has receded nearly 50 yards during the last forty years. Below the Falls, the river flows in a channel upwards of 150 feet deep, and 160 yards wide, for a distance of seven miles; and this channel has manifestly been produced by the action of the river.

Sometimes, during floods, rivers produce great changes in very short periods. A flood caused by the bursting of the barrier of a lake in the valley of Bagness, Switzerland, moved at first with the tremendous velocity of 33 feet per second. From the barrier burst by the waters to Lake Geneva, there is a fall of 4187 Paris feet; the distance is 45 miles; and the water flowed over all this space in five hours and a half. It carried along houses, bridges, and trees; and masses of rock equal in size to houses were transported a quarter of a mile down the valley.

The matter carried down by rivers is often deposited at their sides, when it constitutes what is called *alluvial land*. Sometimes it is deposited at the bottom of lakes, when it forms what are termed *lacustrine deposits*. In many instances it has been deposited in large quantities at the mouths of rivers, giving rise to what are denominated *deltas*. Deltas are so called on account of their resembling the fourth letter of the Greek alphabet. The triangular form of a delta is produced by the river, at a certain point inland, dividing itself into two streams which gradually diverge till they reach the ocean, enclosing the space which constitutes the delta. As an instance of the great amount of new land formed at the mouths of rivers, the delta of the Ganges is 220 miles in one direction by 200 in another. The lower part of this delta, a wilderness inhabited by tigers and crocodiles, is as large as the principality of Wales!

The matter carried down by rivers, and thus deposited, is nothing in amount compared to that transported to the ocean. The quantity of sand and mud brought down by the Ganges to the Bay of Bengal, is in the flood season so great that the sea is discoloured with it 60 miles from the river's mouth. According to Mr. Lyell, the quantity of solid matter brought down by this river every day, is equal in bulk to the greatest of the Egyptian pyramids. According to Captain Sabine, the muddy waters of the Amazon river may be distinguished 300 miles from its mouth.

The constant action of the sea upon the land is strikingly apparent to the inhabitants of coasts. Whole islands have been destroyed by the action of tides and oceanic currents, while the remains of others rise above the surface of the water, like the ruins of some desolated city. Many instances of the encroachment of the sea upon the land have been recorded. An inn on the coast of Norfolk, built in 1805, then 70 yards from the sea, was, in 1829, separated from the coast by only a small garden. A church on the coast of Kent, which in the reign of Henry VIII. was a mile inland, is now only about 60 yards from the water's edge. The island of Nordstrand, on the coast of Schleswig, was, in the thirteenth century, 50 miles long and 35 broad. About the end of the sixteenth century, it was reduced to an area of only 20 miles in circumference. The inhabitants erected lofty dykes for the purpose of saving their territories; but in the year 1634 a storm devastated the whole island, by which 1340 human beings, and 50,000 head of cattle perished. Three very small islets are all that now remain to point out the place where once flourished the fertile and populous island of Nordstrand. It is an old notion that Great Britain was once united to the continent of Europe; and the identity in structure of the opposite coasts of the strait of Dover seems to favour the supposition. There is reason to believe that the Island of Ceylon was at one period united to Hindostan. Humboldt is of opinion that the West India islands once constituted a circuit of land which enclosed the Gulf of Mexico.

It thus appears that there are causes in continual operation, for the wearing down of the elevated parts of the earth's crust, and taking the component particles into lower levels. The effects of these causes may be easily traced in the aqueous rocks, many of which are simply deposits of sediment carried by water from high into low places, and subsequently hardened, probably by heat from below and pressure from superincumbent materials. Were such causes not in some way counteracted, dry land could not long exist: all would be taken down and buried in the sea. We find the counteraction in what are termed the *Elevating Causes*.

Elevating Causes.

As Degrading Causes are chiefly owing to water, Elevating Causes are chiefly owing to fire. They are therefore sometimes comprehended under the term *Igneous Agency*.

The manifestations of igneous agency at present observable, may be considered under three heads—namely *volcanoes*, *earthquakes*, and *gradually elevating forces*. These phenomena may be viewed as the effects of subterranean heat, operating under different circumstances. A volcano may be described as an opening in the earth's surface, bearing the general appearance of a vent of subterraneous fire, and through which smoke, cinders and ashes, are almost continually issuing, but which sometimes discharges great fragments of rock, and vast quantities of melted rocky matter. The general effect is a throwing up of earthy material from a low to a high level.

Geographers at present reckon about 200 volcanic vents in activity throughout the earth. The greater number of the whole are in a line along the west coast of South and North America. There are many in the islands of the Pacific and Indian Oceans, and in the centre of Asia. In Europe, there are only three in great activity—Ætna in Sicily, Vesuvius in Italy, and Hecla in Iceland. But a vast number of hills throughout France, Britain, and other countries, bear the appearance of having once been active volcanoes. As volcanic action often takes place in the sea, and as there are probably many on land not yet described by geographers, the number of such vents throughout the earth must be considerably more than 200.

Of the power of volcanoes to throw up large quantities of solid matter, we have many examples. During an eruption of Ætna, a space around the mountain, 150 miles in circumference, was covered with a layer of sand and ashes, generally about twelve feet thick. In the first century, the cities of Herculaneum and Pompeii were buried beneath such a layer of matter by Vesuvius. In 1660, the Philosopher Kircher, after accurately examining Ætna, and the ground adjoining its base, calculated that the whole matter thrown out by it at its various active periods would form a mass twenty times as large as the mountain itself, which is 10,870 feet high, and 30 miles in diameter at the base. From this mountain, in 1775, there issued a stream of lava a mile and a half in breadth, twelve miles long, and 200 feet thick. At an earlier period, there was a stream which covered eighty-four square miles. In 1538, a large hill, since named Monte Nuovo, was thrown up in the neighbourhood of Naples in one night; and in 1759, in a district of Mexico, previously covered by smiling plantations, a sudden outburst of volcanic action, which lasted several months, terminated in leaving six hills, varying from 300 to 1600 feet in height above the old plain.

Of the effect of submarine volcanoes, some interesting observations have been made in recent times. In June 1811, an island was thrown up by volcanic agency, near St. Michael's, in the Azores. Columns of cinders rose 700 or 800 feet above the surface of the sea, with a noise resembling that of distant artillery. In the course of a few days, the island was a mile in circumference, and about 300 feet in height, having a crater in the centre, full of hot water. Some time afterwards, it disappeared. In July 1831, a similar island was thrown up, under precisely similar circumstances, in latitude 37° 11′ N., and longitude 12° 44′ E., off the coast of Sicily. It consisted of stones, mud, and cinders, and was of a circular form, about a mile and a half in circumference, with a crater of hot water in the centre, 400 yards in diameter. This island, named Sciacca, or Graham's island, existed so long above the sea, as to allow of many persons landing upon it. The Bay of Santorin, in the Greek archipelago, which is about six miles long and four broad, contained, a few years ago, three volcanic isles, the first of which rose about the year 200, the second in 1650, and the third in 1709. In a part of the bay, where the water is generally several hundred feet deep, a shoal has for several years been gradually rising: about 1816, there were fifteen fathoms water upon it; in 1830, there were only three or four; the later accounts reduced it to two and a half. This rising mass was ascertained to be of solid rock, about half a mile in length, by one-third of a mile in breadth: the water deepening suddenly all round it. In 1825, a new island was observed to rise in the Pacific Ocean, about 300 miles north of New Zealand. It consisted of solid rock, had a pool in the middle, and sent forth smoke from several chinks.

Many islands which have long been inhabited by man, bear all the appearance of having risen, in like manner, from the bosom of the deep. The islands of St. Helena and Ascension, the Azores, the West India islands, Iceland, and many of the islands in the Pacific are evidently the produce of volcanic action. "Owhyhee," says M. de la Beche, "is a magnificent example of such an island: the whole mass, estimated as exposing a surface of 4000 square miles, is composed of lava, and other volcanic matter, which rises in the peaks of Mouna Roa and Mouna Kaa, to the height of between 15,000 and 16,000 feet above the level of the sea."

The causes of Earthquakes have not as yet been satisfactorily explained, but they are now generally allowed to be connected with volcanic agency. They occur less frequently, and generally with less tremendous effect, in Europe, than in some other parts of the world, those parts where volcanic agency is most active being also the parts where earthquakes are most frequent and most dreadful. Though their effect is sometimes to cause a sinking of the ground, they may, upon the whole, be considered as among elevating causes. It is conceived that they are produced by gases confined in the molten interior of the earth, similar to those which find vent by volcanoes. Such gases, prevented by local circumstances from escaping, may, it is thought, thus shake the solid ground over a large tract, and even cause it to rise to a certain extent above its former level. The most striking proof which has been adduced in support of this doctrine, is the effect of the earthquake which took place in Chili in 1822. This is part of that continent in which volcanoes are most numerous and active. On the occasion referred to, a shock was felt along the coast for more than 1000 miles. The land for 100 miles along the coast, and backward to the line of the Andes, was raised above its former level. At the shore, and for some distance along the bottom of the sea, the rise was three or four feet, so that rocks formerly submerged, and covered with shell-fish, were now exposed above the sea. Old beaches, similar to that now raised, were also observed in parallel lines along the land, the highest being about fifty feet above the ocean.

It has since been observed that old beaches, similar to those in Chili, exist in the neighbourhood of many seas. Along the Frith of Forth, in Scotland, there is one about forty feet above the present level of the sea, and which generally appears as a kind of bank a few hundred yards back from the present shore. In the firths of Clyde and Cromarty, similar beaches are traced. They may always be detected by their terrace-like level, and the presence of sea-shells, rounded pebbles, gravel, and sand, such as usually compose beaches at the present day. In some places, old beaches have been conspicuous enough to become objects of popular wonder. In the vale of Glenroy, in Inverness-shire, as also in some neighbouring vales connected with Glenroy, there are three terraces along the sides of the hills, at various heights, which the ignorant people of the district firmly believe to have been roads formed by the hero Fingal for hunting, but which are now shown pretty clearly to have been the shores of quiet estuaries or arms of the sea, similar to many which still exist in the Scottish Highlands—three successive elevations, probably the effect of earthquakes, having elevated the land above the water, so as to leave as many terraces. Among the Alps, and in South America, there are vales marked in exactly the same way as Glenroy.

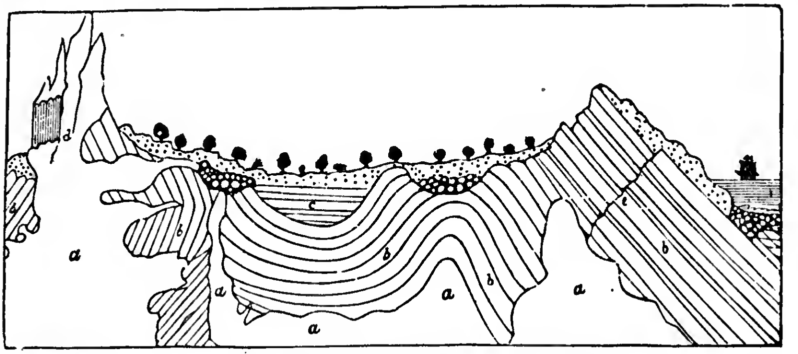
The existence of a force which *gradually elevates* the land in many places out of the water, was discovered by Mr. Lyell. His chief observations were made upon the shores of the Gulf of Bothnia, which he ascertained to have risen several feet in the course of the last century, and a few inches even since 1820.

Besides the greater elevating causes arising from subterranean fires, there are some lesser ones of less mysterious origin. The sands deposited on beaches are sometimes blown by winds in upon the land, covering the vegetable soil throughout a large space, and in some instances forming hills of considerable height and magnitude. Some parts of the coast of Holland are thus fenced with ranges of sand-hills, the whole mass of which has been blown back from the sea. On some parts of the French coast, large tracts, once smiling with cultivation, are thus buried under a sterile layer of sand, which is continually advancing, notwithstanding every effort of man. On the coast of Moray, in the north of Scotland, a tract once forming the barony of Culbleen, has been transformed into a sandy tract since the fifteenth century. Such sand-beds readily become converted into strata of sandstone, if saturated with water containing a limy infusion.

In various parts of the world, land is raised out of the sea by the efforts of coral insects. The works of these creatures are seen upon a vast scale in the Pacific, where whole ranges of islands are formed by them. On the coast of New Holland, there is a coral reef which stretches out to a thousand miles in length. The insects do not commence their laborious operations at a great depth below water; from 60 to 100 feet is considered the utmost extent to which the islands extend downwards. They are generally of a circular or oval shape; and Mr. Lyell is of opinion that corals build upon the rims and in the craters of submarine volcanoes. The outer wall of the building emerges first above the waves, enclosing a pool of tranquil water. The seeds of vegetables are either brought there by sea-birds, or wafted by the ocean, and the islands soon become clothed with a mantle of green. The substance of which these islands and reefs are composed, is lime, which the insects secrete from the sea-water, and cement together with a glutinous matter contained in their bodies. Mr. Lyell, while surveying the Isthmus of Panama, detached a quantity of these animals, and placed them on some rocks in a shallow pool of water. On returning to remove them a few days afterwards, he found they had secreted stony matter, and had firmly glued themselves to the bottom.

If we consider the operation of the elevating causes, we can be at no loss to understand how we should now see, as composing dry land, and sometimes in very lofty situations, strata which were once at the bottoms of seas; neither will it be surprising, if the irregular nature of volcanic forces is considered, that the strata, so elevated, rarely are found in their originally level position, but in all degrees of inclination, sometimes quite on edge, and even in certain rare instances folded backwards, so as to be upside down.

The changes produced by the united operations of aqueous and igneous agency are in part represented in the subjoined engraving of a supposed section of part of the earth's crust.



a Primary Rock, which has been thrown up, so as to disturb and mix itself with the Secondary Rocks.
b Secondary Rocks, thrown into inclinations and curves by the rising of the Primary Rock
c Tertiary Formation, deposited in a hollow formed by the disturbance of the Secondary Rocks.
d Basaltic Columns. *e* A fault or hitch in the strata.
The Circles are Boulders or detached stones, rounded by travelling in water, and deposited in hollows formed by water.
The dots indicate beds of gravel, immediately beneath the soil.

SECTION III.—DESCRIPTION OF ROCKS AND ORGANIC REMAINS.

PRIMARY.

Granite.

Geologists have been accustomed to describe this as the lowest and oldest of all rocks. Certainly, no other rock is ever found beneath it, except in peculiar circumstances afterwards to be described: if the mass of the earth, therefore, were to be judged of from the small superficial crust with which we are acquainted, granite might appear to constitute the bulk of our planet—a vast nucleus on which all the stratified rocks rested. Geologists are now disposed, under a sense of their limited knowledge, to speak of granite, not as the lowest and oldest of all rocks, but as the lowest as yet discovered, and as one which, though in most of its forms old, is yet sometimes found of recent formation. Granite, in fact, often appears as a volcanic rock, which has been thrown up in a state of fusion through superincumbent strata of all kinds, penetrating into their chinks, and spreading over them on the surface. Even tertiary rocks are found permeated and covered by it—a proof that it has been formed since the deposition of those rocks, which is one of the most recent events in geological chronology. These are the peculiar circumstances in which it may be said that other rocks sometimes lie beneath granite.

Granite, then, may be described as generally forming a basis or bed for all the other rocks—as rising in some places from its unmeasured depths into chains of lofty hills—and as in other places penetrating in veins through superincumbent rocks, and partially covering them at the top. It composes some part of the mountain ranges of Cornwall, Cumberland, and the Scottish Highlands, and veins of it are found upon or near the surface in many other parts of England and Scotland.

Three substances usually enter into the composition of granite; namely, (1) *quartz*, a gray glassy substance, composed of the oxygen of the atmosphere in union with one of the newly discovered metallic bases (silicium); (2) *felspar*, also a crystalline substance, but usually opaque and coloured pink or yellow, composed of sandy and clayey matter, with a small mixture of lime and potash; (3) *mica*, a silvery glittering substance, which divides readily into thin leaves or flakes, and consisting principally of flint and clay, with a little magnesia and oxide of iron. In some granites, instead of mica, we find *hornblende*, a dark crystalline substance, composed of alumina, silex or flint, and magnesia, with a considerable portion of the black oxide of iron. Such granites are called *Syenite*, from having been first found in the island of Syene. Other varieties are—*Serpentine*, in which there are dark spots like those on the skin of the snake (hence the name), and *Porphyry*, of which the distinguishing peculiarity is its containing little angular pieces of felspar enclosed in the mass.

In man's economy, granite is a rock of great importance. Its uncommon hardness makes it very suitable for the erection of buildings where great durability is desired. Hence, the docks of Liverpool, Waterloo Bridge in London, and many other buildings of a similar nature in England, have been composed of it, notwithstanding that it had to be brought from a great distance. Nearly the whole city of Aberdeen is built of the granite found in the neighbourhood; and the houses have consequently a glittering appearance when the sun is shining upon them. This stone is also the component material of Memnon's Head and Pompey's Pillar, two ancient structures in Egypt.

Inferior Stratified Series.

Above the granite, in its ordinary position, lies the inferior stratified series, consisting mainly of two kinds of rock, gneiss and mica-slate, with alternating strata of hornblende rock, quartz rock, eurite, talcose slates, chlorite slates, and argillaceous slates; of all of which it may be said that they follow no determinate order. These rocks are of the same materials as granite, in a very slightly modified form, and they are nearly as crystalline in their texture. Geologists also find in many places that the granite *passes* into them—a term expressing a blending of the characters of rocks at the line of their juncture. These two facts have led to the supposition that the inferior stratified rocks were formed from the materials of the granite, disintegrated by mechanical or chemical means, and washed into the beds of vast oceans, where, on their deposition, they were reached by the high temperature of the interior, and thereby reconsolidated in a crystalline form. To account for the rocks composed exclusively of one of the materials of the granite, we may suppose a chemical separation of those materials.

The most prevalent rock of the series is *gneiss*, a compound, like granite, of quartz, felspar, mica, and hornblende, and so highly crystalline as to be sometimes scarcely distinguishable from granite. A great portion of the Highlands of Scotland is composed of strata of gneiss, of vast thickness. It is remarkable for its richness in veins of the metals. *Mica-slate*, or *schist*, the next most prevalent rock of the series, is composed of mica and quartz. It is the surface rock of many extensive tracts of country. *Quartz rock*, which we may suppose to have been formed by a chemical separation of that component of granite, is also a prevalent rock. Humboldt takes notice of a mass of it in South America, more than 9500 feet in thickness. The round white pebbles, or candy stones, so often found on sea-beaches, and in the beds of rivers, are pieces of quartz rock. *Eurite*, of which felspar is the main ingredient, and *hornblende rock*, the chief element of which is signified by its name, may also be accounted for by a chemical origin.

Clay-slate is the geological term for the well-known stone with which houses are roofed. It is, as its name imports, composed mainly of clay—a substance too liberally diffused amongst the ingredients of granite, to admit of any wonder as to its being found in a nearly distinct state in this rock. Mica-slate and clay-slate are *fissile* in their structure—that is, capable of being split into very thin plates: hence the utility of slate, as a material for covering houses. But a curious diversity exists in this respect between mica-slate and roofing slate. In the former, the *cleavage*, or direction in which it splits, is in the same line as the stratification; but in roofing slate, the cleavage is always more or less transverse. What makes the latter circumstance the more remarkable—when strata of roofing slate are found, as often happens, contorted or wavy, the direction of the cleavage is in one straight line through them all, indicating that the influence which produced the cleavage in that rock took effect after the whole had been laid down, and after, by some subsequent accident of pressure, they had been forced into a wavy direction. Probably this phenomenon is of an electric nature. Clay-slates are found in great abundance in Cornwall and in the Scottish Highlands. A fine kind makes the slates used at school, and from a kind still finer are cut the pens used for writing on school-slates.

In the inferior stratified series, there occur a few small beds of limestone, sometimes called *Saccharine Limestone*, from its resemblance to refined sugar, and sometimes *Primitive Limestone*, from the period of its occurrence in the series. In Greece and Italy this rock has been subservient to the development of national talents, the highest that have ever been known of their class, for it is the marble from which the works of the Greek and Italian sculptors have been formed. In the geological history of our globe, its first appearance in the ascending series of rocks is an event of no small consequence, for limestone strata form a large proportion of the superior formations, and the manner in which they have been formed has engaged much attention. Limestone is the *carbonate of lime*, that is, a combination of the earth lime (itself a union of the metal calcium and oxygen) with carbonic acid (this being, again, a union of oxygen with the elementary substance carbon). Carbon is the largest element in the composition of vegetable and animal substances, and this its first appearance in the structure of rocks is of course a point of much interest, more especially as it is generally concluded that many of the superior limestone strata have been entirely formed of animal remains. We are thus tempted to surmise that the formation of the limestone beds of the inferior stratified series marks some early and obscure stage of organic existence on the surface of our planet. No distinct remains of plants or animals have, indeed, been found in this series; and it is customary to point to the next upper series, in which both do occur, as the era of organic life. Yet many geologists are of opinion that the inferior stratified rocks might have contained such remains, though the heat under which the rocks seem to have been formed may have obliterated all trace of such substances.

TRANSITION.

Grauwacke Group.

All the rocks hitherto described are of crystalline texture, and, apparently, chemical phenomena have attended their formation. In the group we have now arrived at traces of mechanical origin and deposition become apparent; but still a few strata resembling the preceding occur throughout the lower parts of this series, as if the circumstances under which the earlier rocks were formed had not entirely ceased. Hence the term *transition* for the series, as implying a passing from one state of things to another.

The rocks forming the lower part of this group, and which are sometimes separately classed as the *Lowest Fossiliferous Group*, are an alternation of beds of chlorite, talcose, and other slates, resembling those of the inferior stratified series, with beds of clayey and sandy slate, of apparently mechanical origin, and in which a few fossils are found. It thus appears that the cessation of the chemical origin of rocks, and the commencement of organic life, are events nearly connected; and it has thence been surmised that the temperature of the earth's surface was now for the first time suitable to the production and maintenance of organic things. At the same time, the alternation of the rocks teaches us the instructive fact that the change was not direct or uniform, but that, for some time, the two conditions of the surface superseded each other. This is conformable with a general observation, which has been made by an eminent geologist,* namely, that, however sudden changes may have taken place in particular situations, a general change of circumstances attending rock formations is usually seen to have been more or less gradual. The few fossils found in this part of the series are, as far as ascertained, the same as those of the next higher rocks.

These are a series of arenaceous and slaty rocks, of evidently mechanical origin, intermixed with small beds of limestone, in which that peculiarity is less distinct, the whole being termed more particularly the *Grauwacke* group. The general composition of the grauwacke indicates its having been formed of a fine *detritus* (matter washed from other rocks), and its having been deposited slowly; but it sometimes has fragments of rock, of various sizes under that of a man's head, imbedded in it, and is occasionally *passes into* conglomerates. The limestones

* M. de la Beche—Manual, 474

mixed with the grauwacke beds are larger and more numerous than in the preceding group, indicating an increase of the causes which produced carbonic acid. Fossils are also more numerous in them than in some of the other beds.

The grauwacke forms the immediate surface in many large districts in Scotland, England, France, Germany, and North America, showing that, at the time of its formation, "some general causes were in operation over a large portion of the northern hemisphere, and that the result was the production of a thick and extensive deposit enveloping animals of similar organic structure over a considerable surface."*

Fossils of the Grauwacke Group.

The fossils of the grauwacke (a few of which extend to the clayey and sandy slates immediately below) are of both plants and animals. Amongst the plants are algæ, or sea-weeds, showing that seas like the present now existed. Some land plants are also found, but of the simpler structures; as *filices*, or ferns; *equisetaceæ*, a class of plants of the character of the mare's tail† of our common marshes; and *lycopodiaceæ*, a class of the character of our club mosses.‡ All of these land plants are *monocotyledons*, that is, produced from seeds of a single lobe, and therefore *endogenous*, that is, growing from within—timber plants being, on the contrary, the produce of two-lobed seeds, and growing by exterior layers. The *flora* of this era thus appears of a very simple kind, indicating the existence only of marshy and damp grounds.

The animals are also, in general, of an humble and simple kind. There is abundance of those creatures (*Polypi*) resembling plants, which fix themselves on the bottom of the sea by stalks, and send forth branch-like arms for the purpose of catching prey, which they convey into an internal sac, and digest. At present these creatures abound in the bottoms of tropical seas, where they live by devouring minute impurities which have escaped other marine tribes, and thus perform a service analogous to that of earth-worms and other land tribes, the business of which is to clear off all decaying animal and vegetable matter. But the class of creatures found in greatest numbers in the grauwacke series of rocks are *shell-fish*, possibly because the remains of these creatures are peculiarly well calculated for preservation. All over the earth, wherever grauwacke rocks are found, shell-fish are found imbedded in vast quantities, proving that shell-fish were universal at the time when that class of rocks were formed. In a work entitled "Remarks on the Geology and Mineralogy of Nova Scotia," by Abraham Gesner,§ it is stated that they abound to a surprising degree in the valuable iron ores which in that province accompany or form part of the grauwacke rocks. In reference to the beds at Nictau, the author says, "The impressions made by marine organic remains in the ore and slate are extremely beautiful and distinct. Millions of shell-fish, of the molluscous and crustaceous tribes, which once enjoyed a perfect animal existence, have been swallowed up by this ore, where their remains and perfect likenesses are yet to be seen in the same natural and symmetrical beauty they possessed when alive."‖ At New Canaan, another of the places where these rocks are dug, the *lily encrinite*, a remarkable example of the radiated tribes, is found. It is so called from its resemblance to a lily resting on its stalk; "it is supposed," says Mr. Gesner, "that the animal resided in the bottom of the flower; and those portions of it which were movable, stood stretched out like arms to seize its prey. In the grauwacke at New Canaan, this animal appears like the lily with its capsule and petals closed. It is often of large dimensions; some were procured during our last visit to their stony graves, as large as water-melons, although in general they are much compressed, and have been flattened by the weight of the rock resting above them when in a soft state. This species of radiated animals is now altogether extinct, and many ages have passed since a living species could be produced. It has never been discovered in any of the strata placed above the new red sandstone; and as it does not appear but in a few of the older strata, the whole race must have enjoyed but a short existence."

Among the shell-fish of the early seas, a few of the most remarkable kinds are described by geologists as *ammonites* and *nautili*. These fishes have been found in great varieties of size; but one peculiarity pervades them all, that the greater part of the shell is a curve containing air-cells, while the animal itself resided in the outer portion, as if a human being were to have a house consisting of a long row of chambers, and live only in the front room. The ammonite receives its name from its resemblance to the curved horn on the head of the statue of Jupiter Ammon. It has been an animal of wonderful character and habits. Some of them have been of a minuteness scarcely visible, and others four feet wide. They are found over the whole surface of the earth. The economy of this animal destined it to live in general at the bottoms of deep seas, but to be able to rise occasionally to the surface. While it lived in the outer part of its wreathed shell, the interior curls were hollow, containing air, so as to make it of nearly the same weight with the element in which it lived. As the pressure of the water at the bottom of a deep sea would break in the plates of any ordinary shell, as it does a bottle when one is lowered to a considerable depth, the shell of the ammonite has been strengthened by a curious kind of internal arch-work, so as to be able to resist the weight of the incumbent fluid. This arch-work so completely meets all human ideas of ingenious contrivance for the purpose which it was destined to serve, as to form one of the most striking examples of that adaptation of means to ends which is universal in the works of nature, and which is so well fitted to impress the conviction of a great designing First Cause. The weight of the ammonite was so nicely adjusted to an equality with the water, that its filling with air or water a small central pipe which runs through the whole extent of the curve, was sufficient to make it rise as high or sink as low as might suit its inclination.

The *Trilobites* are another of the early species which deserve particular notice. Their remains, like those of the ammonites, are universal over the earth. It is curious that, while they have long ceased to live, other genera or kinds of the same class of creatures (*Crustacea*) still exist, and serve to afford some knowledge of their habits. The trilobite had a head and eyes, below which there was a body of no great length, covered with shelly plates in the manner of a lobster's tail, and terminating in a narrow rounded point. It is supposed that it had soft paddles to make way through the water, which have not of course been preserved. But the most interesting feature in the trilobite was its eyes, of which several specimens have been obtained in a nearly entire state. The eye of the trilobite has been formed with 400 spherical lenses in separate compartments on the surface of a cornea projecting conically upwards, so that the animal, in its usual place at the bottoms of waters, could see every thing around

* De la Beche.

† The mare's tail is an elegant plant, having a succulent erect jointed stem, with attenuated foliage growing in whorls round the joints, the latter being protected by a distinct striated sheath; the parts of fructification constitute a scaly catkin at the apex of the stem.—*Mantell.*

‡ Herbaceous prostrate plants found in damp woods and bogs, having their leaves simple and imbricated, that is, lying over each other.

§ Halifax, Nova Scotia. Gossip and Coade. 1836.

‖ "They are almost all bivalves," he adds, "of the genus *anomia*, although some were obtained resembling the *nautilus disens* and *planorbis equalis*." He elsewhere mentions that the encrinite and trilobite, which in Germany are said not to have been found in rocks earlier than the mountain limestone, are found in the iron ore and clay-slate of Nova Scotia.

As there are two eyes, one of the sides of each would have been useless, as it could only look across to meet the vision of the other; but on the inner sides there are no lenses, that nothing may, in accordance with a principle observable throughout nature, be thrown away. It is found that in the serolis, a surviving kindred genus, the eyes are constructed on exactly the same principle, except that they are not so high, which seems a proper difference, as the back of the serolis is lower, and presents less obstruction to the creature's vision. It is also found that in all the trilobites of the later rocks, the eyes are the same.

This little organ of a trivial little animal carries to living man the certain knowledge, that, millions of years before his race existed, the air he breathes, and the light by which he sees, were the same as at this hour, and that the sea must have been in general as pure as it is now. If the water had been constantly turbid or chaotic, a creature destined to live at the bottom of the sea would have had no use for such delicate visual organs. "With regard to the atmosphere," says Dr. Buckland, "we infer that, had it differed materially from its actual condition, it might have so far affected the rays of light, that a corresponding difference from the eyes of existing crustaceans would have been found in the organs on which the impressions of such rays were then received. Regarding Light itself, also, we learn, from the resemblance of these most ancient organizations to existing eyes, that the mutual relations of Light to the Eye, and of the Eye to Light, were the same at the time when crustaceans endowed with the faculty of vision were placed at the bottom of the primeval seas, as at the present moment."

A few bones of fishes have been found in the grauwacke; but some obscurity rests on the point. If such really have been the case, the remains of this era may be said to include specimens of all the four divisions of the animal kingdom—radiated, jointed, pulpy, and vertebrated animals, or radiata, articulata, mollusca, and vertebrata

SECONDARY.

Carboniferous Group.

This is a very comprehensive group, embracing not only the coal strata, and the beds of sandstone, limestone, and others alternating with these, but two great formations on which the proper coal group may be said to rest (though in a state of intimate connection), named the Mountain Limestone, and the Old Red Sandstone.

The *Old Red Sandstone* is a rock composed of grains of sand, cemented by the oxide of iron (the same substance as common iron rust), which gives it its red colour. Its strata are sometimes thin, and sometimes of the thickness of several thousand feet.

Mountain Limestone is an abundant rock. It forms the surface of a vast portion of the central counties of Ireland. Quick-lime, for the improvement of soil, and the preparation of the mortar used in building, is made from mountain limestone. It is also used in many countries as a building stone. Great caverns often occur in this rock, being probably owing to some chemical phenomenon in its formation. One of these at Mitchelston, in Ireland, comprehends passages several miles in extent. Mountain limestone is frequently traversed by beautiful veins of calcareous spar, at times appearing to be principally composed of organic remains, while at others not a trace of these can be detected. This rock is of various colours, but mostly gray, varying in intensity of shade. In some situations it affords good marble, which is susceptible of a considerable degree of polish. From its durable nature, it is likewise used in building. That stupendous work, the breakwater at Plymouth, is composed of it. Many valuable veins of lead ore occur in this rock.

The superior group more particularly called *Carboniferous*, and variously termed the *Coal Measures*, is composed of beds of that mineral, often very numerous, alternating with beds of sandstone, shale, limestone, ironstone, and some other substances. As many as forty beds of coal exist in the neighbourhood of the town of Newcastle. The great utility of this mineral as a domestic fuel, and in the arts, gives it a high importance, and happy is the country in which it exists in any considerable quantity. In a merely geological point of view, it is equally important. This rock is entirely a mass of vegetable matter, which has accumulated in certain situations, and afterwards been covered over and pressed into a hard consistence under other strata.

Two suppositions have been formed respecting the circumstances under which coal was formed. According to one, the vegetable matter must have grown in a dense forest for many years; then the land must have sunk, and become the basin of a lake or estuary, in which situation rivers would wash into it mud and sand, which would cover over the vegetable mass, and form superincumbent beds of shale and sandstone respectively. Then, the ground would be once more elevated, or sufficiently shoaled up, to become again a scene of luxuriant vegetation. When the vegetation had again become accumulated, the land would be again sunk, and become once more the basin of a lake, in which case the beds of mud and sand might again be formed by rivers. And this alternating process is supposed to have taken place as often as there are beds of coal to be accounted for. The other theory is, that, into some great estuary or lake, rivers coming from different quarters would bring the various matters forming the strata of the carboniferous group, a river from one direction bringing the mud which would form shale, another from another direction the vegetable matter which would form coal, and so on, each deposit perhaps taking place through the efficacy of some local circumstances, while the causes for the other deposits were temporarily suspended. At present great difficulties beset both theories.

Fossils of the Carboniferous Group.

In this group of rocks, about 300 species of plants have been discovered, all of them now extinct. About two-thirds of them are ferns; the others consist of large *coniferæ* (allied to the pine), of gigantic *lycopodiaceæ*, of species allied to the *cacteæ* and *euphorbiaceæ*, and of palms. Most of these plants probably exist in the coal beds, forming in fact their sole composition; but the peculiar nature of this mineral renders it difficult to detect them by examination.* Thin slices, however, have been examined by the microscope, and the vegetable structure has then been detected, where no external trace of it was visible. In cannel coal, a kind peculiarly hard, the vegetable structure is observed throughout the whole mass, while the fine coal retains it only in small patches, which appear as it were mechanically entangled. Slate and cannel coal often bear distinct impressions of plants. The plants are such as grow in hot moist situations; and it is therefore presumed, that a climate of that nature existed at an early period where coal is now found, even in Melville's Island, which is within the polar circle. Dr. Hutton thought that the vegetables must have been carbonized (or charred) by heat; but Dr. Macculloch contends, on good grounds, that the change has been effected solely by water and pressure, and that by these agents peat is capable of being converted into coal.

Large fragments of trees are often found in the shale and sandstone beds of the carboniferous group, more frequently in the former than in the latter. As usual with fossil substances, they are converted into the material in which they are imbedded, but preserve all their original lineaments, except that they are generally changed from their original round to a flattened form, the result of the

* Maclaren's Geology of Fife and the Lothians.

pressure they have sustained. In most instances, these fragments of trees appear to have been transported from a distance, and laid down horizontally in their present situation; but some have been found with their roots still planted in their native soil of mud, and the stems shooting upwards through several superior beds of various substances. Even in some coal beds, there are found stems of trees in their original vertical position; the roots being imbedded in shale beneath. In these instances, we must suppose the fossil to be on the spot where the living tree was planted, grew, and died. In the Bensham coal seam, in the Jarrow coal-field, a few years ago, there was found an upright tree of the kind called lepidodendra, thirteen and a half feet wide at the base, and thirty-nine feet high, the branches at the top being also entire; the lepidodendron, a common plant in this group, is so called from the scaly appearance of its stem, the scales being the roots of the leaf stalks. Various fossil trees have been discovered in the sandstone beds of the carboniferous group, at Craigleith and Granton, in the county of Edinburgh. One found in Craigleith quarry was twenty feet long, three feet in diameter, with scars where the branches had been torn off, and was ascertained, by microscopic inspection of slices of the trunk, to have been a conifera of the genus *Araucaria*, of which living species exist in New Holland.

The animal remains of the carboniferous group are much the same as those of the grauwacke—zoophytes, mollusca, crustacea, and a few fishes.

NEW RED SANDSTONE GROUP.

This group of strata, lying above the carboniferous group, comprehends rocks called—

The *Red Conglomerate*, formed of pieces of earlier rocks, some rough, some smoothed by rolling, all caked together;

Zechstein, a kind of limestone, abounding in Germany;

Red or *Variegated Sandstones*, a group of many varieties of colour, and principally of argillaceous and siliceous consistence, much used for building in England and other countries;

Muschelkalk, a limestone varying in texture, but most frequently gray and compact; not found in Britain or France, but occurring in Germany and Poland;

Variegated Marls—beds of rock of different colours, red, blue, and gray, composed of the remains of shell-fish.

To this group also belong beds of *rock salt*, of which many exist in England, particularly in the county of Chester. Rock salt is a crystalline mass, forming regular strata, sometimes of the thickness of many feet. The substance is rarely pure, but generally contains some portion of oxide of iron, which gives it a red colour. It is dug like coal and other minerals, and when melted and subjected to proper purification, is sold for domestic purposes.

FOSSILS OF THE NEW RED SANDSTONE GROUP.

The vegetable remains of this group are much the same as those of the preceding; but in the department of animal life, when we arrive at the Muschelkalk, or Shell Limestone, we find a great difference, leading to a supposition that, at this era of geological chronology, "circumstances had arisen changing the character of marine life over certain portions of Europe; that certain animals abounding previously, and for a great length of time, disappeared never to reappear, at least as far as we can judge from our knowledge of organic remains;"* and that certain new forms of a very remarkable kind were added.

The new creatures were of such a class as we might expect to be the first added to the few specimens of fish which had hitherto existed: they were of the class of Reptiles, creatures whose organization places them next in the scale of creation to fish, but yet below the higher class of animals which bring forth their young alive and nourish them by suck (mammalia). The earth was as yet only fit to be a partial habitation to creatures breathing its atmosphere and living upon its productions. It is supposed to have been under so high a temperature as to be unsuitable for mammalia: the lands which existed were probably low and marshy, with a hot, moist atmosphere, so as to present an appropriate field of existence only for lizards, crocodiles, and creatures of similar character. It is also to be supposed that the land was at this period undergoing frequent changes and convulsions, so that only a class of creatures to which submersions and deluges were matters of indifference, could reside upon it without a greater waste of life than was part of the Great General Design. The Reptiles, which first begin to appear in the Muschelkalk, continued to flourish while a great succession of other rocks was forming: throughout the whole of the Secondary Formation, there were few other land animals. In fact, the world must have been in the possession of reptiles for a many thousand times longer period than it appears to have yet been in the possession of man. "When we see," says Dr. Buckland, "that so large and important a range has been assigned to reptiles among the former population of our planet, we cannot but regard with feelings of new and unusual interest, the comparatively diminutive existing orders of that most ancient family of quadrupeds, with the very name of which we usually associate a sentiment of disgust. We shall view them with less contempt, when we learn, from the records of geological history, that there was a time when reptiles not only constituted the chief tenants and most powerful possessors of the earth, but extended their dominion also over the waters of the seas; and that the annals of their history may be traced back through thousands of years antecedent to that latest point in the progressive stages of animal creation, when the first parents of the human race were called into existence."*

The Reptiles of this early age were peculiar both in size and in structure. Some, which inhabited the seas, resembled lizards, but were of gigantic size; others, designed for land as well as sea, resembled the crocodiles which still exist in warm climates.

One of the most remarkable kind (genera) has received the name of *Icthyosaurus* (Fish Lizard), of which seven species or varieties have been discovered. The head is like that of the crocodile, composed of two long slender jaws, provided with a great number of teeth (in some cases 180), and eyes of great size (in one instance, the cavity for the eye has been found to measure fourteen inches), while the nostril, instead of being near the snout, as in the crocodile, was near the anterior angle of the eye. The body was fish-like, arranged upon a long spinal column, which consisted of more than a hundred joints, and to which a series of slender ribs was attached and terminating in a long and broad tail, which must have possessed great strength. The whole length of some specimens of the Icthyosaurus was about thirty feet. Instead of the feet, with which the lizard and crocodile are furnished, the Icthyosaurus had four paddles like those of the whale tribes, fitting it to move through the waters in the manner of those animals. It had also a construction of the sternum or breast-arch, and of the fore paddles, similar to that found in the Ornithorynchus, an aquatic quadruped of New Holland, and evidently designed, as in the case of that animal, to enable it to descend to the bottoms of waters in search of food. While the Icthyosaurus, then, is mainly allied to the lizard tribes, it combined in itself the additional characters of the fish, the whale, and the Ornithorynchus. "As the form of the vertebræ by which it is associated

* De la Beche's Manual. 404

* Bridgewater Treatise, .. 167.

with the class of fishes seems to have been introduced for the purpose of giving rapid motion in the water to a lizard inhabiting the element of fishes, so the further adoption of a structure in the legs, resembling the paddles of a whale, was superadded, in order to convert these extremities into powerful fins. The still farther addition of a furcula and clavicles, like those of the Ornithorynchus, offers a third and not less striking example of selection of contrivances, to enable animals of one class to live in the element of another class."* Such deviations cannot be considered as monstrosities; they are perfect adaptations of a creature to its purposes in the theatre of being. Only the spine of the Icthyosaurus as yet existed in other animals. Its head, its paddles, and its breast-arch, were all detached parts of future animals. How strange to reflect, that some of these contrivances were allowed to become extinct, and, as it were, lost to nature, and ultimately, after a long interval, were revived in connection with new creatures!

The internal structure and the modes of living of the Icthyosaurus, have been in a most unexpected manner made clear by the discovery of the half-digested remains of animals found within them or in their neighbourhood. It appears that the creature possessed a large stomach, extending throughout nearly its whole body, and that it lived upon fish and other reptiles, including its own kind. It must have occasionally devoured creatures several feet in length. Masses of the refuse of the Icthyosaurus, petrified as hard as the finest marble, and well known to geologists under the name of *coprolites*, are found to be marked spirally, like the refuse of certain species of sharks and dog-fish, the intestinal gut of which winds greatly, in order that it may take up the least possible room. We thus obtain a distinct idea of the nature of a very important part of the bodily economy of this long extinct race of animals. The stomach occupied so large a space in their bodies, for the reception of large quantities of food, and it was at the same time so necessary that the speed of the animal in pursuit of prey should not be clogged by a very large or long body, that the smaller intestines had been, by a wise arrangement of nature, reduced nearly to the state of a flattened tube, coiled like a cork-screw around itself; "their bulk being thus diminished," says Buckland, "while the amount of absorbing surface remained nearly the same as if they had been circular."

The name *Plesiosaurus* is applied to another highly remarkable reptile of gigantic size, which inhabited the world before the days of mammalia. A particular species has been described as having a body and paddles which bore some resemblance to those of the Icthyosaurus, the former being more bulky, and the latter longer and more powerful. At the end of a long neck, like the body of a serpent, was a head resembling that of a lizard, but also partaking of the characters of the head of the crocodile and Icthyosaurus. The tail was short. The backbone of this creature, and the neck and tail continuing it, contained in all about ninety vertebral pieces, thirty-three of which composed the neck; and the vertebræ are found to be of a less fish-like structure than those of the Icthyosaurus, and not nearly so well calculated for rapid motion. The ribs describe a large circle, and, being formed in four parts, seem to have been designed to contain a capacious set of lungs, and to rise and fall as the lungs were inflated or emptied: in this respect they resemble the ribs of the chamelion, whose changes of colour are now known to be occasioned by the varied depth of its inspirations. It is therefore surmised, though with little confidence, that the Plesiosaurus was also capable of changing its colour—a power which must have been highly necessary to a creature of its unwieldy character, both to enable it to elude the quicker and equally voracious Icthyosauri, and that it might more readily ensnare and seize the creatures designed to be its prey. The Plesiosaurus probably lived chiefly on or near the surface of the water, breathing the air, and dabbling for prey like a duck or swan, but might also be able to descend to the bottom, and even to move, though awkwardly, upon land. One part of its organization is peculiarly striking, as foreshadowing a structure of a more important kind. The paddles, which may be considered an advance or improvement upon the fins of fishes, are at the same time the type of the legs of quadrupeds and of the arms and limbs of man. The fore paddle consists of scapula (shoulder blade), humerus (shoulder), ulna (upper bone), and radius (lower bone), succeeded by the bones of the carpus and metacarpus, and the phalanges, equivalent to those which compose the palm and fingers of a human being. The hind-paddle presents femur, tibia, and fibula, succeeded by the bones of the tarsus and metatarsus, and five toes. Thus "even our own bodies, and some of their most important organs, are brought into close and direct comparison with those of reptiles, which at first sight appear the most monstrous productions of creation; and in the very hands and fingers with which we write their history, we recognise the type of the paddles in the Icthyosaurus and Plesiosaurus."*

Of the Crocodile family found in abundance in this class of rocks, the *Iguanodon*, of which remains have been found in the fresh-water formation at Welden in England, may be cited as a specimen. It was a huge animal, resembling the present Iguana of South America, which chiefly lives upon plants and seeds. The smallest part of the thigh-bone of an Iguanodon was found to be twenty-two inches in circumference, and much larger than that of any existing elephant. Species resembling the present Gavial of the Ganges have also been found. It may fairly be inferred from the present habits of the Gavial and other kinds of Crocodilea, that at the time when the extinct species flourished, the world must have contained many low shores and savannahs, fitted for the residence of such creatures. Some parts of England are thus proved to have had at one time shores of lakes and estuaries resembling those of the Ganges, the Nile, and other waters in hot countries, and consequently a much higher temperature than at present.

But perhaps the greatest wonder of the Reptile Age, was the creature called the *Pterodactyle.* Mainly a reptile of the lizard kind, its body possessed some of the characteristics of the mammalia; it had the wings of a bat, the neck of a bird, and a head furnished with long jaws full of teeth, so that in this last part of its organization it bore some resemblance to the crocodile. Eight species of the Pterodactyle which have been found, vary from the size of a snipe to that of a cormorant. The eyes were of enormous size, apparently enabling it to fly by night. From the wings projected fingers terminated by long hooks, like the curved claw on the thumb of the bat. These must have formed a powerful paw, wherewith the animal was enabled to creep or climb, or suspend itself from trees. It has been conjectured that the Pterodactyle would chiefly live on flying insects, of which, it is important to notice, several varieties existed at the same time, their remains being found in the same rocks. And it is likely, from the size of the eyes, that it searched for prey by night as well as by day. But it has also been argued, from the great length and strength of the jaws, and the length of the neck, that the Pterodactyle did not live solely upon flies, but likewise sought for fish in the manner of our own present sea-birds.

Tortoises also existed during this age, as is proved by the marks of their feet on sheets of sandstone, and by their remains. But as yet no animals of a higher class

* Bridgewater Treatise, i. 185.

* Buckland's Treatise, i. 213

had appeared upon earth for the remains of certain creatures of the Opossum family, found in the oolite at Stonesfield, near Oxford, stand as yet so solitary, that we cannot consider them as proving that mammalia were added to reptiles. With, then, flocks of Pterodactyles flying in the air in pursuit of huge dragon-flies; gigantic crocodiles and tortoises crawling amidst the jungles of low, moist, and warm shores, and such monsters as the Ichthyosaurus and Plesiosaurus swarming on the surface of the sea, while its depths were peopled by infinite varieties of fish, shelled and vertebrated; we can form some faint idea of what sort of world it was while the strata between the coal and the chalk were in the course of being deposited.

Olitic Group.

Next in order is a group which derives its name from a kind of limestone conspicuous in it, called oolite. Oolite, again, is named from its resembling the eggs or roe of fish. The oolite group comprehends, besides oolite itself, various alternating clays, sandstones, marls, and limestones.

Oolite is a carbonate of lime, intermixed with other ingredients. The oolites found at Bath, Portland, and Purbeck, are much esteemed in building. In the *oolite* which occurs over a considerable part of western Europe, there is a general uniformity of structure. In other parts of the world it differs very considerably, especially in its mineralogical character; and when this is the case, in order to determine whether certain rocks belong to the group or not, recourse has been had to the organic remains contained in them. In some parts of Europe these are very abundant, and in other places the reverse. To account for this difference, it has been supposed that in those parts of western Europe where they are abundant, shallow seas existed; while in those places, such as Italy and Greece, where few remains are found in the formation, the waters were deep.

With respect to the deposition of the oolitic group, nothing very satisfactory can be said. Whence came the immense quantity of carbonate of lime, is a question not easily answered. To account for it by springs, similar in size and saline contents to these we now see, appears to be unphilosophical. Many limestones are nearly altogether composed of organic remains; and this has led to a theory, that these animals extracted lime from the water, leaving their shells, produced through millions of generations, to be gradually converted into limestone. Notwithstanding all that we can suppose was deposited from springs and organic bodies, "there remains," says De la Beche, "a mass of limestone to be accounted for, distributed generally over a very large surface, which requires a very general production, or rather deposit, of carbonate of lime contemporaneously, or nearly so, over a great area."

In the oolitic group is comprehended by some geologists an important subordinate group, named the *lias*, which may be generally described as an argillaceous and calcareous deposit, sometimes the clayey material predominating, and sometimes the limey.

Fossils of the Oolitic Group.

In this group are found, as in some of the preceding, *algæ* (sea-weeds), *equisetaceæ* (mares' tails), *filices* (ferns), and *coniferæ* (allied to the pine). The animal remains are nearly the same as in the preceding group, but of a greater variety of species.

Cretaceous or Chalk Group.

This group, the uppermost of the secondary series of rocks, is so named from the beds of chalk of which it is mainly formed. Chalk is a carbonate of lime. It is very plentiful in England; and at Dover and other places it runs along the coast in cliffs and mountains of considerable size. Nodules or small masses of flint, sometimes containing remains of shells and animals, are abundant in chalk, and it is extremely difficult to account for their presence there. In the lower parts of the English chalk deposits, the flints disappear, becoming gradually more rare in the passage downwards. From this circumstance, the group has been sometimes divided into *upper*, or *chalk with flints*, and *lower*, or *chalk without flints*. But this characteristic does not universally prevail. Beneath the chalk there is a rock called *greensand*, which in Normandy is used as a building stone. An argillaceous deposit called *gault* also occurs; it is of a bluish-gray colour, and is frequently composed of clay in the upper, and marls in the lower part.

The cretaceous group, taken as a mass, may, in England, and over a considerable portion of France and Germany, be considered as cretaceous in its upper part, and sandy and clayey in its lower part. The group is extensively distributed over Europe; and M. de la Beche makes the following observations upon its mineralogical character in general:—"Throughout the British islands, a large part of France, many parts of Germany, in Poland, Sweden, and in various parts of Russia, there would appear to have been certain causes in operation, at a given period, which produced nearly, or very nearly, the same effects. The variation in the lower portion of the deposit seems merely to consist in the absence or presence of a greater or less abundance of clays or sands, substances which we may consider as produced by the destruction of previously existing land, and as deposited from waters which held such detritus in mechanical suspension. The unequal deposit of the two kinds of matter in different situations would be in accordance with such a supposition. But when we turn to the higher part of the group, into which the lower portion graduates, the theory of mere transport appears opposed to the phenomena observed, which seem rather to have been produced by deposition, from a chemical solution of carbonate of lime and silex, covering a considerable area.' M. de la Beche goes on to state, that no springs, or set of springs, could have produced the great deposits of chalk which cover immense surfaces. "But," says he, "although springs, in our acceptation of the term, could scarcely have caused the effects required, we may perhaps look to a greater exertion of the power which now produces thermal waters for a possible explanation of the observed phenomena." Mr. Lyell states, that chalk must have originated in the sea, in the form of sediment, from tranquil water; and that, before the existence of the rocks above it, must have been raised in large portions above the water, and exposed to the destroying power of the elements.

Fossils of the Cretaceous Group.

In this group, *confervæ* and *naides* were added to the vegetables; to the animal remains some fishes are added, but the number of the saurian reptiles is diminished.

A species of rocks, called the *Wealden rocks*, occur beneath the lower green sand of the English series, and are characterized by the presence of terrestrial and fresh-water remains in abundance.

TERTIARY.

The cretaceous group was at one time thought to be the uppermost; but it was in time discovered that, in several places, and particularly under the sites of the cities of London and Paris, there existed a still higher group or series, to which the name supra-cretaceous was therefore at first given, afterwards changed to the Tertiary Formation or Tertiary Series.

The tertiary rocks appear as if they had been formed in great hollows or basins in the former surface: hence it is customary to speak of the *London Basin*, the *Paris Basin*, &c. The Paris basin has been well explored and is supposed to present a good example of the Tertiary Formation. It consists of five subordinate groups or series, whereof the first, third, and fifth, appear, from the organic remains found in them, to have been formed in fresh water, and the second and fourth in sea water. They have been thus arranged in an ascending order:—

1. Fresh-water formation,	Plastic clay. Lignite. First sandstone.
2. Marine formation,	Calcaire grossier.
3. Second fresh-water formation,	Siliceous limestone. Gypsum, with bones of animals. Fresh-water marls.
4. Second marine formation,	Gypseous marine marls. Upper marine sands and sandstone. Upper marine marls and limestone.
5. Third fresh-water formation,	Millstone without shells. Shelly millstone. Upper fresh-water marls.

Plastic Clay.—This substance has been so named from its easily receiving and preserving the forms given to it, and, from possessing this property, it is used in the potteries. It rests upon a surface of chalk, which is very irregular, and furrowed out so as to present an alternation of hills and valleys. This clay is of various colours; and above it, and separated by a layer of sand, there frequently occurs another bed of clay, which scarcely can be called plastic. It is black, sandy, and sometimes contains organic remains. In this deposit, considered as a mass, it is stated that organic remains do not occur in the lower parts. In the central portion, fresh-water animals commonly occur, and in the upper part there is a mixture, sometimes an alternation, of marine and fresh-water remains.

Calcaire Grossier, as its name implies, is composed of a coarse limestone, which is employed for architectural purposes. It is frequently separated from the plastic clay beneath by a bed of sand, and it alternates with argillaceous or clayey beds. The animal and vegetable remains enclosed in it are numerous, and generally the same in corresponding beds, presenting considerable differences when the beds are not identical.

Siliceous Limestone is sometimes white and soft, sometimes gray and compact, and penetrated by silex. It is often full of cells, which are occasionally large, and communicate with each other in all directions.

Gypsum and Marls.—Gypsum is a crystalline substance composed of lime, in union with sulphuric acid and water. Its colours are gray, white, and yellow; but different varieties of it have different hues. It was used in ancient times for window glass. The gypseous rocks consist of an alternation of gypsum and limey and clayey marls; these marls are also found in thick beds above this alternation. These beds are considered as having been deposited in fresh water, and above them are others, which, from their organic remains, are believed to have been deposited in the sea.

Upper Marine Sands and Sandstones.—These consist of irregular beds of siliceous sandstone and sand. The animal remains in the lower portion of these beds are broken and very rare. In some situations, however, millions of small bodies have been found. These beds are occasionally covered with a species of rock which is filled with marine shells.

Upper Fresh-Water Formation.—This rock sometimes consists of white calcareous marls, at others of different siliceous compounds; from one of these, millstones of a celebrated kind are formed. They are sometimes charged with shells and petrified wood.

The supra-cretaceous rocks of England are commonly known by the names of plastic clay, London clay, Bagshot sands, the fresh-water formations of the Isle of Wight, and the crag of Norfolk.

Plastic Clay.—This deposit, though it occasionally contains an abundance of clay, employed for various useful purposes, is also mixed with beds of pebble, irregularly alternating with sands and clay. It thus differs from that of Paris, but it agrees with it so far as it reposes upon an uneven surface of chalk. The organic remains are principally marine, but those of fresh-water and terrestrial animals are intermingled with them.

London Clay.—The great argillaceous deposit which underlies the London district, has [illegible] this name. It is of a bluish or blackish colour, and contains a portion of calcareous matter; beds of [illegible]stone are also said to be occasionally present in it. This clay varies considerably in thickness, sometimes from seventy-seven to seven hundred feet. Besides the remains of a great variety of shell-fish, those of a crocodile and turtle have been found; masses of wood have also occurred in this stratum.

Bagshot Sands.—These rest upon the London clay, and consist of layers of various kinds of sands and marls containing fossil shells.

The Isle of Wight and London formations, although differing considerably in the nature of their deposits from those of Paris, present such an analogy in the organic remains of some parts of the group, that we are justified in referring the deposit to the same epoch, local circumstances and accidents having determined their characters.

It may be observed, that volcanic agency has been very active during the formation of this group. Ætna, it would appear, has for a long series of ages given forth its igneous products, and a considerable portion of these rest upon supra-cretaceous rocks. In central France, where extinct volcanoes are numerous, this is still more evident; a volcanic mass, called the Plomb du Cantal, appears to have burst through and fractured the fresh-water limestones of the Cantal, which, according to Mr. Lyell, are equivalent to the fresh-water deposits of Paris, and some of those in England.

Fossils of the Tertiary Series.

As yet, no distinct traces of the higher forms of organization have appeared. No vestige of the mammiferous or sucking animals, either terrestrial or aquatic, which form so large a portion of the existing animal kingdom—no marks of the bird class, now so extensive and important—and scarcely any token of such marine and fresh-water shells and other productions as abound in the present time—have been discovered either in the earlier or later secondary strata of the globe. The rare and indeed almost unique, cases of supposed exception to this statement, have all been found capable of such explanations as leave the general truth unshaken.

In the Tertiary Formation we find a striking and wonderful change of appearances. These strata are rich beyond all that go before them in animal remains. At the time of their formation, the aptitude of the earth for the maintenance of organic life has vastly increased, and was continually increasing, as the period approached when man himself and the higher orders of being were to become its inhabitants. The way was paved, it will be seen, for this consummation, by the same regular and progressive steps which characterized the organic changes of the geological eras already described.

From their relative position, and from the organic remains contained in them, geologists have been enabled to distinguish, in the tertiary series of strata, four great eras of formation. One of the most striking and novel features of these formations consists, as already mentioned, in the repeated alternations of *fresh-water* deposits with marine ones; a circumstance established beyond question by the character of the fossil shells and bones found respectively in these deposits. To the oldest of the tertiary eras, the term Eocene is applied; the second is called the Miocene period; the third the Older Pliocene; and the fourth and latest, the Newer Pliocene; names founded on the respective proportions which they fossil shells bear to shells of existing species. In each of these periods is included a great fresh-water, as well as a marine, formation or deposit. Of the living beings which flourished in each of these periods, we shall endeavour to give some account, commencing with the most ancient, the Eocene.

After the chalky formation, a period of considerable repose seems to have ensued, during which a large portion of the existing continents, and in especial the hollows and basins on their surface, appear to have been the site of vast lakes, rivers and estuaries. From these was deposited the first great fresh-water formation of the Eocene period. While this deposit was going on, the globe, no longer an entire stagnant marsh, but as yet incapable of affording much support to terrestrial animals, was tenanted only by such quadrupeds as live beside rivers and lakes. Nearly fifty extinct species of mammalia, chiefly of this character, were discovered by Cuvier in the first Eocene fresh-water formation. The most of these belonged to the class Pachydermata (*thick-skinned* animals), of which the elephant, the rhinoceros, the hog, the tapir, and the horse, are remarkable existing examples. This class of Pachydermatous animals, it may be observed, only includes such thick-skinned creatures as have no more prominent mark to distinguish them than their *skins*. The seal and the river-horse, for example, are thick-skinned, but then they are *amphibious*, and that is a more prominent distinction. The extinct animals to which we now refer resemble the tapir more than any of the other Pachydermata. Among these extinct creatures, the most worthy of notice are the Palæotherium, the Anoplotherium, the Lophiodon, Anthracotherium, Cherapotamus, and one or two other families, including, some of them, not less than eleven or twelve distinct species. These mammiferous families had some general traits of resemblance, and the description of the great *Palæotherium* may afford an idea of the main features of all. This animal was of the size of the horse, or about four feet and a half in height to the wither. It was more squat and clumsy in its proportions than the horse; the head was more massive, and the extremities thicker and shorter. On each foot were three large toes, rounded, and unprovided with claws; the upper jaw was much longer than the under. The tapir, and partly, also, the hog, if large enough, would closely resemble the great Palæotherium. "The Palæotheria (says Buckland) probably lived and died upon the margins of the then existing lakes and rivers, and their dead carcases may have been drifted to the bottom in seasons of flood." The other mammiferous families of the first Eocene formation, were all, like the Palæotheria, herbivorous, and had, it is probable, similar habits.

The number of animals, aquatic and terrestrial, whose remains are found in the other deposits of the Eocene period, is immense. In some gypsum (sulphate of lime) quarries of that era, scarcely a block can be opened which does not disclose some fragment of a fossil skeleton. The following list of the animals found in the gypsum quarries of Paris will show sufficiently how very different from the gigantic reptiles of the secondary eras were the creatures that tenanted, and found fitting sustenance on, the earth during the Eocene period. Besides various extinct Pachydermatous families, there were found extinct species of the wolf and fox, of the raccoon and genette, among the Carnivorous tribes; of the opossum; of the dormouse and squirrel; nine or ten species of birds, of the buzzard, owl, quail, wood-cock, sea-lark, curlew, and pelican families; fresh-water tortoises, crocodiles, and other creatures of the Reptile class; and several species of Fishes:—all of these animals, be it remembered, being *extinct species* of existing families, exclusive of the Pachydermatous animals, and the Fishes, which were extinct species of *extinct families*. The occurrence of the birds mentioned in the preceding list of the Eocene animals, forms (says Dr. Buckland) "a remarkable phenomenon in the history of organic remains." The number of fossil shells found in the Eocene formations is estimated by Mr. Lyell at 1238. As in the case of the terrestrial creatures, few of these shell-fish are of recent or existing species, not more, at the utmost, than 3½ in every hundred. We do not, moreover, recognise in the strata now under consideration, those prodigious accumulations of *microscopic* shells, as they are called from their extreme minuteness, that distinguish the formations of the secondary or preceding ages. One small piece of rock, of the ages in question, has been found to contain above ten thousand chambered shells, though the whole weighed only an ounce and a half. In fact, great beds of secondary limestone seem to be almost wholly composed of microscopic shells. Such phenomena are not presented in the Eocene or subsequent tertiary formations. The shells of these periods, as has been already observed, approximate more to the character of recent or existing species.

In the Eocene period, then—the earliest of the Tertiary eras—we perceive, for the first time, the existence in the animal kingdom of a similar order to that which now prevails, indicating that the earth and its atmosphere were in a certain degree assimilated to their present condition. It seems impossible, however, to agree with Mr. Lyell in the subjoined remark on the Eocene era:—"When we reflect (says that writer) on the tranquil state of the earth, implied by some of the lake-formed and sea-formed deposits of this age, and consider the fulness of all the different classes of the animal kingdom, as deduced from the study of the fossil remains, we are naturally led to conclude that the earth was at that period in a perfectly settled state, and already fitted for the habitation of man." Several strong arguments might be adduced against this conclusion, but we shall only refer to one objection—the temperature. From the frequency of the remains of crocodiles and other tropical reptiles in the Eocene formations, and from the frequency of palm-leaves and trunks, as well as from other evidences, the atmosphere may be regarded as having been still at too high a temperature for human comfort. Volcanic action, moreover, appears to have been of very common occurrence.

The second, or Miocene period, however, of the Tertiary ages, brings us a step nearer to the existing condition of things. A strong proof of this is derived from the shells alone of the strata of this period. Whereas only three in the hundred Eocene fossils were of recent species, of the Miocene shells we find eighteen in the hundred to have existing representatives. Along with the mammalia, also, of the Eocene period, we find that the Miocene deposits present us with the earliest forms of animals existing at the present time. In Dr. Buckland's Bridgewater Treatise, a table is given, exhibiting the animals found at Darmstadt, in a bed of sand referable to the Miocene period. In this list are mentioned two skeletons of the Dinotherium, a large herbivorous animal, called by Cuvier the Gigantic Tapir; two large Tapirs; Calicotherium—two large Tapir-like animals of this name; two Rhinoceroses; Hippotherium, an animal allied to the horse; three Hogs; four large Cats, some as large as a lion; the creature called the Glutton; Agnotherium, allied to the dog; and Machairodus, an animal allied to the bear. From this list the reader will perceive the gradual approach in the Miocene animals to existing species. The largest of the terrestrial mammalia yet discovered belongs to the period now under notice; it is the Dinotherium, or Gigantic Tapir, already mentioned. No complete skeleton has yet been discovered; but from the bones found, Cuvier and others imagine the animal to have reached the extraordinary length of eighteen feet. The most remarkable peculiarities of its structure consists in two enormous tusks at the end of its lower jaw, and the shoulder-blade, which resembles that of a mole, and is calculated to have given the power of digging, or other free movement, to the fore-foot. It seems probable that this stupendous creature lived in fresh water lakes, and had the half-terrestrial, half-aquatic habits of the walrus or river-horse. The tusks might be used in digging up roots and plants, and also in sustaining the head on banks during sleep, or in pulling the body out of the water, as the walrus uses a similar pair of tusks. "In these characters (says Buckland) of this gigantic, herbivorous, aquatic quadruped, we recognise adaptations to the lacustrine (lake-covered) condition of the earth, during that portion of the tertiary periods, to which the existence of these seemingly anomalous creatures seems to have been limited."

In the Miocene period, the seas became the habitation of numbers of marine mammalia, consisting of Dolphins, Whales, Seals, Walrus, and the Lamantin, or Manati. Few of these animals were of the same species as those which exist at present, but the differences were far from being great or remarkable. This circumstance, as well as the considerable number of fossil shells identical with existing ones, exhibits an approach in the character and tenantry of the Miocene seas to the present state of things in these respects. The discovery, also, of true terrestrial mammalia, as the Rhinoceros and Hog, in the Miocene formations, shows, that since the era of the gigantic reptiles, no slight portion of the earth's surface had assumed the condition of dry land, fit for the support of the common herbivorous creatures. At the same time, the occurrence of such animals as the Dinotherium in the Miocene strata, proves, as Dr. Buckland remarks, that many regions were still covered with great lakes and estuaries.

It now remains to inquire into the nature and peculiarities of the animals characterizing the Pliocene age, which, for convenience, has been arranged into two periods, the Older and Newer Pliocene, the latter of which immediately preceded the formation of the Diluvial layer constituting the present superficial matter of the globe.

Proceeding from the deepest seated portions of the terrestrial crust upwards, we find a progressive approach, as has already been stated, in the character of the animal remains to the existing varieties of animal life. A remarkable proof of this is presented by the shells of the Pliocene periods. Whereas only eighteen in the hundred of the Miocene shells were of recent species, in the Older Pliocene from thirty-five to fifty, and in the Newer Pliocene not less than from ninety to ninety-five in the hundred, are identical with shells of existing species. This great change is accompanied by the disappearance of the Palæotherian family and others, which formed the most striking animal remains of the periods immediately preceding. In place of these extinct species of *extinct* Pachydermatous or thick-skinned families, we observe in the strata of the Pliocene periods a vast number of remains of *existing* Pachydermatous families, such as the elephant, the rhinoceros, and the hippopotamus, though these remains belong to varieties that are now extinct. The first traces also now appear of Ruminant animals—of oxen, deer, camels, and other creatures of the same class. But though it is of importance to notice the existence of such remains in the Pliocene ages, in order to exhibit the progressive approach to the present state of things in the animal kingdom, it is in the huge and extraordinary creatures, now no longer to be seen on the face of the earth, that the interest of such an investigation as the present chiefly lies. The Pliocene ages are not less rich in these wonders than the periods already described, and to this portion of the subject we shall now turn our attention.

The enormous creature called the *Great Mas'odon*, belongs to the Pliocene era. Of all the fossil animals whose skeletons have been found *complete*, or nearly so, the Mastodon is the largest. Much confusion has existed relative to this animal's true character, many naturalists regarding it as an extinct species of the elephant and others holding that it approached nearer to the hippopotamus. Cuvier, however, determined it to be the head of a distinct family, comprehending several other species. It is about one hundred and twenty years since remains of the Mastodon were first discovered in America, and vast quantities of them have been since found in the same region, buried chiefly in marshy grounds. One skeleton nearly complete was dug up on the banks of the Hudson in 1801, and it is from this that a correct knowledge of the animal has been principally derived. In height, the Mastodon seems to have been about twelve feet, a stature which the Indian elephant occasionally attains. But the body of the Mastodon was greatly elongated in comparison with the elephant's, and its limbs were thicker. The whole arrangement of the bony structure resembled that of the elephant, excepting in one point, which Cuvier regarded as of sufficient consequence to constitute the Mastodon a different genus This was the cheek-teeth, which are divided, on their upper surface, into a number of rounded, obtuse prominences, arranged not like the elephant's, but like those of the wild boar and hippopotamus; whence it is concluded, that, like the latter animals, the Mastodon must have lived on tender vegetables, roots, and aquatic plants, and could not have been carnivorous. The lower jaw of the skeleton found on the Hudson is two feet ten inches in length, and weighs *sixty-three pounds*. Like the elephant, the Mastodon had two tusks, curving upwards, and formed of ivory, and, in the opinion of Cuvier, it had also a trunk of the same kind with the former animal's.

Altogether, making an allowance for several additional feet of length, the larger specimens of the elephant must be considered as varying little from the Great Mastodon. Though not an aquatic animal, the Mastodon, as has been mentioned, appears to have lived, like the hippopotamus, on aquatic vegetables, and this is corroborated by the marshy situations in which its remains are generally found in the greatest profusion. The Indians of Canada had observed these bones, and believed them to belong to a peculiar animal which they called the *father of oxen*. There have been found many bones, belonging, it is conceived from the teeth and other peculiarities, to smaller varieties of the Mastodon. No complete skeletons, however, having been yet dug up, it is unnecessary to attempt any detailed description of what these minor Mastodons must have been. From the immense number of Mastodon bones which have been dug up in various parts of the earth, and particularly in the New World, we must conclude, that at no distant period of time the terrestrial surface was extensively peopled by these enormous creatures. How strange would the spectacle have been, could a human being have been set down in the midst of the great marshes of the ancient world, and beheld these animals browsing in hundreds, all like moving mountains of living matter!

Another creature, belonging to the later Pliocene ages, if not indeed to the era of the Diluvial formation, has been discovered in America, both north and south. This is the *Megatherium*, an animal more widely removed in character from any existing creature, than any of the other fossil remains that have been yet observed. The Megatherium was discovered towards the end of the last century. A skeleton, almost entire, was found nearly at one hundred feet of depth, in excavations made on the banks of the river Luxan, several leagues to the south-west of Buenos Ayres. The Megatherium was a tardigrade (slow-moving) animal, like the sloth, and was at least the size of a common ox. Its limbs were terminated by five thick toes, attached to a series of huge, flat, metatarsal bones, or those bones with which the toes are continuous, as in the human foot. "Some of the toes (says Buckland, in his notice of this creature) are terminated by large and powerful claws of great length; the bones supporting these claws are composed partly of an axis, or pointed core, which filled the internal cavity of the horny claw; and partly of a bony sheath, that formed a strong case to receive and support its base." These claws, from their position, were admirably calculated for the purpose of digging. The legs of this creature were of enormous thickness, its thigh bone being nearly three times the thickness of the same bone in the elephant. The other bones of the Megatherium were almost proportionably heavy. A still more remarkable feature, however, in the animal's structure, was the coat of armour, of solid bone, varying from three-fourths of an inch to an inch and a half in thickness, which covered its hide, in the same manner as the armadillo's is encased by the same substance.

The habits and peculiarities of this stupendous sloth, for so the Megatherium may be termed, are well described and explained in Dr. Buckland's Bridgewater Treatise. After stating that with the head and shoulders of a sloth, it combined, in its legs and feet, an admixture of the characters of the ant-eater and the armadillo, and resembled them still more in being cased in a coat of armour, he continues, "Its haunches were more than five feet wide, and its body twelve feet long and eight feet high; its feet were a *yard in length*, and terminated by most gigantic claws; its tail was probably clad in armour, and much larger than the tail of any other beast among living or extinct terrestrial mammalia. Thus heavily constructed, and ponderously accoutred, it could neither run, nor leap, nor climb, nor burrow under the ground, and in all its movements must have been necessarily slow; but what need of rapid locomotion to an animal, whose occupation of digging roots for food was almost stationary? and what need of speed for flight from foes, to a creature whose giant carcass was encased in an impenetrable cuirass, and who by a single pat of his paw, or lash of his tail, could in an instant have demolished the cougar or the crocodile? Secure within the panoply of his bony armour, where was the enemy that would dare encounter this behemoth of the Pampas (the South American region where it existed), or in what more powerful creature can we find the cause that has effected the extirpation of his race?

"His entire frame was an apparatus of colossal mechanism, adapted exactly to the work it had to do; strong and ponderous, in proportion as this work was heavy, and calculated to be the vehicle of life and enjoyment to a gigantic race of quadrupeds; which, though they have ceased to be counted among the living inhabitants of our planet, have, in their fossil bones, left behind them imperishable monuments of the consummate skill with which they were constructed."

Another extinct tardigrade creature, presenting many of the characters of the Megatherium, was discovered in a calcareous cavern in Virginia, and received from President Jefferson, who first described some of its bones, the name of the *Megalonyx*. Jefferson conceived the claw to be that of an extinct feline animal of vast size (that is to say, an animal of the same description as the tiger, lion, cat, and lynx, all of which are beasts of prey); but the French naturalists declared the possessor of the claw to have been herbivorous, or calculated to live on herbs; and this was triumphantly proved by the discovery of others of its bones. The Megalonyx appears (for a complete skeleton has not yet been found) to have been a little smaller in size than the Megatherium. But the Megalonyx, according to Cuvier, was herbivorous after the manner of the sloth, since its teeth were conformed precisely like that animal's. From the resemblance of their feet, also, he concludes that their gait was similar, and all their movements alike. The difference in volume of body, however, must have prevented the habits of the Megalonyx from being perfectly analogous to those of the sloth. The Megalonyx could but seldom have climbed up trees, because it must rarely have found any sufficiently strong to support its weight. But its height would enable it to browse, like the sloth, among the leaves of trees, without its being under the necessity of climbing any but such tall and strong ones as could bear its weight. It is even possible that the weight of the creature may have been serviceable in bending down, and perhaps in breaking, the elevated branches which contained its food.

The next fossil animal to which we shall refer, is that long called the *Mammoth*, under the impression that it was a distinct genus, but which is now universally denominated the *Fossil Elephant*, as being an extinct species of that existing family. The Mammoth (which name we shall retain for the sake of distinction) is rather to be regarded as a creature of the Diluvial than of the Pliocene period (that is to say, belonging to the age, when, by means of floods, the present beds of gravel and hard clay so often found between the rocks and vegetable soil were laid down upon the earth), as some specimens have been discovered in Siberia, with portions of the flesh and hair actually preserved along with the bones among the ice. It was at first thought, when numbers of Mammoth bones were discovered in Italy, and other southern countries of Europe, that they were the remains of elephants brought by the Romans and others from Asia and Africa; but the incalculable quantities of them ultimately detected in Russia and other districts, where elephants were never brought in the shape of oriental tribute, as they were to Rome, showed that their presence was to be attributed to natural causes, and not to the casual agency of man. In truth, the beds of the Volga, Don, and other northern rivers, are filled with them, and this can be accounted for only on the hypothesis, either of an alteration in the habits of the elephant, or of a great change of climate in these parts, or of some immense moving force on the face of the earth, which has carried them thither. The instance in which part of the flesh was found along with the bones, will supply us with a general description of the Mammoth. When the animal, on this occasion, was first seen through the mass of ice in which it lay, the soft parts were nearly entire. After the natives had fed their dogs for a long time with the mountainous bulk of flesh, Mr. Adams of St. Petersburgh heard of it, and set out to see it. When he reached the spot, the skeleton was entire, with the exception of a fore leg. The spine of the back, a shoulder-blade, the pelvis, and the rest of the extremities, were still united by ligaments and a portion of the skin. The other shoulder-blade was found at some distance. The head was covered with a dry skin. One of the ears, in high preservation, was furnished with a tuft of hair, and the pupil of the eye was still discernable. The brain was found in the skull, but in a dry state. The neck was furnished with *a long mane*, and the skin, generally, was covered with black hairs and a reddish sort of wool. Of the quantity of hair and bristles that had been on the body, some idea may be formed from the fact that thirty pounds of them were gathered from the ground, where the dogs, in eating the flesh, had dropt them. The tusks were more than nine feet long, and the head, without the tusks, weighed more than four hundred pounds. Altogether, the skeleton of this Mammoth was about the size of a large elephant's.

Skeletons similar to this have been found in abundance in the islands of the Arctic sea. They differ in several minute points of structure from the common elephant, and on this circumstance the most rational explanation of their being found in such cold climates is founded. This explanation is, that the Mammoth Elephant was of a species fitted to be a native of cold countries; and of this reasoning, the different structure and the long thick hair, are held to be proofs. Whether this may be the case or not, it seems certain that the Mammoth's existence must have been very recent, and must have approached closely to if not encroached on, the era of man.

SUPERFICIAL.

Diluvium, Alluvium, Peat, and Vegetable Soil.

In many parts of the earth's surface, a thick bed of compact clay, containing stones of various sizes, and sometimes of a red, sometimes of a blue colour, is found above the hard rocks: it is called *Diluvium*, as supposed to have been deposited by a deluge which had swept over the earth after the most of the present rocks had been formed, and placed in their present arrangement. Some of the stones contained in the diluvium are rounded as by the act of rolling; others contain seams or grooves, which are supposed to have been occasioned either by their rubbing on some hard substance in passing, or having been rubbed against by smaller stones passing them. All over the earth large blocks of stone are found on or near the surface, which it is certain have been carried from great distances, as rocks of the same kind in their original position are not to be found near. There are blocks of this kind in Cumberland, which appear to have originally belonged to hills in the south of Scotland; and some have been found in the district between the Trent and Thames, which geologists suppose to have been brought hither from Norway.

The *Alluvium* is the matter carried down by rivers, and deposited in large level spaces beside their banks, or in islands at their mouths.

Peat is an accumulation of decayed vegetable matter mixed with water. It is well known for its properties as fuel.

The *Vegetable Soil* is generally composed of the inferior substances in a pulverized state, or of detritus carried from a distance, mingled with decayed vegetable and animal matters.

Remains in the Diluvium, &c.

The period when the diluvium was deposited, being that immediately preceding the existing order of things on the earth's surface, is marked by the remains of animals, many of which still exist, while others are extinct. The chief evidence on this point is derived from bones, and fragments of bones, found in caves which are supposed to have served, about the time of the diluvial action, as retreats for Hyænas and other beasts of prey. That of Kirkdale, in Yorkshire, discovered a few years ago, was found to contain remains of twenty-three species; namely, Hyæna, Tiger, Bear, Wolf, Fox, Weasel, Elephant, Rhinoceros, Hippopotamus, Horse, Ox, three species of Deer, Hare, Rabbit, Water-rat, Mouse, Pigeon, Raven, Lark, a species of Duck and Partridge. The bones, in all these cases, were broken into angular fragments or chips, and were all more or less decayed, though the gelatinous matter yet remained in some of them. They were covered by a layer of mud about a foot deep, the nature of which led to the supposition that it must have been deposited during the action of the diluvium.

Till a recent period, no trace of any animal of a higher order was discovered in rocks. Some remains of a human skeleton had been found in a cave in Guadaloupe, imbedded in stony matter; but it was concluded, in that case, that the enclosing matter was of recent formation, and that the human being whose relics were discovered in it, might have been alive at no distant era. Latterly, however, fossil zoology has made one step in advance. In 1838, a fossil jaw-bone of one of the *quadrumana* (four-handed or monkey tribes) was discovered in the tertiary formation at the northern foot of the Pyrenees, in the department of Gers, in France. Two deposits there are very rich in fossils, affording remains of no fewer than thirty mammiferous animals. In the second and newer of these, which is lacustrine, or a deposit from a fresh-water lake, the jaw-bone of the monkey was found, containing, four incisor teeth, two canini, four false grinders, and six true grinders in a continued series. The monkey is supposed to have been about three feet in height. The bone occurred in a stratum of marl, covered by compact limestone. Another jaw-bone of a monkey was discovered with other remains, in August, 1839, in a brick-field at Kingston, near Woodbridge, in the county of Suffolk: the particular bed in which it was found has not been stated. The bone indicates a species of the quadrumana not now existing.

These must be considered as very interesting discoveries. The earliest animals and plants are of the simplest kind. Gradually, as we advance through the higher strata, or, in other words, as we proceed through this record of progressive creation, we find animals and plants of higher and higher structure, till at last we come to the superficial strata, where there are remains of kinds approximating to the highest of all the animated tribes, namely, man himself. But, before the above discoveries, there remained one remarkable gap in the series. The quadrumana, or monkeys, who form an order above common mammalia, but below the bimana, or human tribes, were wanting. Now this deficiency is supplied; and it is shown that every one of the present forms of animated existence, *excepting the human*, existed at the time when the superficial strata were formed. The only zoological event of an important nature subsequent to that period is the creation of man; for we may consider of a lesser importance the extinction of many of the specific varieties which flourished in the geological ages, and the creation of new.

VOLCANIC.

Rock of this kind owes its origin to internal fire, which seems to have sent it up in a state of fusion. It is spread over large parts of the surface of the earth, particularly in France, where there are many extinct volcanoes. The apertures through which it has forced its way from below, and the chinks and rents formed at the time of its eruption in adjacent rocks, are often found filled with it. Large mountains are also composed of volcanic rock. It is remarkable for the fine soil formed out of it.

The chief varieties of volcanic rock are:—

Trap, a term from the Swedish, expressive of the appearance of stairs which a hill of this rock often presents —a bare precipice alternating with a grassy platform or terrace. In trap rocks, nodules are often found; that is, little isolated masses of a different consistence from the including matter: the rock is then said to be of *amigdaloidal structure*, from the Greek word for an almond. This peculiarity is owing to the porousness of the original matter: it contained many small air-cells, which, being afterwards filled up with silex, carbonate of lime, zeolite, and other ingredients, became nodules of those substances.* In Plutonic rocks, no such peculiarity is ever found.

Basalt, a dark gray rock, of crystallized form, masses of which resemble groups of pillars, the various pillars generally having regular sides and angles, and the whole joined compactly together. The Giant's Causeway, in Ireland, and the Island of Staffa, in the Hebrides, are notable examples of basalt. The structure of basalt is found to have originated in the manner in which refrigeration, or cooling, took place at its formation. The process has been imitated on a small scale by the fusing of a few hundred-weights of basalt, and allowing the mass to cool in the furnace: as the cooling gradually proceeded,

* Lyell's Geology, iv. 272.

globules appeared; these enlarged till they pressed laterally [sideways] against each other, and became converted into polygonal [many-cornered] prisms. Thus the rock was replaced in something like its original form, in a common furnace.

Greenstone, a compact, hard, tenacious rock, of dark grayish colour, slightly tinged with green.

Lava (a term from the Gothic, signifying *to run*), the product of modern volcanic mountains.

Section IV.—MINERAL VEINS.

Throughout the primary, transition, secondary, and tertiary rocks, but particularly the two first kinds, there occur what are called *veins*, containing divers substances, most commonly metals, quartz, and calcareous spar, the last being a hard and shining substance deposited from lime. The form and direction of veins may be best understood from the way in which they mostly seem to have originated, namely, by chinks or cracks formed in all directions throughout the rocks, and which have subsequently been filled with various substances.

Those filled with metals penetrate downwards so far, that their lower ends are rarely found, and miners have an idea that they reach quite through the earth. Near the surface of the earth, they are generally found poorest in the metal they contain, richer at a certain distance down, and then poor again. They also often change their metal at different depths. In France there are veins which contain iron above, then silver, and next copper. One of the Cornwall mines have zinc above, and copper in great quantity below. These veins also change their width at different depths: thus, the Dalcoath mine in Cornwall varies from forty feet to six inches in width.* What at first appears extremely strange, a vein will sometimes be rich, or contain abundance of the metal at the place where it passes through one kind of rock, and poor where it passes through another. Thus, for instance, a copper vein will be productive as long as it is dug through slate, and become poor when it passes into granite. Such a vein, it may also be remarked, is generally found richest in the slate when it approaches the granite.

Till a recent time, two theories as to the formation of metallic veins were predominant—one representing them as the result of a forcing of fused matter from below into the chinks, the other accounting for them by supposing an infiltration of the matter in water from above. These theories, respectively termed Huttonian and Wernerian, are now given up: "many veins are fissures of mechanical origin, into which metalliferous matter has been sublimed from the effects of high temperature; but others have resulted from an electro-chemical 'separation or segregation of certain mineral and metallic particles from the mass of enveloping rock, while it was in a soft or fluid state, and their determination to particular centres.'"† Within the last few years, much light has been thrown on the subject by electro-chemical experiments, whereby the workings of nature, in this department of her economy, were imitated on a small scale. Becquerell and Mitcherlich, foreign mineralogists, have succeeded in forming crystals by electricity. Our own countryman, Mr. Andrew Crosse, of Somersetshire, has in like manner formed calcareous spar out of water which had percolated through a limestone rock, and which was forming crystals naturally at the place where the experimentalist obtained it. The same gentleman produced quartz crystals, and thus made the formation of what are called precious stones no longer a mystery. The electric apparatus used by Mr. Crosse was of small power, but kept long in operation, such being the way in which nature works the same ends.

In Mr. Crosse's experiments, the same solution produces different substances at different ends of the electric pole. For example, a battery operating for six months on fluat of silver, produced at the negative pole six-sided cubes of silver, and at the positive, crystals of silica and chalcedony. This opens up a most interesting field of speculation. The difference of substances found in certain veins, their comparative richness and poorness, may have been the consequence of different electric states in the rocks in which they were deposited.

[WORKS ON GEOLOGY.

Geology, like all other branches of natural history, is best studied in the fields. Accurate and extensive observations are absolutely necessary to the acquisition of any considerable knowledge of this vast and important science. Books are useful chiefly in directing attention to the things which are necessary to be *observed*. A comparison of the various theories of different philosophers, respecting the structure of the earth, with the phenomena upon which those theories are founded, will enable the careful and judicious observer to form and modify his own theory in conformity with his own observations. Theories are chiefly valuable for the assistance which they afford us in classifying facts, and every one who proposes to take up any subject of natural science in earnest, will read the most noted general works on that subject. Cuvier's Theory of the Earth is important as the production of the greatest naturalist since Linnæus. Lyell's *Principles of Geology* should be read for general information on this subject, and his Travels in the United States, as well as Featherstonhaugh's Excursions in the Slave States, and Jameson's Discovery and Adventure in Africa, are important for those who are desirous of learning the geology of this country and Africa. Brande's *Dictionary of Science, Literature, and Art* is a useful book of reference with respect to the meaning of terms used in this as well as the other sciences.

Buckland's *Reliquiæ Diluvianæ*, the Transactions of Geological Society of London, and Leonhard's *Characteristics of Rocks*, are also valuable. Mineralogy, which is a subordinate branch of Geology, is extremely interesting, and throws light on all the kindred branches of science. On this subject Cleaveland's Treatise is one of the best that has been written. The Transactions of the American Philosophical Society, and the Academy of Natural Sciences of Philadelphia, contain many interesting tracts on Geology and Mineralogy.—*Am Ed.*]

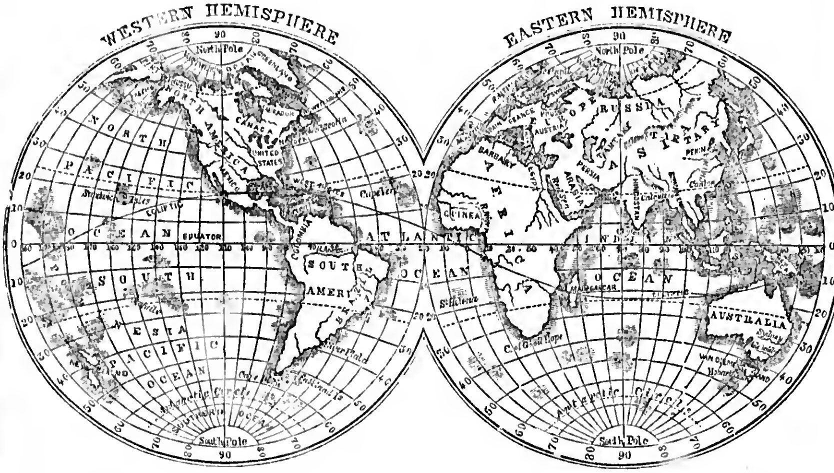
GEOGRAPHY.



INTRODUCTORY.

The Earth which we inhabit, as has been explained in the article Astronomy, is a nearly round globe or mass of matter, forming one of eleven primary planets, which at various distances revolve round the sun as a centre, and receive from that splendid luminary the blessings of light and heat. The earth is one of the smaller sized of the planets, being only about a fourth of the diameter of Uranus, and an eleventh of the diameter of Jupiter, and forms, therefore, a comparatively small portion of the planetary system, and, with reference to the stars, only a speck in the vast extent of creation.

According to the calculations of astronomers, the earth is 7902 miles in mean diameter, and measures about 25,000 miles in circumference. But the diameter or thickness is greater at the middle, or equinoctial line, than in the contrary direction. The cause of this has been explained in Astronomy, but may here be briefly adverted to. The diurnal motion of the earth on its axis, or imaginary poles, causes a greater whirl at the middle than the extremities of the mass, and the earth, originally in a soft state, has been there bulged out all round. The extent of this bulging is twenty-six miles on the whole thickness, or thirteen miles from the surface to the centre of the earth. Thus, the form of the globe is that of an orange, or flattened sphere, and its diameter is twenty-six miles greater from one side to another, at the equinoctial line, than betwixt the poles. Such is the nice adjustment of the daily motion of the earth on its axis, that if it were only a little greater, the sea would rise and fly off, and if the velocity were still more increased, the whole mass of earth and water would be dispersed in fragments, or, in other words, be destroyed. The earth, as far as can be ascertained, is a solid body, well balanced in all its parts, and consists of two kinds of matter, land and water—the land being composed of rocks, metallic ores, soils, and a variety of other substances (see Geology); while the water, as is well known, is of two qualities, fresh and salt—the former in lakes and rivers, and the latter in the sea or ocean. The greater part of the earth consists of solid land or rocky matter, but a large proportion of it is covered by the waters of the ocean; and therefore, to appearance, the ocean forms the principal portion of the globe. It is so, however, only in appearance, notwithstanding its imposing extent, the water being merely a superficial covering to the land.

The manner in which the land is mixed with the ocean is quite irregular, and the relative situation and dimensions of each are constantly shifting. From causes which have been explained in the article Geology, the sea is daily making encroachments on the land, while the land at other places is in the course of being left dry by the sea. Thus, in point of fact, the external features of the globe are ever changing; and it may be safely averred, that in the course of ages there has been a thorough alteration over the whole surface of the globe—that not one part now resembles that form which it originally possessed.

In order to facilitate the operations of the navigator and traveller, and with the view to mark the relative situation of every spot on the earth's surface, the globe has been subjected to divers measurements, by means of ideal lines drawn from north to south, and east to west, as represented in the figure which forms the frontispiece. In the first place, the whole surface is represented as spread out in the form of two hemispheres—the Eastern Hemisphere containing the continents of Europe, Asia, and Africa, and the Western Hemisphere North and South America. The line which appears to cut across the hemispheres at the middle is the *equator* or equinoctial line, and from this are measurements in degrees of latitude.

The earth's surface has been calculated to contain 198,943,750 square miles, of which scarcely a third part is dry land; the remaining two-thirds are water. The land is composed principally of two large masses or tracts, one of which comprehends the continents of Europe, Asia, and Africa; the other comprehends the continent of America. Australia, which lies in the ocean in a southerly direction from Asia, is so extensive as to be entitled to the name and character of a fifth division. All the detached and smaller masses of land, called islands, when taken together, are computed to contain as much land as the continent of Europe. In reference to maps of the earth, Europe, Asia, Africa, and Australia, with their islands, are distinguished as lying in the eastern hemisphere; while America, with the West Indian and other islands, are comprehended in the western hemisphere. The seas which encompass these extensive tracts of land have locally various names; but the two principal expanses of water are the Atlantic and Pacific Oceans—the former separating Europe, Asia, and Africa, from America, on the west, and the latter lying betwixt the western shores of America and the eastern shores of Asia. The extensive oceans surrounding the north and south poles are called the Polar Seas, which have not been explored sufficiently for us to be able to say whether any large tracts of land lie in these remote quarters of the globe. Great diversity of opinion prevails with respect to the depth of the ocean. By numerous investigations, it does not appear that the depth is anywhere much more than two or three miles, generally it is a great deal less; and it might be argued, that notwithstanding the large surface of the ocean, the body of its waters can only be considered as lying like lakes in the hollows of the land; for the earth, as already noticed, is eight thousand miles in diameter, and to that huge mass of dense matter the sea bears no proportion in its depth. While the surface of the land exhibits a variety of mountain ranges, hills, vales, and plains, so also is the bottom of the sea varied in its configuration, abounding in sandbanks, hills, rocks, and reefs, dangerous to the mariner; and the islands which rear their heads above the surface are only the tops of the highest hills and mountains in the sea.

The waters of the ocean, as every one knows, are salt to a greater or lesser degree—a quality which is considered necessary to preserve them from putridity. How they should possess this saline property, no one has yet been able to explain satisfactorily. Some have imagined that the saltness is caused by rocks of salt at the bottom of the sea, but this is obviously incorrect, for rocks of salt do not abound to such an extent as would be required for performing this important office. It is more probable that the saltness is an inherent property in the water itself; there is at any rate nothing more strange in this than in the circumstance of the atmosphere being in *its* nature composed of divers kinds of air or gases. For an examination of this point, however, and for a regular account of the ocean and its tides, we refer to the article THE OCEAN.

According to the beautiful harmony of design manifested in all departments of creation, the earth, with its ocean, its atmosphere, its rivers, and its varying climates, forms an appropriate field for animal and vegetable existence. The manner in which animals and plants are thus distributed in situations and circumstances exactly suited to their character, is a matter of deeply interesting observation. Nature—by which, as a phrase of convenience, we denote the great Creating and Disposing Power—has appointed very few forms of animal or vegetable life to be localized in any portion of the globe approaching to its entire terrestrial surface. Most of them are calculated for certain degrees of heat and cold, dryness, and moisture; and, accordingly, are to be found distributed in rings or zones around the globe, or at certain elevations, with a direct reference, in all cases, to the temperature and other conditions of the situation.

It appears, from the researches of geologists, that the distribution of animal and vegetable forms has, in the course of ages, undergone variations conformable to alterations of condition in soil, climate, and other circumstances. Races of animals have thus entirely disappeared from the surface of the earth, while insular tracts of land, which have risen from the bosom of the deep, have become clothed with vegetation, and are now the appropriate theatre of existence of various kinds of animals. The dispersing power of winds and currents, not to speak of the active interference of man, is supposed to be capable of accounting for the distribution of many plants; but it is clear, that without the ever-vigilant superintendence of an all-wise Providence, the earth, taken in its whole extent, could not exhibit those remarkable forms of animal and vegetable life which are so nicely suited to the localities in which they are placed. In Europe, and nearly all other temperate regions, we find the horse, the cow the dog, the cat, the crow, the sparrow, the house-fly, and other creatures with which we are familiar, because the nature of these animals is suited to climates of moderate heat and cold. In the warm and dry regions of Asia and Africa, other forms of animal life prevail—as the lion, tiger, and camel; the latter being suited to traverse wide sandy deserts, and to endure privations of drought for a greater length of time than any other beasts of burden. America has the condor, the Washington eagle, the llama, and other great birds and beasts of prey peculiar to itself. A remarkable distinction in animal forms is that found in Australia. There, as will be afterwards mentioned, the quadruped races are furnished with pouches for their young, and move forwards by leaping, peculiarities conformable to the locality in which they happen to be placed.

EUROPE.

Europe is the smallest of the great divisions of our globe, but distinguished above the rest by the character of its population, the superior cultivation of the soil, and the flourishing condition of arts, sciences, industry, and commerce, the multitude of large and well-built cities, and its power and influence over the other parts of the world.

It is washed on three sides by the sea, which is called by different names, and belongs either to the Northern Arctic or the Atlantic Ocean. A narrow strait of the Mediterranean separates it from Africa. On the east alone it joins the mainland, being there separated from Asia by an imaginary line. Europe is situated in the northern frozen and the northern temperate zones, between 10° and 73° east longitude, and 36° and 71° north latitude. Including the islands, which contain about 317,000 square miles, the whole extent of Europe amounts to about 3,250,000 square miles, of which Russia comprises nearly one-half. The greatest length, from Cape St. Vincent, in Portugal, to the northern extremity of the eastern boundary, at Waygatt's, is about 3500 miles. The greatest breadth, from Cape Matapan in the Morea, to the North Cape in Norway, is about 2500 miles.

Europe is remarkably well watered, although its rivers have not so long a course nor such large cataracts as those in other parts of the globe, particularly in America. The principal rivers are the Ebro, the Rhone, and the Po, running into the Mediterranean; the Danube, the Dneiper, and the Dneister, into the Black Sea; the Don, into the Sea of Azoph; the Wolga, into the Caspian; the Dwina, into the Arctic Ocean; another Dwina or Duna, the Vistula, and the Oder, into the Baltic; the Elbe, Weser, and Rhine, into the North Sea; the Seine into the English Channel; the Thames into the German Ocean; the Loire and Garonne, the Douro and Tagus, the Gaudiani and Gaudalquiver, into the Atlantic. The Wolga and Danube are the longest. By the Danube, which penetrates the continent on its southern, and the Rhine which penetrates it on its north-western side, Europe is almost cut in two by water-courses. The Rhine is celebrated for the romantic beauty of its banks, on the middle and higher part of its course. At the distance of 200 miles from the sea, it is as broad as the Thames at Westminster, and suitable for navigation with steamboats and small vessels.

Europe possesses numerous large lakes, but none so extensive as those in North America. The largest is

Lake Ladoga in Russia. The lakes celebrated for their beauty and extent are Lake Constance and Lake Leman in Switzerland, or on the borders of that country.

A great part of Europe is mountainous; the southern more so than the northern. The most elevated region is Switzerland, from which there is a descent, which terminates on the side of the North Sea and the Baltic, in low plains. The lowest and most level parts are Holland and Northern Germany, Denmark, Russia, and Prussia. The highest mountains are the Alps, in Switzerland and Italy, which spread from those countries in various directions, extend westwardly into France, and are connected by the Cevennes with the Pyrenees, which separate France from Spain. One chain of the Alps stretches south towards the Mediterranean; then, taking an easterly course, runs through Italy, under the name of the Apennines. Several branches run eastward from the Alps, through the south of Germany, as far as the Turkish provinces. Another chain, the Jura, runs to the north, and separates Switzerland from France. In the east of Europe are the Carpathian mountains, which on one side meet the Sudetic range, and on the other the mountains of Turkey in Europe. The highest mountain in Europe is Mont Blanc, in Savoy, one of the Alps, which is said to be 15,766 feet above the level of the sea.

Several of the European mountains are volcanoes; as Ætna, Vesuvius, and Hecla. It is a fact worthy of notice, that none of the volcanoes of Europe are to be found in any of the great chains of mountains which have just been enumerated. The only one on the continent is Vesuvius, and this is too much detached to be considered as properly forming one of the Apennines. Ætna, in the Island of Sicily, rising to the height of ten or eleven thousand feet above the level of the sea, is the largest European volcano. The Lapari Islands, anciently called the *Æolian*, a few miles to the north of Sicily, bear evident marks of a volcanic origin; and in several of them, subterranean fires are still in operation. Iceland, too, presents the most abundant tokens of the presence of volcanic fire, and has often suffered under its devastations; Mount Hecla is the most noted, although not the only source of the eruptions on this island. To the possession of many inland seas, and, consequently, of a line of coast very extensive in proportion to its area, Europe is greatly indebted for the great advancement of its inhabitants in civilization; these circumstances being favourable to that intercourse without which nations never make great advances.

The chief islands belonging to Europe are—Iceland, in the north sea, lying in the 65th degree of north latitude; Great Britain, Ireland, and other British Islands, in the Atlantic and German Oceans; Majorca, Minorca, Sardinia, Sicily, Corsica, Elba, the Ionian Isles, Malta, Candia, and Cyprus, in the Mediterranean Sea. The European peninsulas are six in number: Scandinavia, Jutland, Crimea, Italy, Spain, and Greece. The soil of Europe, though not equal in luxuriance to that of the tropics, is almost throughout fit for cultivation. The tracts in the northern zone are almost the only exception.

With respect to climate, Europe may be divided into three parts—the warm region, where the lemon-trees grow wild, as far as 48° north lat., having a pleasant spring, a hot summer, and a short winter; the temperate, as far as 65° N., in which grain ripens; and the cold region, to the extreme north, where nothing will grow but reindeer moss, and no domestic animal can live except the reindeer. The products are not so various as in other parts of the world, and many of them were originally brought from foreign countries and naturalized; but, on the other hand, Europe can boast of a more perfect cultivation. Among the animals are horses, some of which are of the nobler breeds; horned cattle; sheep in Spain, Saxony, and England, of the finest wool; asses, goats, swine, dogs; reindeer; wild beasts of different kinds valuable for their flesh or fur; whales; sea-cows, sea-dogs; abundance of wild and tame fowl; large quantities of fish in the seas, lakes, and rivers, among which the herring, in particular, affords sustenance to many of the inhabitants; useful insects, such as bees, silkworms, kermes, gall-flies, and Spanish-flies. Oysters and pearl mussels also abound. It produces all kinds of grain, and sufficient for its consumption; beautiful garden plants; abundance of fruits, including those of southern climates, such as figs, almonds, chestnuts, lemons, oranges, olives, pomegranates, dates; also flax, hemp, cotton, madder, tobacco: the best kinds of wine; and a great variety of wood for fuel, and for house and ship building. The birch and the willow best endure the cold of the northern polar circle. Europe produces all the varieties of metals and minerals in great excellence and abundance. In gold and silver, Hungary and Transylvania are the richest; in iron, the northern countries, Sweden, Norway, and Russia. Salt of all kinds, rock, sea, and spring salt, is also abundant in Europe.

The inhabitants, estimated by Malte-Brun at 200 millions at least, are unequally distributed; in Russia and Sweden there are from fifteen to eighteen to a square mile; in the Netherlands, where the population is most dense, Italy, France, Great Britain, and Germany, the same extent supports from one hundred and fifty to two hundred and fifty persons. The inhabitants consist of several different races, speaking distinct languages. The stocks to which the principal languages belong, are—the Teutonic, which is the mother of the German, Dutch, English, Swedish, and Danish; the Latin, or Roman, now spoken only by the learned, but the mother of the Italian, French, Spanish, Portuguese, and Wallachian; the Slavonic, to which belong the Russian, Polish, Bohemian, Bulgarian, Vandal, and the Servian, or Illyrian. Besides these, there are the modern Greek; the Turco-Tartaric; the Finnish and Hungarian; the Celtic in Wales and the north-west part of France (Bretagne); the Highlands of Scotland and Ireland; the Basque, among the Pyrenees. The most widely spoken is the German, with its kindred languages, formed by a union of the Roman with the Teutonic.

The prevailing religion is the Christian, which includes several churches, viz., the Roman Catholic, which is the most numerous; the Protestant (Lutheran, Calvinistic, and Anglician), consisting of numerous sects—Anabaptists, Mennonites, Quakers, Unitarians, Methodists, Moravians, and the Greek church. A part of the inhabitants profess the Jewish, a part the Mohammedan religion. Among the Laplanders and Samoeides, there are also some heathens, but their number is small.

Agriculture has made great advances in Europe, and is daily improving. In this respect, those countries are particularly distinguished where the Teutonic languages are spoken, as also are France and a part of Italy. In no part of the world are manufactures carried to such perfection as in several of the European countries, especially in Great Britain, France, the Netherlands, and Germany. The inhabitants work up not only native European, but also foreign products, and supply all the wants and luxuries of life. Commerce is not less active, and is promoted by well-constructed roads and canals, by well-organized posts, banks, insurance companies, commercial companies and fairs. The commerce of Europe extends to all quarters of the world, and every sea is filled with European ships. In this respect, Great Britain is most distinguished. Europe is the seat of art and science; to her belongs the honour of discovering the most important truths, of giving birth to the most useful inventions and the finest productions of genius, and the improvement of all the sciences. In intellectual progress, the Teutonic races, and those who speak the languages derived from the Latin, have surpassed the Slavonic nations. The

Turks have remained strangers, in many respects, to the literary and scientific improvement which has marked the other European nations. Eighty-five universities provide for the higher branches of education; numerous gymnasia and academies for the preparatory studies, and a great number of lower schools, particularly in Germany, are employed in educating the common people. In many places there are academies of science, and societies of all kinds, for the cultivation of the arts and sciences.

By its physical situation, Europe is divided into East and West Europe. West Europe comprises the Pyrenean peninsula (Spain and Portugal), the country west of the Alps (France), the countries north of the Alps (Switzerland, Germany, and the Netherlands), the country south of the Alps (Italy), the Islands of the North Sea (Great Britain, Ireland, and Iceland), and the countries on the Baltic (Denmark, Norway, Sweden, and Prussia). East Europe contains the countries north of the Carpathian mountains (Russia and Gallicia), and the countries south of the Carpathian mountains (Hungary, in its more comprehensive sense, and Turkey).

The following are the political states of Europe:—The three empires of Austria, Russia, and Turkey; seventeen kingdoms, viz., Portugal, Spain, France, Great Britain, Holland, Belgium, Denmark, Sweden, (including Norway), Sardinia, the Two Sicilies, Greece, Prussia, Bavaria, Saxony, Hanover, and Würtemberg; one ecclesiastical state, the papal dominions; eight republics, namely, Switzerland, the Ionian Islands, San Marino, Hamburg, Lubeck, Bremen, Cracow, and Frankfort; one electorate, Hesse; six grand-duchies, Baden, Hesse-Darmstadt, Saxe-Weimar, Mecklenburg-Schwerin, Mecklenburg-Strelitz, and Tuscany; twelve duchies, viz., Oldenburg, Gotha, Meiningen, Altenburg, Brunswick, Nassau, Dessau, Bernburg, Cöthen, Modena, Parma, and Lucca; one landgraviate, viz., Hesse-Homburg; twelve principalities, viz., Hohenzollern-Hechingen, Hohenzollern-Zigmaringen, Schwarzburg-Rudolstadt, Schwarzburg Sondershausen, Waldeck, Lippe-Detmold, Schaumburg-Lippe, Lichtenstein, Reuss-Greiz, Reuss-Schleiz, Reuss-Lobenstein, and Reuss-Ebersdorf.

Austria, Prussia, Bavaria, Saxony, Hanover, Würtemberg, Hamburg, Lubeck, Bremen, Frankfort, Hesse, and the above grand-duchies and duchies, compose the region which we call Germany, but the proper name of which, as given by the natives, is Deutschland—the land of the Teutones, an ancient people of central Europe.

THE BRITISH ISLANDS.

These islands, the most important belonging to Europe, lie at a short distance from the north-west coast of France, betwixt the Atlantic Ocean on the west and the German Ocean on the east. From their southernmost boundary upon the British Channel to the most northerly of the Shetland group, is a distance of very nearly eleven degrees, measuring from the 50th to the 61st degree of north latitude. The main island, which since the Union has been called Great Britain, is composed of two portions, with considerably distinctive features, under the names of England and Scotland. England forms the larger, the most southerly, and much the finest portion of the island, and lies betwixt the 50th and 55th degree. Scotland lies on the north of this division, and reaches the 58th degree. Ireland is a large and beautiful island lying to the west of England, from which it is separated only by a channel half a day's sail in breadth, and extends in length from 51° 10′ to 55° 20′ north latitude. Its greatest length, measuring from N E. to S W., is about 300 miles; the greatest breadth about 60 miles. The chief of the minor islands are the Isle of Man, lying in the Irish Channel; Anglesea, on the coast of Wales; the Hebrides, a series of large and small isles on the west coast of Scotland; the Orkney Islands, separated from the north point of Scotland by the Pentland Frith; and the Shetland Islands, lying considerably north of the Orkneys. Besides these, there are some Islands in the British Channel, near the coast of France, called Guernsey, Jersey, Alderney, &c. Reckoning large and small, the British islands amount to some hundreds in number but many of the smallest are not inhabited.

In 1831, the population of England and Wales was 13,894,569, of Scotland 2,365,807, and of Ireland 7,734,365; adding the number of individuals in the army and navy, 277,017, the total population amounted to 24,271,758. Reckoning the inhabitants of foreign countries subject to Great Britain, the entire population of the British empire amounts to about 118,000,000.

[It is considered unnecessary here to say any thing further of the British Islands, as they form the subject of various other articles, entitled HISTORY OF GREAT BRITAIN, DESCRIPTION OF ENGLAND, DESCRIPTION OF SCOTLAND, DESCRIPTION OF IRELAND, CONSTITUTION AND RESOURCES OF THE BRITISH EMPIRE, not to speak of the accounts of Canada, West Indies, East Indies, and other foreign possessions, each forming distinct numbers of the present work.]

FRANCE.

After Great Britain, France is usually reckoned the most powerful and influential country in Europe. In point of territorial extent and amount of population, it stands much higher than Great Britain, which is but a small country, and it likewise possesses a finer climate; nevertheless, such have been its unfortunate political and religious dissensions and misarrangements, that it has permitted itself to be outstripped in the race of improvement by England. Yet under all its backwardness, in many points France forms a great nation, well deserving of the sympathy and respect of its neighbours; and it is greatly to be desired that in future a good understanding should subsist between it and Great Britain.

France is situated between latitude 42° 20′ and 51° 5 N., and longitude 3° 51′ E. and 9° 27′ W., comprising an extent of 213,800 square miles, with a population, according to official returns, in 1827, of 31,851,545. It is bordered on the north-east by the Low Countries, the Prussian province of the Lower Rhine, and Rhenish Bavaria; on the east, it is separated from Baden by the Rhine, and touches Switzerland and Sardinia; on the south, its boundaries are the Mediterranean, the Pyrenees, and the Bidassoa; the ocean bounds the rest. The island of Corsica, and the Hières, in the Mediterranean, and the Isles of Oleron, Ré Noirmoutier, Belle-Isle, Dieu, and Ushant in the Atlantic, belong to France. The foreign possessions are of little value. They are in Asia, Pondicherry and Karical on the Coromandel coast, Yanaon in the Northern Circars, Chandernagore in Bengal, Mahe on the Malabar coast, a factory at Surat, and some factories in Arabia, containing in all 179,000 inhabitants, in Africa, Senegal, Goree, the Isle of Bourbon, and some factories, containing 93,000 inhabitants; in America, Martinique, and Gaudaloupe with its dependencies, Guiana, and the small islands of St. Pierre and Miquelon, near Newfoundland, containing 225,000 inhabitants. The territory is divided into 86 departments, which generally derive their names from the rivers. They are subdivided into 363 arrondissements, 2844 cantons, and 38,339 communes. Each department is governed by a prefect and each arrondissement by a subprefect. The cantons have no administrative powers. The communes are under a mayor. The provincial officers generally are appointed by the home minister, only those of towns under 5000 inhabitants being appointed by the prefect.

The principal mountains of France are—1. The Vosges on the north-east. They are of a rounded outline, with gentle slopes, and afford much open pasturage. The highest summit is not more than 4500 feet high. 2. The Jura mountains lie to the south of these, and their summus rise to the height of 6000 feet. 3. Many Alpine branches intersect Dauphiny and Provence. In the centre of the kingdom are—4. The mountains of Auvergne, of volcanic origin, of which the Puy de Dome, the Monts d'Or, and the Cantal, are the most conspicuous. 5. The Cevennes lie to the south-east of the range last mentioned. Their highest summit is Mont Lozère (about 6510 feet). 6. The Pyrenees form the principal part of the boundary between France and Spain. These mountains divide the country into four great basins, the form and exposure of which necessarily have a great influence on their climate and productions. The narrow valley of the Rhone runs from north to south, while the open basins of the Seine, the Loire, and the Garonne, stretch in a north-western direction. The Adour rises in the Pyrenees, and washes the walls of Bayonne. The other rivers are principally tributaries. The Marne and the Oise fall into the Seine; the Allier, the Loire, the Sarthe, and the Mayenne, into the Loire; the Rhone receives the Saône, the Isère, the Durance, the Ain, and the Sorgue; the Tarn and the Dordogne join the Garonne. The numerous branches of these rivers are joined by canals, which form an extensive internal water communication.

In respect to soil, the richest part of France is the northern division, comprehending the provinces of Flanders, Artois, Picardy, Normandy, and the Isle of France, where there is a deep rich loam; about 18,179,590 acres in extent. The valley of the Garonne is composed of a friable sandy loam, with a calcareous mixture, and moisture sufficient for every purpose. This district contains 7,654,561 acres. The great valley of Languedoc is extremely prolific, though the soil is not so fine as that of the preceding districts. The Limagne, a valley of Auvergne, is considered to have one of the finest soils in the world. It consists of beds of earth, said to be twenty feet deep, formed from the decomposition of soft basalt. The calcareous and chalk formations are extensive. The chalk provinces are unfruitful in grain, but the genial influence of the sun allows them other riches. The calcareous loam on the borders of the chalk formation is more productive. The Bretagne, Anjou, and Maine, are immense heaths. The *landes* are extensive tracts of sandy deserts, producing nothing but broom, heath, and juniper. The most extensive are the landes of Bordeaux, twenty leagues in length by twelve in breadth. In the remaining provinces, gravel, or a gravelly sand, is the predominating soil. The woods and forests are estimated to cover a space of 18,795,000 acres. The principal are those of Ardennes, Orleans and Fontainebleau. The northern and western coasts are formed in a great proportion by immense downs and sandbanks; and where the shores are formed by cliffs, they are seldom bold enough to be approached with safety. The harbours are therefore few. On the Mediterranean, the coast of Languedoc is very dangerous, but Provence abounds in good harbours. The culture throughout the northern half of the kingdom, consists of wheat, barley, oats, pulse, and, of late much more than formerly, of potatoes; in the southern half, corn (particularly maize), vines, mulberries, and olives. The eastern parts, being more elevated than the western, have more rigorous winters and more ardent summers. Coal and iron are found in abundance. The most common fuel is wood.

The superficial extent of France has been recently estimated by Baron Dupin at 53,533,426 hectares, or 132,694,000 English acres. The amount of capital invested in agricultural pursuits is estimated at 37,522,061,476 francs; the gross annual produce at 4,678,708,885 francs; the expenses of cultivation at 3,334,005,515; leaving a profit of 3½ per cent. on the capital. The produce of wheat in the best cultivated districts, and on the best soil, hardly exceeds eighteen bushels per acre: an English farmer expects twenty-five on the same extent. In 1812, the number of horses in France was 2,176,000; but in 1819, the horses and mules together amounted only to 1,657,671; at present the number is estimated at 2,500,000. The number of horned cattle is 6,973,000; of sheep, about 45,000,000. The total number of all kinds of poultry is about 51,600,000. The French are the best wine-makers in the world. The Champagne, Burgundy, Claret, Hermitage, are universally celebrated. For a long time, the choicest growths were in the hands of the church; and in the frequent changes of property which have taken place since the Revolution, many vineyards have deteriorated in consequence of bad management. The brandies of France are believed to be unrivalled. The value of the whole produce of wine and brandy is about 800,000,000 francs. The culture of the vine is supposed to have increased nearly one-fourth since the Revolution, owing principally to the small proprietors, each of whom endeavours to supply his own consumption by a little patch of vineyard. M. Dupin says that many hectares of French territory are yet uncultivated, merely for want of cattle to stock and manure them; that two-thirds of the inhabitants are without animal food; that more than one-third subsist entirely on oats, buckwheat, rye, chestnuts, or potatoes, and that the agricultural population is too great for the prosperity of France. Two-thirds of the population is agricultural.

France possesses a soil and climate capable of furnishing her with all the raw materials of manufacture except cotton. The manufacture of fine woollen cloths at Sedan was introduced under the auspices of Colbert. The machinery used was very defective until M. Chaptal engaged an English machinist to instruct the French artisans. Steam-engines are rare; the spinning-mills being worked chiefly by water or by horses. The quantity of native wool manufactured in 1819 was 38,000,000 kilogrammes (of about 2⅕ lbs. each), and, in 1826 42,000,000, with 8,000,000 of imported wool; the value of the manufactured articles was 265,000,000 francs; of the raw wool, 105,000,000: the quantity exported was about one-thirteenth of the whole quantity manufactured. By the exertions of Henry IV., the mulberry-tree was cultivated in all the southern provinces. At Tours, silk stuffs for furniture are chiefly manufactured; at Ganges, and other places in the Cevennes, silk stockings. Lyons is the principal place for silk manufactures of all kinds. Paris ranks next after Lyons. In 1812, the value of the raw material amounted to 45,560,000 francs, of which 22,000,000 were the price of imported silk. The value of manufactured goods, at the same period, was 107,560,000 francs, of which less than one-third was exported. Forty years ago, the spinning of cotton by machinery was hardly practised in France. Cotton mills have been established within that period, and the manufactures of Alsace are now superior to those of England in the brilliancy of their colours. In 1812, 10,362,000 kilogrammes of cotton were spun by machinery; and in 1825, 28,000,000 of greater fineness. The cambrics, gauze, and lawn of St. Quentin, Valenciennes, and Cambray are among the most valuable products of French industry. Lace is made in great quantities.

The whole produce of the linen and hemp manufactures is estimated at 200,000,000 francs. In 1814, 100,000,000 kilogrammes of cast-iron were produced; in 1825, 160,000,000. Gilding and watch-making are carried on, chiefly in Paris, to the annual value of about 38,000,000 francs each. Printing also employs a great number of persons at Paris. In 1814, the number of printed sheets was 45,675,039; in 1820, 80,921,302; and in 1826, 144,561,094. Notwithstanding the low price of labour in France, the industry of that country cannot enter into competition with that of England. One of the circumstances which depress it is the want of internal communication by roads and canals. The practicable roads of France are not more than one-third of the extent of those of England. The cross-roads are few, and the great roads are seldom kept in good order. The length of the canals in France is not more than one-eleventh of those of England. Another point in which France is inferior is in the use of steam-engines, attributable in part to the deficiency of coal, or the difficulty of transporting it. The total force of steam-engines in France is reckoned to be equal to that of 500,000 men; that of England is equal to a power of 8,000,000 men. All the power derived from machinery of every sort, or from constructive ingenuity, and applied to purposes of industry in France, is only one-fourth of the similar power employed in England.

The commerce of France has been very much diminished by the loss of her colonies. The value of the colonial imports, in 1788, was 227,000,000 francs; in 1824, it was only 50,000,000. The exports for 1788 amounted to 119,000,000; in 1824, to 44,000,000. The total value of exports from France in 1824 was 440,542,000 francs; of which 163,056,000 were productions of the country, and 277,486,000 manufactured articles. The amount exported to the United States was 55,000,000, being more than that to any other country. The imports for the same year were of the value of 454,861,000 francs; of which 272,873,000 francs were raw materials for manufacture, 121,957,000 natural productions for consumption, and 60,030,000 manufactured articles.

The French are descendants of the Roman provincials and ancient Gauls, and hence their language is a mixture of modified Latin and the tongue of the original inhabitants, but much altered in orthography and in tone of speech in modern times. The kingdom was for many centuries governed in a despotic manner by a line of sovereigns of different dynasties, from Clovis, in the year 481, to that of the Bourbons in the person of Louis XVI., 1793. One of these monarchs, Louis XIV., who reigned during the latter half of the seventeenth century, exhausted the resources of the nation in foreign wars and personal extravagance, and, besides, greatly corrupted the manners of the people. This laid the foundation of a course of events which terminated in the national ruin and fearful outbreak of the Revolution in 1789. This revolution deluged the country in blood, and ended with the establishment of a republic; but this was speedily succeeded by the elevation of Napoleon Bonaparte, first as consul, and next as emperor. The career of Napoleon closed in 1815, with the battle of Waterloo, and the Bourbons were restored by the arms of Britain and other nations. The Bourbons were expelled in 1830, since which period the reigning monarch has been Louis Philippe, a descendant of the brother of Louis XIV., and in whose male descendants the monarchy is hereditary.

On the establishment of the present limited monarchy in 1830, the national constitution was reorganized on the following footing:—The king is the supreme head of the state; he commands the land and sea forces, declares war, makes treaties of peace, alliance, and commerce; appoints to all offices of the public administration, and makes all the regulations and ordinances necessary for the execution of the laws under the responsible advice of his ministers. Any of the three branches of the legislature can propose laws; the Chamber of Peers may sit without that of the Deputies only as a court of justice; peers may speak in the house at the age of twenty-five years; princes of the blood may sit in the House of Peers without a special summons from the king; the deliberations of the peers are public; the renewal of one-fifth of the deputies every year is abolished; persons are eligible as deputies at the age of twenty-five years; the deputies elect their president without the concurrence of the king; and the electors choose the officers of the electoral colleges without the interference of the king; articles 46 and 47 of the old charter, respecting amendments, and the adoption of the tax acts by the deputies, previously to being sent to the peers, are repealed; as is also article 56, exempting the ministers from impeachment, except for treason or extortion; the *prevôtal* courts are abolished; the king takes the constitutional oath, not at the time of the coronation, but on his accession, as in England. Besides this, provision is to be made, by separate laws, for—1. The trial of offences of the press by a jury; 2. The responsibility of ministers, and other agents of power; 3. For the re-election of deputies promoted to offices with salaries; 4. The annual vote of supplies for the army; 5. The organization of the national guard; 6. The settling the rank of all naval and military officers; 7. Departmental and municipal governments founded on the elective system; 8. Public instruction provided for; liberty of teaching allowed to all; 9. The abolition of the double vote, and of the electoral candidates and their eligibility. The charter is intrusted to the protection of the national guard, and the patriotism of the nation. The charter, with the "changes and modifications expressed in the declaration of the Chamber of Deputies," was presented to Louis Philippe, who, on the 9th of August, 1830, took the constitutional oath; and thus the *constitution octroyée* was changed into a real contract between the ruler and the people.

By the letter of these provisions, France possesses a free constitutional government; but such is the influence of the executive, that, practically, the people enjoy much less liberty than the British. So unsettled, likewise, is the system of things, that a large standing army and militia force (National Guard) has to be maintained, at a heavy expense and inconvenience to the nation. In 1837, the army amounted to 300,000 men. The national expenditure in 1838 was about £44,000,000, to which the revenue was inadequate: the national debt at the same time amounted to 254,566,496 francs. The French navy, in 1836, consisted of 49 ships of the line, 62 frigates, 31 corvettes, 49 brigs, and with other vessels amounted to a total of 321.

Previously to the revolution of 1789, the Roman Catholic was the established religion, and the country contained a vast number of monasteries and convents. Latterly, since 1830, there has been no established church, but the Roman Catholic worship predominates, and is adhered to by the reigning family. In 1836 there were 14 archbishops, 66 bishops, 174 vicars-general, 660 canons, 3401 curés, 27,776 desservans, and 6184 vicaries—total of clergy, 37,275. The bishops have each about £600 a year of salary, and the working clergy from £20 to £60 each. There are about 1,000,000 of Protestants in France. The entire cost to the state of religious establishments, Roman Catholic, Protestant, and Jewish, amounted in 1838 to 35,443,500 francs. With respect to education, France at present possesses 26 universities, 363 high-schools, or academies, in the large towns and districts, 73 normal schools for training teachers, 873 boarding-schools, 36,000 elementary schools for boys, and 11,000 elementary schools for girls. The whole are under the supreme direction of the minister of public instruction; and the total cost in 1838 was, 19,005,673 francs, or nearly £800,000.

France possesses a considerable number of towns, with populations of from five to thirty thousand, and more particularly about twelve thousand, but not many of any consequence with a larger amount of inhabitants. Paris, the capital, in 1827, had a population of 890,531, which is about half the amount of the population of London. The other chief towns are Lisle, with a population of 69,860; Rouen, 90,000; Strasburg, 49,708; Nantes, 71,739; Boulogne, 19,314; Havre, 21,049; Rheims 34,862; Brest, 26,655; Cambray, 17,031; Lyons, with suburbs, 170,875; Marseilles, 115,943; Toulon, 30,171 Aix, 23,132; Grenoble, 22,149; Clermont, 30,010; Besançon, 28,795; St. Etienne, 30,615; Dunkirk, 24,517;

Amiens, 42,032; and Orleans, 40,340. The chief port in the north of France is Havre, on the English Channel, and Marseilles and Toulon are the principal outlets on the south. In point of capability for maritime trade, France is far inferior to Great Britain, from its want of good harbours, though perhaps that circumstance is of less consequence than the peculiar genius of the people, which is adverse to naval adventure.

Paris, the capital, is a beautiful city, built of white sandstone, situated on a flat ground, on both banks of the river Seine. Here reside the most learned and accomplished men in France, and also the court of the king in the palace of the Tuileries. At a few miles' distance is Versailles, a royal residence of extraordinary extent, built by Louis XIV., and since considerably improved. Paris has been long distinguished as a place of residence of literary and scientific characters, and in the present day is the place of publication of an immense quantity of books in all departments of literature; it is likewise celebrated as a depôt for works in the fine arts, as painting, engraving, and sculpture, in which it is superior in many respects to London. The character of the French people has usually been represented as exceedingly frivolous, but in this there has been much exaggeration; and it is certain that in recent times they have demonstrated an anxious desire for improvement in the useful arts, and for a settled form of government.

SPAIN AND PORTUGAL.

Spain, or the Peninsula, as it is frequently called, is an extensive country, occupying the south-western extremity of Europe between latitude 36° and 44° N., and is surrounded by the Atlantic Ocean and the Mediterranean Sea, except on the north-east, where part of the Pyrenean chain of mountains form its boundary with France. In its dimensions, this country extends 700 miles in length by 500 in breadth, forming an area of 350,000 square miles. Portugal, afterwards to be mentioned, lies like a patch on the side of the Peninsula, facing the Atlantic. Spain, proper, is divided naturally into two unequal compartments, one of which includes the central region, and the other that of the coast. Spain is essentially mountainous. It consists chiefly of extensive plains traversed by lofty ridges, towering to a height of from eighteen hundred to two thousand feet. There are comparatively few trees in the country, and the air being dry, the number of rivers is not great. The principal are the Ebro, Douro, Tagus, Gaudiana, and Guadalquiver; but from the bad system of things, they are not put to their full uses for navigation and trade. On the lower parts of Spain, particularly on the east, the climate is delightful, but in the high central plains the heat is as intense in summer as the cold is piercing in winter. The productions of Spain are rich and various. Iron, tin, copper, quicksilver, and indeed every valuable mineral, abound in the Peninsula. There are also a number of coal and salt mines. Wheat of the finest quality is produced in most of the provinces. The other principal productions of the soil are oats, barley, maize, rice, oil, honey, sugar, hemp, flax, cork, cotton, silk, and barilla; the wool, as is well known, is of a very superior quality. There are many fine fruits grown, as figs, oranges, pomegranates, lemons, &c. Among the animal productions, the horse of Andalusia, a province on the Mediterranean, opposite Africa, is esteemed among the finest in the world. The sheep are millions in number; and the sea-coast supplies abundance of fish.

The country is divided into 14 provinces or districts, as follows:—Navarre; Biscay; the Austurias; Galicia; Arragon; Catalonia; Leon; Old Castile; New Castile; Estremadura; Valencia; Andalusia, including Cordova, Seville, and Granada; Murcia; and the Balearic Isles in the Mediterranean. The capital, and seat of the cortes or parliament, is Madrid, in the province of New Castile, at the centre of the kingdom. Population in 1825, 201,344. The principal seaport is Cadiz.

About the beginning of the present century, the population of Spain amounted to 10,409,079 individuals, among whom were the following classes:—Beginning with the religious bodies, there were 148,242 clergy and monks, and 32,000 nuns, exclusive of about a fourth of the population living on their property without doing any thing; there were 100,000 individuals existing as smugglers, robbers, pirates, and assassins, escaped from prisons and garrisons; about 40,000 officials appointed to capture these, and having an understanding with them; nearly 300,000 servants, of whom more than 100,000 were unemployed and left to their shifts; 60,000 students, most of whom begged, or rather extorted, charity at night; and if to this melancholy list we add 100,000 beggars, fed at the doors of monasteries and convents, we shall find that there existed in Spain nearly 600,000 persons who were of no use in agriculture or the mechanical arts, and who were only calculated to prove dangerous to society. Having made these, we find there then remained 964,571 day-labourers, 917,197 peasants, 310,739 artisans and manufacturers, and 34,339 merchants, to sustain by their exertions upwards of ten millions of inhabitants. These results, which are as applicable at the present day, when the population has increased to about 14,000,000, as at the time when they were deduced, exhibit a state of society so radically corrupt and debased, as to render all hopes for its regeneration very nearly desperate. Lately, on the death of Ferdinand, the reigning monarch, the queen, in the capacity of regent, made a powerful attempt to establish constitutional government, which was the first step towards practical reform of abuses. Her daughter Isabella, according to the will of Ferdinand, was proclaimed queen whereupon ensued a civil war betwixt her forces and those of her uncle Don Carlos, who wished to assume the sovereignty. This war has greatly injured Spain and what its results may be no one can foretell.

Portugal, which lies on the western frontier of Spain, facing the Atlantic, and measures 41,500 square miles in extent, is an ancient small kingdom, intimately resembling Spain in almost every particular, and at present in much the same unsettled condition. The country possesses two fine rivers, the Douro, which forms the great maritime emporium of Oporto, and the Tagus, which is that of Lisbon, the capital. Portugal is rich in natural productions, but wants the cultivation of industrious hands. The rich mines of precious metals are now neglected, on account of want of hands and fuel. The chief source of profit is in the fruits, which are exported in abundance, particularly the orange and grape. Wines of several sorts, port and sherry in particular, are produced, and exported chiefly to England. Agriculture, commerce, the arts, every thing in short, is neglected in Portugal, which in the present day is a miserable poverty-struck country. Like Spain, it is eaten up by clergy, secular and regular; and these classes have moreover rendered at least a third part of the year holidays, greatly to the loss of the nation. The late Don Pedro, father of the present queen Maria, had the address to abolish the monastic institutions, and to sequestrate the property to the state, which was an important measure of national regeneration.

The assumption of sovereignty by Maria led to a civil war or contest betwixt her forces and those of her uncle Don Miguel, which was most injurious to the country Miguel was ultimately defeated and expelled. The population of Portugal was stated in 1826, at 3,214,000.

ITALY.

Italy, once the seat of the Roman empire, but which, since the overthrow of that power, has never formed an independent whole, is a narrow peninsula, extending from the Alps (46° to 38° N. lat.) into the Mediterranean Sea, which on the east side of Italy is called the Adriatic, on the west, the Tuscan Sea. The Apennines, rising near the maritime Alps, are the principal chain of mountains, and stretch through the country, dividing Lombardy from the Genoese territories and Tuscany, and Tuscany from Romagna, intersecting the states of the Church, and running through the kingdom of Naples to the Strait of Messina. Upper Italy (Lombardy) is remarkably well watered. The Po, which receives a great number of rivers from the large lakes at the foot of the Alps (Lago Maggiore, di Lugano, di Como, d'Iseo, and di Garda), and the Adige, are the principal rivers. They both rise in the Alps, and flow into the Adriatic Sea. In Middle Italy (Tuscany and the states of the Church) are the Arno and the Tiber, which rise in the Apennines, and flow into the Tuscan Sea. In Lower Italy (Naples) there are no large rivers, on account of the shortness of the course of the streams from the mountains to the sea: the Garigliano is the principal. The climate is warm, without excessive heat, and generally salubrious. The winter, even in Upper Italy, is very mild: in Naples it hardly ever snows. The abundance and excellence of the productions of the soil correspond with the beauty of the climate. In many places both of the north and south there are two, and even three, crops a year. The volcanic character of the coasts of Lower Italy is particularly remarkable in a geological point of view, especially in the region of Puzzuoli and Vesuvius. The neighbouring islands of the Mediterranean are distinguished by the same character. The present number of inhabitants is much inferior to the former population of this delightful country, the total amount being 21,.97,500.

The national character of the Italians, naturally cheerful, but always marked by strong passions, has been rendered, by continued oppression, dissembling and selfish. The Italian, moreover, possesses a certain acuteness and versatility, as well as a love of money, which stamp him for a merchant. In the middle ages, Venice, Genoa, Florence, and Pisa, were the chief marts of the European commerce with the East Indies; and Italians (then called Lombards, without distinction, in Germany, France, and England) were scattered all over Europe for the purposes of trade. The discovery of a passage by sea deprived them of the India trade, and the prosperity of those republics declined. The Italian, restricted almost solely to traffic in the productions of his own country, has nevertheless always remained an able and active merchant. Before Rome had (2100 years ago) absorbed all the vital power of Italy, this country was thickly inhabited, and for the most part by civilized nations. In the north of Italy alone, which offered the longest resistance to the Romans, dwelt a barbarous people, the Gauls. Farther south, on the Arno and the Tiber, a number of small tribes, such as the Etrusci, the Samnites, and Latins, endeavoured to find safety by forming confederacies. Less closely united, and often hostile to each other, were the Greek colonies of Lower Italy, called Magna Grecia. The story of the subjection of these nations to the Roman ambition, belongs to the history of Rome. Italy, in the middle ages, was divided into Upper, Middle, and Lower Italy. The first division comprehended all the states situated in the basin of the Po; the second extended between the former and the kingdom of Naples, which formed the third.

Italy is in modern times cut up into a number of distinct states, partly independent, with native princes, partly under the rule of Austria, and a portion under the civil sway of the head of the Romish church. Throughout the greater part of this fine country the system of police is wretched, and robbery is exceedingly common; commerce, agriculture, and the useful arts, are in a low condition; bigotry prevails, and the national character is reduced to the lowest moral standard. The most civilized and best governed part of Italy is Tuscany which differs very materially from the adjacent states. In the present day, Italy is only celebrated for its music, and its collections of works in the fine arts. The following sketch gives a view of the amount of population in the five great divisions into which Italy is partitioned:—

The population of the states of the Church is about 2,600,000. The capital is Rome, the seat of empire of the ancient Romans, but now greatly altered in figure and appearance, and completely changed in character; this venerable city possesses a population of 150,000 The other chief towns are—Bologna, with a population of 65,000; Ancona, 30,000; Perugia, 30,000; Ferrara, 24,000; and Ravenna, 24,000. There are other eight towns, with a population of from 7000 to 14,000.

The duchy of Tuscany, in 1826, had a population of 1,275,000 inhabitants. The capital of this state is Florence, the population of which amounts to 80,000. The other chief towns are—Leghorn, 66,000; Pisa, 20,000; Sienna, 18,000; Prato, 10,000; Pistira, 9600; Avezzo, 7000; and Crotona, 5000.

Austrian Italy, or the Lombardo-Venetian kingdom, which consists of the great plain of the Po, is subdivided into the governments of Milan, Venice, Parma, and Modena. The chief towns of the state of Milan are—Milan, 151,000; Brescie, 31,000; Cremona, 26,000; Mantua, 25,000; Pavia, 21,000; Lodi, 18,000; and Como, 7600. The chief towns in the state of Venice are—Venice, 101,000; Verona, 48,000; Padua, 35,000; Vicenza, 19,000; Udina, 18,000; Treviso, 15,000; Belluno, 8000, and Rovigo, 7000. The state of Parma has the town of Parma, 30,000; Placentia, 28,000; and Guastalla, 5000. The state of Modena possesses the town of Modena, 27,000; Reggio, 18,000; and Mirandola, 6000.

The Sardinian States are composed of Piedmont, Genoa, Savoy, and the Island of Sardinia, the whole of these divisions having a population of 3,831,350. The principal town and sea-port in this district is Genoa, which possesses a population of 80,000 inhabitants.

The fifth division of Italy is composed of the states now included in the kingdom of the Two Sicilies. This forms the southern, and perhaps the finest portion of the Italian peninsula, and branches out into the two smaller peninsulas of Otranto and Calabria. Naples is the chief town, with a population of 354,000 inhabitants, being thus the largest city in Italy. Naples is famed for the beauty of its environs, particularly the bay on which it is situated, and for the exceeding fineness of its climate. Sicily, an island belonging to the kingdom of Naples, measures 180 miles long by 150 in breadth, and is one of the most beautiful islands of Europe. It is chiefly distinguished for its celebrated volcano, Mount Etna. Malta, an islet in the Mediterranean, about fifty-four miles to the south of Sicily, now belongs to the British government.

RUSSIA.

The Russian empire stretches over the half of Europe, and the whole of Northern Asia, from the Baltic to the Pacific, and includes vast territories on the north-western coast of North America. It lies between lat. 38° and 79° N. It is bounded on the north by the Northern or Icy Ocean, west by Norway, Sweden, the Baltic Sea, Austria, and Prussia, and south by Turkey, the Black Sea, Persia, the Caspian Sea, Independent Tartary, and China. The total superficial area is estimated at 8,000,000 square miles, of which about 1,500,000 are situated in Europe, and 5,600,000 in Asia. The Russian dominions compose about one-seventh of the habitable globe. The surface of Russia is generally level, and some tracts of land of this flat nature, frequently bleak and barren, are called steppes. The country also possesses chains of lofty mountains in different quarters. Russia raises vast quantities of corn, which it exports; and it produces fruits and wine in abundance. The forest also yields important articles of export. Cattle of all kinds, horses, and sheep, are likewise bred in immense numbers, chiefly for the exportation of their skins. The mines of the country are productive of platina, zinc, copper, quicksilver, alum, and salt, all of which are continual sources of revenue. Russia possesses various rivers of the first magnitude, and canals are in the course of establishment on a considerable scale.

The population of Russia, including Poland and Finland, is 57,000,000, of nine different races:—1. Slavonians 44,000,000, including the Russians (42,000,000, among whom are the Cossacks, about 600,000 capable of bearing arms) and the Poles; 2. Finns, who are scattered over the country, from Tornia and the Niemen to the Obi (3,000,000); 3. Tartars, from the Dniester to the Caucasus (2,000,000), mostly under their own government, without agriculture or fire-arms; 4. Georgians or Circassians (2,000,000); 5. Samoiedes; 6. Mantchoos; 7. Mongols, to whom belong the Calmucks; 8. Eastern tribes (including Tchutsches, Kuriles, and Aleutians); 9. Jews, particularly in the Polish provinces. Besides these races, there are natives of almost all countries of Europe and Asia, as Greeks, Arabs, Hindoos, Gipsies, French, English, and Danes. There are among these Russian subjects eighty tribes, differing in language, religion, and manners from the rudest state of barbarism to the highest degree of European civilization. The population is divided into four classes, the nobility, clergy, common people or freemen, and peasants or serfs. In 1811, the number of persons subject to do military duty was as follows:—643,135 persons engaged in trade; 6,389,269 crown peasants; 10,113,177 peasants belonging to individuals; 1,077,636 appanage peasants; 112,453 freemen; in all, 18,335,730 men. We find manufacturers of leather, tallow, candles, soap, felt, coarse linen, mats of the bark of the linden tree, hardware and the art of dyeing, among the Russians, before the time of Peter the Great; but since his reign these have been carried to much greater perfection, and many now manufactures have been introduced. In 1815, Russia contained 3253 manufacturing establishments; twenty-three of these deliver to the government annually cloth of 700,000 roubles in value, and there are, besides, one hundred and eighty-one private establishments. Drugs are prepared in forty-tivo laboratories; and there are distilleries of brandy, of which 120,000,000 gallons are consumed in the country. Ship-building is carried on in the large villages on the Wolga and in the sea-ports.

The government is an unlimited monarchy; the emperor is autocrat of all the Russians; the state is indivisible; the ruler cannot be, at the same time, ruler of any other country (since 1815, however, he has been king of Poland), and must be of the Greek religion. In 1797, the succession was settled in the male line, by the rules of primogeniture, and, in failure of males, in the female line. All the princes of the blood are called grand-princes. By the ukase of March 20, 1820, it was declared that only the children of a marriage acknowledged by the emperor are capable of succeeding to the throne. The highest councils are, 1, the imperial council, under the presidency of the emperor, erected January 1, 1810, with four departments—that of legislation (the supreme tribunal in civil and ecclesiastical suits), that of war, that of civil and ecclesiastical affairs, and that of finance; 2, the senate, for home affairs (a deliberative body, consisting of eight departments, three of which have their seat in Moscow); 3, the holy synod; 4, the ministry of state. The ministers have a seat and voice in the imperial council and in the senate. The ministry is divided into three sections—that of foreign affairs, war, the marine, the home department, ecclesiastical affairs, education, and finance; that of the imperial treasury; and that of the public accounts, roads and canals, and justice. The whole state is divided into fifty-one governments and several provinces; of these forty are in Europe, exclusive of the Cossacks of the Don, the Cossacks of the Black Sea, and the kingdom of Poland. The military force of Russia is exceedingly great, yet nothing to excite any dread. By some accounts it is stated as having totally amounted to 870,000 men; but a vast proportion of this force is composed of irregular militia, or armed slaves. It is considered by recent writers on the subject, that the utmost amount of regular force which Russia can bring into the field is 150,000 men, infantry, cavalry, and artillery. It is indisputable that Russia has no pecuniary resources to support a large army long in the field, and therefore any fear expressed by European powers on this score is ridiculous. The principal dependence of Russia is upon England, and a quarrel with the British government would most likely lead to a serious commotion in the state. The prevailing religion is that of the Greek church, with a full toleration of all religions. The state of society is a strange mixture of refinement and barbarism. The population is composed of four different classes, as has already been mentioned. The boors or peasants are the property of the crown or of individuals; they amount to about 35,000,000, and are in a state of great poverty. They are sometimes emancipated by their owners, and are sometimes permitted to purchase their freedom. The noble families are about 150,000, comprising 750,000 individuals, and enjoy some privileges and exemptions. The freemen, not nobles or clergymen, are divided into six classes—the inhabitants of cities, the three guilds (capitalists, according to their income tax), the trades, foreigners or strangers, the notable citizens (*savans*, artists, bankers), and the colonists. In regard to rank, these classes form fourteen gradations; and all who can claim either of the eight highest are considered as noble. Distinction of any kind, however, is only gained by the possession of a superior military rank.

Debased as Russia is, it has recently made great advances in civilized usages. Science, literature, and the arts, are highly cultivated, and liberally endowed. The Russians, it seems, have not much original genius, but they are the best imitators in the world, and quickly adopt foreign manners, language, and improvements. The wretched system of territorial slavery is gradually disappearing, and the peasants are now more protected by the laws than formerly. The punishment of criminals is also becoming more lenient. Russia possesses a number of towns of from 10,000 to 30,000 inhabitants. Petersburg, the capital, has a population of 425,000, and Moscow 240,000. Petersburg, which is built upon the flat banks of the Neva, is considered to be in appearance the most splendid city in the world.

GERMANY.

Germany as it is called by the English, l'Allemagne by the French, and Deutschland by the natives themselves, is a large territory extending from the Baltic Sea on the north to the Gulf of Venice on the south, having Hungary and Russia on the east, and France and the Netherlands on the west. At its south-west corner it is touched by Switzerland. This immensely large territory occupies the bulk of the centre of Europe, and consists of an area of 250,000 square miles. The most remarkable circumstance about Germany is its being composed of a considerable number of states, each less or more independent within its own bounds, but externally dependent on the other states of the confederation, as is mentioned already under the head Constitutional Governments. Altogether, there are thirty-four monarchical states, and four free cities, which enter into a confederation as equal sovereigns. For mutual safety they compose a diet or congress, at which each state has a certain number of votes. The principal states of Germany are Prussia and Austria; Saxony, Bavaria, and Hanover, are of lesser dimensions and importance. The others do not require any notice.

In the days of Roman greatness, Germany, or Germania, as it was then called, was inhabited by a barbarous but powerful people, reckless of control, and ambitious of securing the spoils of richer nations. They broke loose at different periods, overrunning Italy and other fair portions of Europe, and, under the general appellation of Goths, finally prostrated the empire of Rome. The term Goth is now used in a contemptuous sense, but it has to be remarked that modern Europe stands indebted for its liberties to the Goths. The free institutions of Germany were carried into England and other countries, where they have since grown and flourished; and in later times the world has received various useful arts from the same source, in particular the art of printing, which transcends all other inventions. In the eighth century, Charlemagne united the Roman imperial crown (a thing merely so in name) with the German empire, and the great territory we are speaking of was thenceforward called the Holy Roman empire of Germany. This empire lasted till its dissolution in 1806; but long before that era Germany had been broken up into states, by the enterprise of its native dukes and princes, and the name empire was little else than nominal. In 1815, the states entered into the confederation which now binds them.

This large confederated country is watered by 500 rivers, of which the principal are the Rhine, the Danube, the Weser, the Elbe, and the Oder. The most southern chain of German mountains is formed by the Tyrolese Alps, the Alps of Algau, and the Carnian and Julian Alps, running from east to west. To the south-east are the Carpathian mountains, to the north-west the Bohemian forest. There are also alpine regions on the Upper Rhine. In Northern Germany there are sandy heaths and moors, and many districts contain fertile strips only along the large rivers. On the whole, the soil is fertile, and the climate in general is temperate and healthy. The number of inhabitants is estimated at nearly 40,000,000, in 2390 towns, of which 100 have over 8000 inhabitants; 2340 market villages; 104,000 villages, and numerous small settlements. Of the inhabitants, there were in 1825, Germans, 27,705,855; persons of Slavonic origin, 5,325,000; Walloons and French, 309,000; Jews, 292,500; Italians, 188,000; Gipsies, 900; and Armenians and Greeks, 900. In the same year, the number of persons of different religious persuasions was as follows: — Roman Catholics, 18,376,300; Protestants, 15,150,500; Jews, 292,500; Greeks and Arminians, 900. It should, however, be stated, that in this enumeration there are in all likelihood many religionists who are altogether unsettled in belief, although ostensibly belonging to some communion; for in no country in the world is there such latitude in thinking upon points of faith. Germany contains 24 universities, which are attended by about 30,000 students—a class of wild young men, having habits and an appearance very different from what usually characterize attendants at colleges in Great Britain. The publishing and reading of books prevail to a great extent in Germany, which is essentially literary in its tastes. There are public libraries in 150 places, with about six millions of volumes. Ten thousand authors produce annually from about 330 to 5000 new books. There are about one hundred political journals, two hundred and twenty other journals, and at least one hundred and fifty periodical publications. Most of the best English productions are regularly translated and printed in Germany. It is curious that, with all this abundance of literature, and the prevalence of education, with also freedom of religious opinion, Germany is far from being a free country It is despotically ruled by great or petty sovereigns, has only here and there the mockery of representative government, and the people in the mass are destitute of the power to better their condition. Germany, from which all our freedom sprang, is itself ranked among the least free of the nations of Christendom.

One of the chief of the small German kingdoms is Saxony, lying in the centre of Europe, and consisting principally of the plain of the river Elbe, in its upper part, with a population of 1,700,000 inhabitants. It is rich in agricultural produce, and feeds about a million and a half of sheep, the wool of which is remarkably fine and valuable. Saxony has various flourishing manufactures, linen and woollen goods being the staple. It also carries on a brisk trade with various parts of the world. The grand centre of its commerce, and indeed that of all Germany, is at Leipsic, one of its chief towns. Here a great fair is annually held, which is attended by merchants from all parts of Europe, and at which, in particular, the sale of books is very great. The most elegant town in Saxony is Dresden, situated upon the banks of the Elbe.

Germany possesses four free cities, acting as independent states within their own bounds, and individually entitled to vote in the Germanic diet; namely, Hamburg, Lubeck, Bremen, and Frankfort-on-the-Maine. The independence of these towns is a remnant of a confederacy of cities, which was established in the thirteenth century, under the name of the Hanseatic League. Besides these four free cities in Germany, the Polish city of Cracow was declared a free city by the general act of the Congress of Vienna, and is under the protection of Russia, Austria, and Prussia. Hamburg, situated upon the Elbe, which flows into the North Sea, is one of the chief commercial and maritime cities of Europe. It possesses a population within its territory of 150,000 inhabitants.

AUSTRIA.

Austria is a monarchy now forming one of the leading powers of Europe, and is usually esteemed the principal of the German states. Only a portion of the territory, however, belongs to Germany. As a government, it includes a number of ancient states, which have been acquired and added in the course of time by a series of ambitious sovereigns. These are (in addition to Austria Proper, composed of Upper and Lower Austria), Bohemia, Moravia, with the alpine regions of Styria, Carinthia, and the Tyrol; several of the Polish provinces, now called Gallicia; the kingdom of Hungary, and the Lombardo-Venetian kingdom in Italy. This great country is governed by an absolute prince, who takes the title of emperor. It comprises more than 256,399 square miles, and upwards of thirty-two millions of inhabitants. Of these it is reckoned that there are twenty-two millions of Roman Catholics, three millions of the Greek church, two millions of Protestants, and half a million of Jews. The military force of the monarchy in 1819 amounted to 270,000 men, independent of militia. Austria numbers 777 cities, 2224 market towns, and 69,105 villages. The most populous cities are Vienna, Milan, Venice, Lemberg, and Padua. The principal sea-ports are Trieste, Venice, and Fiume; other places of trade are Vienna, Prague, Pesth, Lemberg, Brody, and Gratz.

The capital of Austria is Vienna, which is a city of great extent, situated on the Danube, and greatly improved in modern times. Latterly, much has been done in Austria to establish schools and educate the people, by which they may ultimately be prepared for the enjoyment of political freedom. Meanwhile great improvements are taking place in the condition of the nation by the extension of trade and commerce, steam-navigation, roads, &c.

PRUSSIA.

Prussia is one of the most remarkable kingdoms in Europe. It has risen from nothing at the beginning of last century to be one of the principal continental nations. The increase of its size from its original dimensions, as the Duchy of Brandenburg, to the condition of a first-rate kingdom, has been effected by the intrepidity of its people and the military character of its sovereigns, particularly of Frederick II., or the Great. Prussia, as now constituted, lies in the northern quarter of Europe, with the Baltic Sea on the north, and Russia on the east. It comprises the districts or provinces of East and West Prussia, Posen, Pomerania, Brandenburg, Silesia, Westphalia, and the Rhenish provinces; which divisions include the portion of Poland which was taken by Prussia at the partition of that unfortunate kingdom. The aggregate extent of these territories amounts to 106,852 square miles, with a population of 14,000,000, upwards of eleven millions of which are Germans. Prussia is considered to be greatly weakened as a power by its large scattered extent of territory. The kingdom has three vulnerable parts, towards Russia, Austria, and France; hence its situation is dependent. It is compelled to keep up a large military force, consisting of 180,000 regular troops, with so large an addition of irregulars, as make up in all nearly half a million of soldiers. The king of Prussia is an absolute monarch, yet he is surrounded by a spirit of freedom which necessarily influences his actions. One of the most striking features of this monarchy is the care which it bestows on science and education. The sciences are nowhere fostered with more care, and there are few countries in which common schools are more widely diffused. (See our article EDUCATION.) Prussia carries on some maritime trade by means of the Baltic, and its inland trade is promoted by the rivers Oder, Vistula, Elbe, and Saale, the Rhine, Memel, Pregel, Warta, Netze, Hanel, Spree, Weser, Moselle, &c., which either flow through Prussia, or belong to it. Nine and a half millions of the inhabitants of Prussia are of the Reformed Church, and four and a half millions are Catholics.

SWITZERLAND.

Switzerland is a mountainous territory, occupying the alpine regions betwixt France and Germany, and having Italy on the south. This beautiful and romantic country has, from time immemorial, been occupied by a hardy and independent race of inhabitants, mostly attached to republican forms of government, and always ready to defend their rights and their country from the aggression of the great powers in the neighbourhood. Switzerland measures about 300 miles in length by 140 in breadth, and is supposed to contain 19,000 square miles. Politically, the country is divided into twenty-two small states or cantons, generally independent of each other, but confederated for purposes of mutual protection. Some states are more free in their forms of government than others. The total population amounts to two and a half millions, of which upwards of one-half are Protestantr, and the remainder chiefly Roman Catholics and Jews. The German language is used in most cantons.

Geneva is the smallest but most populous state in proportion to its size, and in this canton is situated the town of Geneva, upon a beautiful lake of about fifty miles in length and eight or ten in breadth. The highest mountains of Switzerland are found in the cantons of Uri, Berne, Underwalden, and Grisons. Of about sixty Swiss mountains which have been measured the highest is Monte Rosa, 15,535 feet high; the lowest, Chalet, is 3000 feet high. Mont Blanc, within the limits of Savoy, is the highest mountain in Europe, being 15,668 feet high. The mountains of Switzerland are pastoral in their lower parts, and in many instances covered at top with perpetual ice, the icy coverings being here characteristically named *glaciers*. The continual alternation of hill and dale affords the most striking natural scenes in every part of Switzerland. In some places, within a short distance, one may see at the same time all the seasons of the year; and it is often possible to stand between spring and summer, so as to collect snow with one hand, and to pluck flowers from the soil with the other. Every mountain has its waterfalls; and as their sources are sometimes lost in the clouds, the cataracts seem to descend from the skies. Switzerland abounds in lakes and rivers, the fisheries of which are valuable, and which serve to embellish the landscape, but none of the rivers are navigable. Small steam-vessels now ply on the lakes of Geneva, Zurich, Constance, and Neufchatel, and are a great convenience to travellers. The chief rivers are the Rhine, the Reuss, the Rhone, and the Tessino. The cultivation of the vine is carried on to a considerable extent in Switzerland; the breeding of cattle is, however, the chief employment of the inhabitants. Swiss cheeses are imported in great numbers into Germany, France, and Italy.

Manufactures of silk, cotton, and linen, have of late years greatly increased in Switzerland, which is rivalling England in some kinds of goods, particularly printed calicoes. Recently great improvements have been made upon the roads through this attractive territory, and travellers are now well accommodated on all the main routes.

The people of Switzerland form one of the best educated, most industrious, and best behaved nations in the world; and consequently they are generally happy and in good circumstances. Although the country does not anywhere touch the sea, and all goods have to be carried many miles by land journey through other states, the Swiss possess a thriving system of trade and commerce, and are rapidly advancing in a career of national prosperity, thus proving that nothing is denied to good conduct and industry.

NORWAY, SWEDEN, AND DENMARK.

These, with the province of Finland, form the north-western frontier of Europe, facing the North Sea or German Ocean, and reaching to the shore of the Baltic on the south. Norway lies on the shore of the North Sea, Sweden is behind it with its southern extremity to the Baltic, and Denmark is formed by the peninsula of Jutland, projected northwards from the Netherlands and Kingdom of Hanover into the mouth of the Baltic. Norway and Sweden are now erected into a kingdom, under one sovereign, much in the same manner as England and Scotland are united. Bernadotte, one of Bonaparte's commanders, has for a number of years been the reigning monarch. The united kingdom measures 1550 miles in length by about 350 in breadth. The country is mostly mountainous and pastoral, and covered with dense forests, producing the finest timber in the world. The climate is dry and cold, but that of Sweden is warmer than that of Norway. The mineral kingdom is rich, particularly in iron, copper, and silver. The inhabitants of these countries are of the ancient Scandinavian races; hardy, honest, industrious, and kind-hearted. In the sciences, the Swedes have shown a sound and penetrating mind. The two kingdoms, Norway and Sweden, had, in 1825, a population of nearly four millions of inhabitants. Stockholm, the capital, had a population of nearly 80,000; Gottenburg, the principal commercial city, had 24,000; Christiana, the capital of the Norwegian division, had 20,600; and Bergen, the chief commercial city in Norway, 20,800. Few towns, however, number more than 4000 inhabitants, and many have scarcely 500.

The Danish monarchy is composed of the peninsula already mentioned, with some islands and detached portions. The principal of the attached territories are the duchies of Holstein and Lauenberg; likewise the Feroe Islands, in the North Sea; Iceland; the western coast of Greenland; some places in Guinea; and the city and territory of Tranquebar, in the East Indies. The exact measurement of so scattered a territory is of little moment; and it is sufficient to state, that Denmark Proper and the duchy of Scleswick contain 17,375 square miles. Denmark Proper is estimated to contain 1,230,000 inhabitants; Holstein and Lauenburg, 370,000; and the total population under the monarchy amounts to something under two millions. The people are partly Danes and partly Germans. Denmark is a level country. The coasts are low, and protected from the sea by dykes. The soil consists partly of marshes and heaths, and is on the whole but moderately fruitful. By the improvident extirpation of the woods which protected the north and north-western coasts of Jutland against the sea, vast extents of fruitful territory have become barren and sandy deserts. The staple productions are grain, rapeseed, and tobacco; and the breeding of cattle forms a principal source of profit. Denmark now contains, without including Iceland and the Feroe Islands, 100 cities, 73 boroughs, 2305 parishes, and 5500 villages. The government is an absolute monarchy. Copenhagen, situated on the east coast of the island of Zealand, is the capital, and contains a population of 105,000 inhabitants.

HOLLAND AND BELGIUM.

These countries, under the general appellation of Netherlands, occupy a large flat territory stretching southward from the confines of Denmark on the north, to France on the south; having Prussia and the small kingdom of Hanover on the east, and the North Sea or German Ocean on the west. They therefore form that part of the continent of Europe which lies opposite the east coasts of Scotland and England. The entire extent of the Netherlands amounts to 24,870 square miles. Through the centre, from east to west, flows the Rhine, one of the finest rivers in Europe, and which parts into a number of channels before pouring its waters into the ocean. On the lower part of one of these channels stands Rotterdam, a large and flourishing commercial city. The surface of the Netherlands is flat, and rich in the luxuriance of vegetation. So low is the land, that it has to be protected from the sea by dykes or embankments. The country is everywhere intersected with canals, which are of prodigious use for commercial and general intercourse. Locally, the Netherlands are divided into a number of districts, among which the old Flemish or Flanders provinces find a place. The whole territory is nearly equally divided into the two distinct states of Holland and Belgium.

Holland is that part of the Netherlands which lies on the north-east side of the Rhine, while Belgium is upon the south-western side, or nearer to France. Holland is composed of the following provinces: North Brabant, Guelderland, North Holland, South Holland, Zealand, Utrecht, Friesland, Overyssel, Groningen, and Drenthe, being ten in number, containing, in 1833, a population of 2,444,550. Of these there are 1,541,748 Protestants, 836,920 Roman Catholics, and 45,493 Jews, besides a few thousands of other sects. The country, however, is essentially Protestant, notwithstanding that all sects are freely tolerated, and their clergy paid on a nearly equal principle by the state. The established church is Presbyterian, resembling that of Scotland both in discipline and doctrine.

Holland has been for ages a commercial country, its people chiefly subsisting in some way connected with ships and maritime traffic. It is, however, not at present advancing very sensibly, owing to the people's want of enterprise, and their hatred of modern inventions and improvements. Since 1830, when the kingdom of the Netherlands was divided by a revolution into Holland and Belgium, the country has been governed separately by a constitutional monarchy. The Hague is the capital of Holland, where the government is conducted, but Amsterdam is the chief town, both for commerce and amount of population—its population was some years since upwards of 200,000. The language of Holland is a species of German, spoken nowhere else in Europe.

The districts or provinces of Luxembourg and Limburg are now considered to belong to Holland. Luxembourg lies on the south of Belgium, and Limburg in the lower valley of the Meuse, on the Belgian side of the Rhine.

Belgium, the country of the ancient Belgæ, and in later times the country of the Flemings, now consists of the provinces of Brabant, Antwerp, East and West Flanders, Hainault, Namur, and Liege, the whole measuring 12,000 English square miles, and containing 4,000,000 of inhabitants. The people of Belgium are from the same original stock as the Dutch, but circumstances have made them widely different in manners. Belgium was long held in subjection by Spain and Austria, and afterwards was attached to France, and partly from this cause the prevalent religion is Roman Catholic, and the language chiefly French. These two peculiarities give a turn to the national feelings. The Belgians, though as industrious as their neighbours, the Dutch, are less steady of purpose, and more enterprising. Nevertheless, they are now a thriving people, under a constitutional monarchy, with Leopold as their king, and many improvements are at present in operation in the country. Brussels, a beautiful large town in Brabant, is the capital—population about 80,000. The manufactures, internal traffic, and commerce of Belgium, are undergoing a rapid extension. The towns next to Brussels in size and importance are Antwerp, a sea-port on the Scheldt, Ghent, Bruges, Louvain, and Liege. The two main rivers are the Meuse, which falls into the Rhine, and the Scheldt.

TURKEY.

Turkey is a territory partly in Europe and partly in Asia, and is inhabited by an Asiatic-Tartar race, called Turks, who in the year 1453 conquered that portion lying within the confines of Europe, formerly the metropolitan part of the western empire of the Romans, and have there ever since, at Constantinople, held a barbarous sway of this beautiful district of Europe. Turkey in Europe is separated on the south-west from Asia only by a long range of straits called the Dardanelles, and by the Black Sea, and is bounded on the northern side by the dominions of Austria and Russia. On the west it has the Adriatic Sea, which in part separates it from Greece, till lately a portion of itself. The Turkish monarchy nominally possesses Egypt and some other possessions in Africa; but, not computing these distant territories, it may be estimated that Turkey in the present day measures in Europe 178,928 square miles (but including the insecure provinces of Moldavia, Wallachia, and Servia), with a population of upwards of nine millions of inhabitants; and in Asia 425,000 square miles, with a population of above ten millions. The bulk of the population in both regions is Mohammedan, and uncivilized. The climate of Turkey is among the most delicious in the world; its soil is generally productive and its natural appearance is beautiful.

Constantinople, the capital (called Stamboul by the Turks), situated on the Bosphorus, a strait betwixt the Mediterranean and Black Sea, is a large and populous, though crowded and inconvenient city, excellently situated for trade, communications being carried on with it by the Mediterranean on the west, and the Black Sea on the east. Every region in Turkey yields its productions in abundance. The staple articles of export are wheat, rice, cotton, tobacco, silk, figs, and other fruits; hair, wool, and opium. Mining is totally neglected; and there is in general little manufacturing industry in the country The inhabitants are at once extremely ignorant, proud, and slothful, and the commerce carried on is chiefly in the hands of Jews and Christians. The spread of knew-ledge has been sedulously prevented; printing, till lately, was carried on only by Armenians, Jews, or Greeks; and transcribing books with the pen is pursued as a common employment. Painting and sculpture are neglected, because the Koran, or Bible of the Mohammedans, forbids the imitation of the human form. A great effort was lately made by the sultan Mahmoud to introduce some civilized usages, and, among other improvements, he established a newspaper at Constantinople, in French and Turkish.

The sultan, as caliph, or successor of the prophet Mohammed, enjoys the character of Pope to the Mohammedan world, and unites the highest spiritual dignity with the supreme secular power. He has unlimited control over the property and lives of his subjects, especially of the highest officers of state, whom he can remove or put to death at will. The people have no rights. Merit, or favour, or intrigue, can raise the lowest to the highest stations. There is no hereditary nobility. The succession to the throne is hereditary in the family of Osman; the will of the people and of the janizaries has often decided upon the individual. Women are excluded from the succession. The padishah or sultan is not crowned; he is merely girded with the sword of Osman, after he has sworn to uphold the religion of Mohammed. The women of his harem are for the most part Circassians or Georgians, who have been purchased as slaves. On account of this plurality of wives, and the number of male descendants, there is generally a contest for the throne at the decease of every monarch. Latterly there has been some improvement in this respect, still the whole arrangements for a regular succession are on a precarious footing.

The most remarkable thing about the Turkish system of government is, that the Koran, or Book of Mohammed, is the source of all civil, political, or criminal law. In addition to the code of laws, the interpretations of the ulema, or priesthood, have great weight in the tribunals. The mufti is not only the chief of the priests, but the highest interpreter of the laws. His decisions are collected. The highest tribunal, the divan chaneb, is held four times a-week by the grand vizier, in his palace, or in his absence by the tchaush-baschi. In the lower tribunals of the large cities, the mollas sit; in those of small towns, the cadis. The moslems are, under them, the executors of the sentences. The administration of justice is as simple as it is prompt and energetic. The common punishments are the bastinado, hanging, drowning, strangling, and impaling. The court or government of the sultan is known by the name of the Porte, Sublime Porte, or Divan, and the sultan has received from Europeans the title of Grand Seignior. In Constantinople and other parts of Turkey, English, French, and other foreigners from western Europe, are generally termed Franks.

The land forces were until recently organized on a miserable Asiatic system. They are now modelled, armed, and disciplined, on the common European principle, and partly dressed on the same plan. The navy of Turkey has been also organized according to the European system. In civil life many reforms have likewise been effected by orders of the late Sultan Mahmoud (deceased 1839), and altogether the Turkish empire may now be described as in a transitive state towards civilization.

GREECE.

The north-eastern part of the Mediterranean is divided into two large bays or gulfs, which run far up into the European continent; that towards the west being called the Adriatic, and the other the Ægean Sea. The peninsula, or tongue of land which lies between the two, is the original country of the Greeks. Colonies of the same nation have, from time beyond the reach of history, occupied the whole coasts and islands of both these gulfs from Sicily almost to Cyprus; but the parent states of the middle peninsula are those to which the Grecian name is indebted for all its splendour; and it is this country only which is properly called Greece. From the situation of the Greeks in a region whose bays, headlands, and islands, present a great extent of sea-coast, habits of adventure and mutual intercourse were produced among them in the earliest times, which had the greatest influence in cherishing a national activity of character, and making each community eager to rival the prosperity of the others. The people were early accustomed to make voyages, sometimes for traffic, sometimes for war, betwixt the opposite coast of their gulfs, guiding themselves by the stars from island to island. From this and other circumstances, Greece in early times attained the first rank as a state, or confederacy of states. (See article ANCIENT HISTORY.) After being conquered by the Romans, it fell a prey to the Turks, from whom it was in part only recently wrested by a skilful rebellion or revolution.

In the present day, Greece comprises in its northern parts the districts of Albania and Macedonia; next, in a southerly direction, Epirus and Thessaly; the Morea (anciently Peloponnesus) is an island-like peninsula, almost cut off from the latter divisions by a strait called the Gulf of Lepanto. Altogether, modern Greece measures about 400 miles in length, and little more than 100 in general breadth. Greece is a mountainous and romantic region, with several beautiful rivers. Its agriculture is in a very rude condition, but its commerce is increasing; and the long-exhausted nation is gradually assuming a settled powerful character. A constitutional monarchy, not very well organized, has been imposed on the newly erected nation by the European powers, with Otho, a Bavarian prince, as king. Athens, the chief town or capital, is now undergoing improvements, and frequently visited by strangers. The population of the continental part of Greece is stated at three millions, and nearly half a million for the islands adjacent.

ASIA.

Asia, which forms the eastern and northern portion of the great tract of land in the eastern hemisphere, is the oldest known portion of the globe, and is usually called the cradle of the human race, of nations, and of arts. It is separated from Australia by the Indian and Pacific Oceans; from America on the north-east by Behring's Straits, and on the east by the great Eastern or Pacific Ocean; from Africa by the Arabian Sea (with which is connected the Persian Gulf), and by the Arabian Gulf, or Red Sea, with the straits of Babelmandel; from Europe by the Sea of Azoph, with the Straits of Caffa, by the Black Sea with the Bosphorus, by the Sea of Marmora and the Dardanelles, and by the Grecian Archipelago. On the other hand, it is united with Africa by the desert Isthmus of Suez, and with Europe by the waters of the Wolga, which rises near the Baltic, and falls with the Ural into the Caspian Sea.

The area of Asia is about 16,175,000 square miles. It extends from 26° to 190° E. longitude, and from 2° to 78° N. latitude. Its greatest breadth, from north to south, is 4140 miles, and its greatest length about 8000. It is four times larger than Europe. It is divided into 1. Southern Asia, comprehending Natolia, Armenia, Curdistan, Syria, Arabia, Persia, Hindostan, Farther India, Siam, Malacca, Annam, Tonquin, Cochin China, Laos, Cambodia, China, Japan; 2. Middle or Upper Asia, containing Caucasus, Tartary, Bucharia, Mongolia Tungousia; 3. Northern or Russian Asia, from 44° N. latitude, containing Kassan, Astrachan, Orenburgh, Kuban, Kabarda, Georgia, Imireta, Siberia, with the alpine regions of Dauria and Kamschatka.

The large portion of Asia composing the northern and middle divisions, inhabited by wandering Tartar races, possesses little interest, and is generally viewed as little else than a great wilderness. The parts which are important, either from their historical interest or their present condition, are the three lobes or masses of land, partially jutting out from the continent on its southern side; the first, on the west, comprehending Arabia, Syria, and Persia, the second, or mid part, Hindostan or India; and the eastern part, China and Japan. Arabia is a fine large peninsular tract lying betwixt the Persian Gulf on the east, and the Red Sea on the west. It contains about 1,000,000 square miles, and is situated between the 12th and 30th degrees of north latitude. Its chief towns are Mecca and Medina, near the shore of the Red Sea. The southern portion is entitled Arabia Felix, or the Happy, and its northern part Arabia Petræa, or the Rocky. Adjacent to this northern division, and stretching along the border of the Mediterranean Sea, is Syria or Palestine, the ancient country of the Jews, but, along with the surrounding country, now held in subjection by the Turkish power, and in a state of barbarism. A description of PALESTINE is elsewhere given in the present work.

The district of country anciently termed Asia Minor, but now forming part of Turkey in Asia, and called Natolia or Anatolia, is a territory 650 miles long, and 400 broad, having Armenia on the east, and a part of the Mediterranean on the west and south. It is a fruitful and delightful part of Asia; its principal town and seaport is Smyrna, with which a considerable traffic is carried on with western Europe.

Persia lies on the eastern shore of the Persian Gulf, between the 25th and 40th degree of north latitude. It has the Caspian Sea, or a great inland lake, on the north, and the Arabian Sea on the south. It comprises about 390,000 square miles, with a population of about 6,500,000. The people are Mohammedans, and in a semi-barbarous condition, governed by a shah or despotic sovereign. Ispahan is the capital. Within a portion of country anciently called Mesopotamia, and now generally entitled Turkey in Asia, and lying at the head of the Persian Gulf, between Persia and Arabia, are the rivers Euphrates and Tigris, also the towns of Bagdad and Bassora. It was by these channels, the Persian Gulf, the Euphrates, and also the Red Sea, that a great trade was once carried on betwixt India and the shores of the Mediterranean Sea; now this traffic is at an end, in consequence of the barbarous state of the whole region round about, and the opening of a communication betwixt India and England. Of INDIA, and also CHINA, no account need here be given, as they are fully described in other parts of the present work.

In all parts of Asia, excepting the mid and northern regions, the climate is delightful, and Nature has spread her most bounteous gifts. "'Tis the clime of the East, the land of the sun," but sunk in false religion, superstition, and in a state of moral and intellectual torpor—"all but the spirit of man is divine"—and when or how it is to be rescued from such a condition, no one can foretell. In the southern divisions within the torrid zone, whose genial warmth converts the juices of plants to spices, balsams, sugar, and coffee, with which Asia has enriched the West Indies, the palms (sago, cocoa, date, and umbrella-palms) reach a height of 200 feet, and the white elephant attains a size surpassing that of all other quadrupeds. From hence the silk-worm was brought to Europe. This region conceals in its bosom the most beautiful diamonds, the finest gold, the best tin, &c., whilst the waves flow over the purest pearls and corals. The temperate zone has given to Europe the melon, the vine, the orange, and many of its most agreeable garden fruits, as well as the most productive farinaceous grasses, and the most charming flowers; and unites, in its productions, symmetry with richness, particularly in the western regions. Here the oldest traditions place Paradise; here lie the enchanting Cashmere and the Garden of Damascus; here blossoms the rose of Jericho, near the cedars of Lebanon. The eastern countries in the same latitude possess the tea-shrub and the genuine rhubarb. The camel, the Angora goat, the Thibetan sheep, the pheasant, and the horse, are natives of this zone. In the north blossoms the Alpine *flora* of Dauria, and from the icy soil grows the dwarf-like Siberian cedar, till, at 70°, vegetation mostly ceases. Here live the smallest of quadrupeds—the shrew-mouse of the Yenisey. Sables, ermines, foxes, otters, &c., afford the finest fur. The mineral kingdom furnishes rich ores, rare precious stones, and remarkable fossil remains of the mammoth, in high northern latitudes.

The inhabitants of Asia (amounting to 390,000,000; according to some, to 580,000,000) are divided into three great branches:—The Tartar-Caucasian, in Western Asia, exhibits the finest features of our race in the Circassian form; the Mongolian race is spread through Eastern Asia; the Malay in Southern Asia and the islands. The north is inhabited by the Samoiedes, Tchooktches, and others. Twenty-four tribes, of different language and origin, may be distinguished, some of which are the relics of scattered tribes of Nomades: Kamtschadales, Ostiacs, Samoiedes, Koriacks, Kurilians, Aleutians, Coreans, Mongols, and Kalmucks, Mantchoos (Tungoos, Daurians, and Mantchoos Proper), Finns, Circassians, Georgians, Greeks, Syrians and Armenians, Tartars and Turks, Persians and Afghans, Thibetans, Hindoos, Siamese, Malays, Annamites (in Cochin China and Tonquin), Burmese, Chinese and Japanese, besides the indigenous inhabitants of the East Indian islands, Jews and Europeans. The principal languages are the Arabian, Persian, Armenian, Turkish, Tartar, Hindoo, Malayan, Mongol, Mantchoo, Chinese, and Sanscrit. The principal religions which prevail are Mohammedanism in the western parts, the worship of the [illegible] Thibet in the central region, Budhism in the B[illegible] territory, and Hindooism or Brahminism in [illegible] These and other religions of the Asiatics are described in the article PAGAN AND MOHAMMEDAN RELIGIONS.

AFRICA.

Africa is a vast peninsula of a triangular form, with its narrowest point towards the south, containing 12,256,000 square miles; situated between 18° W. and 51° E. lon., and from 34° S. to 37° 30′ N. lat.; bounded on the north by the Mediterranean, on the east by Asia, the Red Sea, and Indian Ocean, and on the south and west by the Southern and Atlantic Oceans. It has a great breadth from east to west. The northern portion is much larger than the southern; the greatest breadth, from west to east, from Cape Negro to Cape Guardafui, is 69°. Under the equator, the breadth is 4500 geographical miles. The internal structure of Africa is marked by many peculiarities. It possesses deserts or arid sandy tracts of immense extent, uninhabitable by a settled population, and only traversed by troops of wild Arabs, and caravans or companies of travellers on the backs of camels. In these awful solitudes, lions, tigers, and other wild animals, hunt for a prey, and dispute possession with the savages who intrude upon their domain. Africa also possesses immensely long chains of mountains rising to an enormous height. Such are the Atlas mountains, the Mountains of the Moon, and others. The highest peak of the Camerones is 13,000 feet above the level of the sea. Africa has few rivers suitable for navigation, and hence its impenetrable character. The principal river is the Niger or Joliba, which flows some hundreds of miles from the interior, to the Atlantic on the west coast. In this quarter also are the Gambia, the Congo, and the Senegal. The Nile has been the longest and best known; it flows from Abyssinia through Egypt to the Mediterranean.

Excepting in some small spots on the sea-coast inhabited by European colonists, the whole of Africa is in the possession of races of men, black and fiercely savage, or very slightly civilized, and of a copper complexion. Of the latter variety are the Moors of the extensive region of Barbary on the north, and also the modern inhabitants of Egypt. Egypt, which is little else than the valley of the Nile, and lying adjacent to Arabia Petræa, and Syria in Asia, is the only country of Africa in which we can find any interest from historical recollections. It is described at length in a separate number of the present work. West from Egypt is Barbary, a country in part nominally subject to Tartary, and containing the districts of Tripoli and Tunis, also Algiers, which has lately been conquered and appropriated by the French. The empire of Morocco is likewise in this northern division, in the angle of territory between the Mediterranean and Atlantic. Central Africa comprises a number of savage states, among the rest Guinea on the Atlantic coast. Along this coast are certain British, French, Portuguese, and Dutch possessions. Southern Africa comprises the countries inhabited by the Hottentots and Caffres, and the Cape of Good Hope, which is at the extreme southern promontory, and now forms a flourishing British colony.

The islands considered to belong to Africa are the Madeiras, the Canaries, Cape Verd, and Azore islands, also St. Helena and Ascension, all in the Atlantic; and the large isle of Madagascar, with a few of smaller size, in the ocean to the east of the continent.

Madeira is the finest and most accessible of the African islands. It extends to about 37 miles in length by 11 in breadth, and lies at the distance of about five hundred miles from the coast of Barbary, in the route of vessels proceeding from Europe to the Cape of Good Hope or India. Lying at about the 31st degree of north latitude, it enjoys a delightful climate, suitable for the tender constitution of invalids. Vegetation is luxuriant, and the grape grows to great perfection, and yields a fine wine, usually called Madeira. The island is in possession of Portugal, but many English reside upon it, both for the sake of commerce and health.

The African races of men offer many points of interest to the inquirer. The majority of them are distinguished from the rest of the human family, not only by their black complexion and curly hair, but also by peculiarities in the construction of the bones of the head and even of the nerves. This seems to imply that the negro is originally a distinct race. It is thought that traces of this primitive race may still be detected here and there; for example, of the original Egyptians in the Copts, and of the Guanches (the original inhabitants of the Canaries) in the natives of Barbary. The population is probably between a hundred and a hundred and ten millions. The interior of the country must be very populous, since, within two centuries and a half, it has contributed forty millions of vigorous men to the slave-trade, and, notwithstanding, is any thing but depopulated. Even the countries along the coast are thickly peopled. Jackson computed the population of Morocco alone at seventeen millions, and the Barbary states, with Egypt, which constitute but an eighth part of the continent, contain twenty millions. The torrid Guinea has, on the whole, a numerous population; and large cities are situated on the Joliba, of which we hardly know the names. The inhabitants belong to two branches of the human family; to the black or Ethiopian race, which extends from the Joliba to the southern extremity, comprising, notwithstanding their tawny complexions, the Hottentots; and to the Caucasian race, which includes the natives of Barbary, Copts, the Arabs or Moors, the Agaziones or Abyssinians, and the nations of Nubia. The Arabs are not to be regarded as aborigines of Africa, but they have scattered themselves and become occupants of the greater part of the north and west.

The prevailing religions are Mohammedanism, and different kinds of Paganism. The arts are exercised only on the northern coasts, where the Moors manufacture much silk, cotton, leather, and linen; an active commerce is carried on by them with the maritime nations of Europe, and, by means of caravans, a traffic fully as important, with the interior, to which they convey their own products and those of Europe. The wants of the savage races are exceedingly simple, and every article used by them is prepared by themselves; the cloth which surrounds their loins, the hut which protects them from the weather, the bow and arrow necessary for the chase and self-defence, as well as all their household furniture, are manufactured by themselves; the gold which they collect from the surface of the earth is wrought by them into ornaments, and iron into arms. Commerce, however, with Europeans has taught them many wants, and increased their list of necessaries; among which may now be reckoned fire-arms, powder, brandy, tobacco, different kinds of cloth, glass beads, coral, &c.: for which they barter slaves, ivory, gold, and gums, the staples of Africa. The most odious branch of traffic is that carried on in the sale and export of slaves; although in some respect limited in recent times, it is calculated that still 50,000 negroes are carried off annually for the South American market. Of all the states of Africa, Barbary alone uses coin; in the rest not frequented by Europeans, money rarely serves as a medium of exchange; in some, on the western coast, cowries (small shells) are made to answer the purpose of coin; in others, pieces of salt.

AUSTRALASIA,

Which now ranks as one of the great divisions of the earth, consists of a number of large and small islands in the Indian or South Pacific Ocean, between the 10th and 45th degrees of south latitude, in a south-easterly direction from China, which is the nearest part of the Asiatic continent. These islands also lie in a south-easterly direction from India, or Hindostan. The chief island in the group is Australia or New Holland, which measures 2000 miles from east to west, and 1700 in breadth from north to south. The physical character of Australia is very peculiar. With the exception of some mountain ranges, it is generally flat, and in many places the inclination is inwards, instead of outwards, to the sea. There being a general absence of hills, clouds are not attracted over the land, and hence there is a deficiency of rain in the country; the climate is nevertheless one of the finest in the world, and no country on the globe seems so suitable for sheep pasturing. The chief native quadrupeds of Australia are pouched animals, such as kangaroos, of which there are several varieties. The native human beings are of the Malay race, and in a low state of barbarism.

Australia now possesses three distinct British settlements—New South Wales, which stretches about 1500 miles along its eastern coast, and some hundreds of miles inland; South Australia, on its southern shore, which has been but recently opened for emigration; and Western Australia, or Swan River Settlement. Van Diemen's Land is another British settlement. New South Wales, which is the oldest and most populous of the Australian colonies, lies at the distance of 16,000 miles from Great Britain, and its capital, Sydney, to which most vessels proceed, is reached in from 100 to 120 days' sailing. Lying on the opposite side from us, its seasons are reversed in relation to ours; its winter is in May, June, and July, and its summer in November, December, and January. Sydney, which is agreeably situated on a fine bay of the sea, called Port Jackson, now possesses a population of 25,000 souls. The whole population of New South Wales, free and convict, is understood to be about 110,000, but the number of inhabitants is rapidly increasing.

South Australia, to which no convicts are allowed to be sent from England, is at present a thriving colony; the town of Adelaide is its capital.

Van Diemen's Land is an island of about the size of England, lying at a short distance south from Australia, and possessing many excellent harbours. Van Diemen's Land is more hilly and better watered than Australia, and therefore better adapted for agriculture. Its capital is Hobart Town, on its southern side. On its northern shore, opposite Australia, is Launceston, the second largest town in the island, and a busy seat of trade. The population of the island was lately estimated at 35,000, about one-half of which were convicts.

The New Zealand Islands, which belong to the Australasian group, are situated at a greater distance to the east of Australia.

For a complete description of the whole of these interesting territories, we refer to the articles on the subject, in the present work.

AMERICA.

The continent of America lies in the western hemisphere, in a situation altogether aloof from the continents of the Old World—as Europe, Asia, and Africa, are termed. America, or the New World, was first discovered by Columbus, in the year 1492, but its coasts were not fully known to Europeans for nearly a century after that period. It was long a matter of doubt whether America was connected at its northern extremity with Asia, and many expeditions were fitted out to discover if such were really the case: it is now ascertained that it is not connected with Asia, but is a detached continent. Although Columbus is entitled to be considered the first discoverer of America, it happened that he was robbed of the honour of giving it his name by the superior address of Americus Vespucius, one of his adventurous successors. America consists of two large portions, very nearly separated by the intervening Gulf of Mexico, and only connected by a neck of land called the Isthmus of Darien. The northern portion is named North America; that in the south, South America. From its northern boundaries to the Gulf of Mexico, North America extends about 4376 miles in length, and 3000 miles wide at the broadest part. South America commences at the ninth degree of north latitude, reaching to the 56th degree south latitude, being a length of 4550 miles, by a breadth, at widest, of nearly 3000 miles. On this vast double continent, the works of nature are found on a large scale, calculated to excite our wonder. Mountain ranges, plains and rivers, are all larger and more magnificent in their proportions and appearance than those in the eastern hemisphere. The soil is also very generally fertile, and covered with the most lofty timber and luxuriant vegetation.

At the period of the discovery of America, it was found to be thinly inhabited by a number of tribes of aboriginal people, generally of a copper colour, and more or less savage in character and habits. The subsequent settlement of colonists from Spain, Portugal, Holland, England, France, and other European nati[illegible] had the effect of either extirpating these races, or of driving them westward towards the shores of the Pacific Ocean. They are now comparatively few in number. While they have decreased, the colonists have vastly increased in number by emigration, and the natural increase of population. In a general sense, North America has fallen to the share of British colonists, while South America has become the portion of the Spanish and other bigoted and bad-managing Europeans. In the course of time, the colonists in nearly all parts have emancipated themselves from the dominion of the mother countries, and set up as independent nations. In doing so, they have embraced the opportunity of trying to establish democratic institutions, with an absence of aristocratic distinction. The greatest of the republics thus established is that of the United States of North America. A third race, the descendants of negroes imported as slaves, is rising into a large amount of population over the whole continent, partly emancipated, and still partly as slaves; and being most unfortunately or inhumanely kept as a despised caste, their increasing numbers and condition are at present exciting the attention of the civilized world. It has been computed that the whites and their descendants in all parts of America amount in number to 15,000,000; Indians, 10,000,000; negroes, 8,000,000; mixed breeds, as mulattoes, mestezos, &c., 8,000,000; total, 41,000,000; but the number of Indians is declining so rapidly, that in all likelihood they do not at present amount to more than from six to seven millions, while the whites have increased in an equal proportion. It is reckoned that there are space and fertile soil on the American continent for at least 800,000,000.

South America comprises the states or independent republics of Colombia, Guiana, Brazil, Peru, Bolivia, Chili, Buenos Ayres, or the united provinces of La Plata and Patagonia. The principal range of mountains is the Andes, and betwixt these and the Atlantic are many great flat plains, receiving the name of Pampas. The rivers in South America are among the largest in the world; the principal are the Amazon, La Plata, Orinoco, Panama, Paraguay, St. Francisco, and Magdalena. The principal islands are the Falkland Islands, Terra del Fuego, off the southernmost point of land, Juan Fernandez, and the Gallapagos. For a complete account of South America, we refer to the article on that subject.

North America comprehends the following political divisions:—On the North, the country of the Esquimaux, who form independent tribes; also Greenland, a large insular or peninsular tract, stretching towards the north pole; next these, to the south, Labrador, a country belonging to Great Britain, and chiefly appropriated by hunters and natives; on the north-east coast the island of Newfoundland, a British possession; Canada, Nova Scotia, and New Brunswick, likewise British possessions; thus the larger portion of territory in the northern part of the continent belongs to Great Britain. Adjacent to Canada, and occupying the whole frontage to the Atlantic, are the United States. Behind them, on the west coast, are the united states of Mexico, and in the north-western part a territory claimed by Russia. The extreme southern part of North America, occupying a division of the isthmus of Panama, is the state of Guatemala, which now claims to be independent. Except in Mexico, the larger proportion of the western side of the continent is still in possession of native Indian tribes, but these are quickly disappearing before the advances of civilized man. To this continent belongs a series of islands on the Atlantic side, in the seas between North and South America, now bearing the name of West Indies. Among these are St. Domingo, Jamaica, and other islands of importance, chiefly devoted to the culture of the sugar-cane, coffee, and other tropical productions. (See article West Indies.)

North America abounds in fine large rivers, susceptible of navigation for several hundreds, and, in a few instances, thousands of miles. The principal river in the north is the St. Lawrence, which issues from a series of large fresh-water lakes, the most extensive on the globe; these are Lakes Superior, Huron, Michigan, Erie, Ontario, and others. They in general divide Canada from the United States. Next in size to the St. Lawrence, on the north-east coast, is the Hudson river, which enters the Atlantic at New York. The other chief rivers are the Mississippi, and its tributaries the Ohio and the Missouri. These flow through the central parts of the country, and terminate, on the south, at the Gulf of Mexico. The valley of the Mississippi is separated from the slopes on the Atlantic, by the Alleghany range of mountains. In the western part of the continent is a similar range called the Rocky Mountains, which are the boundary adjacent to the slopes on the Pacific. By means of these and other water-courses, personal and commercial intercourse can be carried on to a boundless extent, and, with the inexhaustible fertility of the soil, will in time render North America the most populous and wealthy region in the earth. Already, within the period of two hundred years, or more properly since the epoch of the American revolution in 1770–80, the Anglo-Saxon race, originally planted as settlers by Britain, has spread over a large portion of the country, and founded an immense number of towns and cities, and otherwise effected the most extraordinary improvements in all the arts of civilized life. The United States were lately twenty-eight in number, as follows:—Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, all which are known as the New England states; New York, New Jersey, Pennsylvania, Delaware, Columbia, Maryland, Virginia, North Carolina, South Carolina, Georgia, Alabama, Mississippi, Florida, Louisiana, Tennessee, Kentucky, Ohio, Indiana, Illinois, Missouri, Michigan, and Arkansas. The number is constantly increasing, by the acquisition of new territories. The principal cities are Washington the capital, New York, Philadelphia, Boston, Baltimore, and New Orleans.

The principal cities or towns in the British possessions are Toronto, Montreal, Quebec, Halifax, and St. Johns. For an account of the UNITED STATES, CANADA and NOVA SCOTIA, we refer to the separate articles on these subjects.

POLYNESIA.

Polynesia—a word signifying "many isles"—is the name now given to the numerous groups of small islands scattered over the Pacific Ocean, but principally lying in an easterly and north-easterly direction from Australia, within about thirty degrees on both sides of the equator. They are perhaps better known under their titles of the Sandwich, Friendly, Society, and Queen Charlotte's Islands, &c. They are many thousands in number, and are inhabited by races of men who have generally been found much more tractable than the barbarous tribes of the other parts of the world. Most of the islands are fruitful and beautiful; some are exceedingly high and romantic, and their climate is reckoned the most delicious on the globe. Otaheite is one of the principal of the Society Islands. Owhyhee, or Hawai, is the largest of the Sandwich Islands, and measures eighty-four miles in length by seventy in breadth. Here Captain Cook, in 1779, fell a victim to a sudden resentment of the natives with whom his party unfortunately had a dispute. The Islands are in the course of being Christianized and improved.

[WORKS ON GEOGRAPHY.

A general knowledge of geography has now become one of the elements of common school instruction. But the subject is sufficiently extensive and interesting to form a study for the riper years of those who have leisure for it. Among the school geographies, Morse's is preferred, on account of the great number and minuteness of the maps, which, in fact, are the principal thing in this study. Murray's Encyclopædia of Geography is a very extensive and interesting work abounding with maps and pictures, and going minutely into every branch of the subject. Malte-Brun's is another of the same class, and is greatly prized by scholars. The most convenient books of reference on this subject, of course, are Gazetteers, and of these Macculloch's is the most recent and extensive. The most agreeable mode of studying geography, however, is by reading books of travels, written by lively and interesting writers, like Stephens, Slidell, Darwin, Dana, Fisk, Mrs. Haight, Humboldt, Kendall, Kay, Kohl, Mackenzie, Dr. Olin, Captains Parry, Reynolds, Sedgwick, Cheever, and others of the same class. By reading their delightful books, with the map before us for reference, we have the features of the countries which they visited indelibly fixed in our minds, in association with the manners, customs, and history of the places.

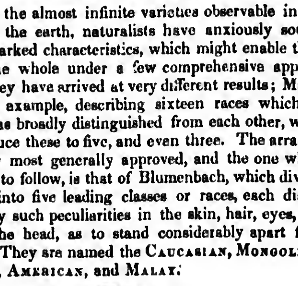
For the purpose of rendering our knowledge of geography still more minute and available, it is an excellent practice to draw maps, and however imperfectly or unscientifically this task may be executed, its effect in assisting the memory is acknowledged by all who have made the experiment. It is worth one's while, also, to embrace any opportunity which may present itself of examining the maps which have recently come into fashion, in which the mountains are represented in relief, being actually raised above the surface of the paper or card of which the map is made. Such maps are common in Europe; but few have reached this country, and we are not aware that the making of them has been attempted here.—*Am. Ed.*]

PHYSICAL HISTORY OF MAN.

The Physical History of Man is a science which proposes to investigate the characters of the different races of the human family, as they exist in different regions of the earth. The great distinctions between the various races must have been marked with wonder at an early period; but no serious effort was made to ascertain the nature and causes of those varieties till the present century, when the subject has been illustrated by the researches of Cuvier, Blumenbach, Pritchard, and some other writers. As yet the science is far from having arrived at distinct or satisfactory results; but much of what has been ascertained is nevertheless of a most interesting nature, and well deserving of general attention.

POPULATION OF THE GLOBE—RACES—THEIR GENERAL FEATURES.

Amidst the almost infinite varieties observable in the nations of the earth, naturalists have anxiously sought for well-marked characteristics, which might enable them to class the whole under a few comprehensive appellations. They have arrived at very different results; Malte-Brun, for example, describing sixteen races which he considers as broadly distinguished from each other, while others reduce these to five, and even three. The arrangement now most generally approved, and the one which we design to follow, is that of Blumenbach, which divides mankind into five leading classes or races, each distinguished by such peculiarities in the skin, hair, eyes, and shape of the head, as to stand considerably apart from the rest. They are named the Caucasian, Mongolian, Ethiopic, American, and Malay.



Caucasian Race.

1. The Caucasian race is one widely spread on the face of the globe, and, in addition to physical beauty of the highest order, is distinguished for intellectual eminence. The skin of this race may be generally described as fair; but it is susceptible of every tint, and in some nations is almost black. The hair is fine, long, curling, and of various colours. The skull is a large rounded oval, and the brow full and elevated. The face is comparatively small, oval in form, and well proportioned. The nose is arched, the chin full, and the teeth vertical. The chief families of the Caucasian variety are the *Caucasians proper*, the *Germanic* branch, the *Celtic*, the *Arabian*, the *Libyan*, the *Nilotic*, and the *Hindostanic*.

The race of *Caucasians proper* are traceable to the confines of the mountainous range of Caucasus, between the Black Sea and the Caspian—a region not far distant from the apparent birth-place of mankind. The Caucasians still dwelling there form at this hour the physical type of this great variety of human beings. The Circassians and Georgians are very perfectly formed, approaching closely in shape and features to the cognate race of Pelasgi or Greeks, who, emanating from this region, spread early over Greece and parts of Italy, and there founded Caucasian nations. At this day a great part of the people of Persia, and especially the upper classes, are of Caucasian descent, the remainder being Mongol Tartars, a race equally distinguishable when pure. The Persian men and women have, generally speaking, fine persons, and they are, like the whole of the pure Caucasian variety, highly imaginative, and fond of music and poetry. The tribes of Affghanistan and Koordistan belong in part to the same variety, and exhibit its wonted physical perfection.

A small body of pure Caucasians founded the Roman nation. The personal differences between them and the Greeks arose, doubtless, from the extensive admixture of the early Romans with the Sabines and other surrounding tribes.

The *Germanic* family, a great branch of the Caucasian variety, formed one of the mighty waves of population, which, emanating from the original seats of the race, passed over a great part of central and northern Europe, filling Germany and Scandinavia, and partly, also, Russia and Poland. In the latter regions, however, they met with Tartars from Asiatic Scythia, and the mixture of these races produced the Slavonic subvariety, and originated the Slavonic tongues. The decline of the Roman power brought out the Germanic tribes from their northern settlements, and, under various names, they formed new locations in the south-west of Europe. Among others, they founded the languages of England, Holland, Denmark, and Sweden, though at different periods. Robust forms, light hair, blue eyes, florid complexions, and large, broad-fronted heads, constitute the chief physical characteristics of the pure Germanic family; while, morally and intellectually, they stand preeminent above all the other tribes of mankind. They are conspicuous, in particular, for what may be called the *industrial virtues*, exhibiting a degree of indomitable perseverance in all improving pursuits, which has rendered them the great *inventors* of the human race. The admixture of German and Tartar blood in the north-eastern nations of Europe, has given to these darker hair and complexions than the preceding section, and has also lessened their propensity to intellectual cultivation. The effects of the Tartar conquest of Russia in the twelfth century by Zenghis Khan, whose successors held the country for 200 years, will probably be observable in the career of this people for ages to come, and, indeed, perhaps as long as the race exists.

The *Celtic* branch of the Caucasians formed extensive settlements, at a very early period, in Western Europe. The whole, it may be said, of Italy, Spain, France (called Gallia Celtica), and Britain, was peopled by them. The successive commingling of races, caused by incursions of the Greeks, Romans, and Germans, did much to obliterate the traces of this variety in its pure state; yet the race, language, and name, still remain in their primitive condition on the outskirts of the original Celtic dominions. We allude chiefly to parts of Scotland and Ireland: In Brittany, Gascony, and Biscay, the traces of the people are also distinctly observable. These pure Celts show us what the physical characteristics of their anceors were. Their frames are athletic, spare, and wiry; their forehe[illegible]rrow, and the head itself elongated; the nose and mo[illegible]arge, and the cheek-bones high; in all, their features are rather harsh. In character, they are hot and fiery, but generous and brave; and they are remarkably patient of fatigue. Intellectually considered, they are acute and ingenious in the highest degree, but are deficient in that breadth and solidity of understanding which distinguishes the Germanic family.

The present population of France partakes largely of the Celtic blood, notwithstanding various invasions of the Germanic tribes, from one of which, the Franks, came the modern name of the country. From the Celts, the French people derive their proverbial vivacity of temper, their quickness of perception, their dashing bravery, and, most probably, their undeniable inconstancy and flightiness of disposition. Britain, again, has retained comparatively slight traces of her early Celtic inhabitants. A branch of the Germans had visited the island even before the invasion of the Romans; and after the latter came Dane, and Saxon, and Norman, in such numbers, that the pure aboriginal stock were left but in the Highlands of Scotland, and partly in Wales. The Scottish Lowlands had early been colonized by the Picts, a people, there is every reason to think, of Germanic origin; and subsequent intermixtures with the southern inhabitants of the island speedily gave the population still more of the Germanic character. In this manner was formed the root of the existing British nation, one of the most remarkable on the face of the earth. Inferior to no one of the Caucasian families in intellectual endowments, and possessed of indomitable courage and unbounded enterprise, it has scattered its colonies over a large portion of the globe, giving to new regions its language, its genius, and its arts. Above all, it has given origin to the great Anglo-American nation—a nation, if inferior at all, inferior only to the parent stock, in those attributes that ennoble the race. Much of the excellence that belongs to the British character certainly arose from the preponderating infusion of Germanic blood, resulting from the incursions of the Norsemen upon the aboriginal Celts. But the sprinkling left of Celtic blood seems to have had its use also, in giving a share of vivacity to the comparatively heavy, massive temperament of the pure Germans. We may judge so from looking at the character of the unmixed Germanic families. The Dutch, for example, would evidently have been an improved race had their specific gravity of character been l[illegible]ned by a little infusion of Celtic mercurialism. The Belgians have a pretty equal share of Celtic and Germanic blood in their veins; and consequently, while they display the industrial virtues of the latter race, they also show no slight admixture of Celtic flightiness.

There may appear some fancifulness in this mode of analysis, but we believe that an accurate examination of the proportions in which the Germanic and Celtic blood are mingled in all the countries of Europe, would fully bear out the views now taken. In Italy, Spain, and Portugal, infusions of Germanic blood took place, but to a comparatively slight extent. The aboriginal Celts of Spain were extensively mingled with Roman immigrants; and it may be said that, at this day, Romanized Celts, with a sprinkling of Gothic (Germanic) and Saracenic blood in their veins, form the existing population. In them, the faults of the Roman character, as well as its haughty virtues, are even yet distinctly traceable. Romanized Celts constitute the basis also of the Portuguese and Italian nation, and the preceding remark applies to their character as much as to that of the Spaniards. The languages of the three countries bear out these observations.

The subject of the Germanic and Celtic branches of the Caucasian variety of mankind, as well as of the Caucasians proper, has been treated of at some length, because these tribes have been the great civilizers of the world. The *Egyptian* or *Nilotic* branch forms almost the only exception to this statement. Most of the existing nations of Europe can distinctly trace their origin to these Caucasian tribes. Dr. Pritchard traces a chain of connection between the roots of the Sanscrit, Greek, Latin, and German languages, which leads him to imagine them to have all sprung from a common original. A remarkable similarity has been traced between the Celtic and Phœnician languages. These and other circumstances, to a certain extent, point to a common origin and place of origin; but the affiliation of nations, as Humboldt justly observes, cannot be distinctly made out in this way. Conquest and colonizations must confuse all such attempts.

After treating of the three great influxes of population which founded the past and existing nations of the European continent, the *Arabian* and *Libyan* branches of the Caucasian family fall to be noticed. Spare but active persons, skins of a light brown, sallowed sometimes by unusual exposure, high foreheads, large dark eyes, oval features, with aquiline noses and small thin-lipped mouths, form the personal characteristics of the Arabs. They have occupied the confines of the present Arabia from time immemorial, and their natural habits have ever been pastoral and migratory. The Bedouin Arabs claim descent from Ishmael, and, however this may be, it is plain, from physical characteristics alone, that they are a cognate race with the Jews. The latter were originally derived from the Chaldeans, an elder branch of the Arab race settled in Babylonia, and they were a pastoral and wandering people like their congeners, until they settled in the cities of Palestine. A body of Canaanite Arabs, expelled by the Jews under Joshua, are understood to have settled in Africa, and become the nation of the Mauri or Moors. Governed by Mohammed and his successors, the Arab race rose to high consequence, and, under the name of Saracens, made great conquests of territory in Asia Minor, Africa, and in Spain. They were afterwards deprived of superiority in some of these countries, but left extensive tribes in the African continent and Asia Minor. The Berbers (or *Libyans*) are a race who seem of Arab descent, but who probably settled in Africa at a far distant date. They resemble the Arabs in person, but are more darkened in complexion. Under the name of Tuariks, they range both to the north and south of Mount Atlas. They are wilder in habits than the Arabs, but may be spoken of as the same race, and with the same capabilities. They form a large part of the existing population of the north of Africa, occupying, with the Arabs, nearly the whole of the Mediterranean shores of the continent, from the Straits of Gibraltar to Egypt; and, either under the name of Moors, of Arabs, of Tuariks, or of Felatahs, they are rapidly insinuating themselves within the tropics, obtaining everywhere that superiority over the Negro race, which the Caucasian family seldom fail to acquire wherever they plant the foot. It seems more than probable that the Arab race will ultimately push the Negroes from Africa; and indeed may annihilate them, as the European whites have done, or are doing, in the case of the Red Indians of America. In the latter instance, but a few centuries have been necessary to accomplish the change of population, and large as the African continent is, many centuries may not pass away ere it rest entirely in the hands of the Caucasian race.* The Negroes have indeed lost more than half of

* The Arabs are likely to be dislodged in turn by a more cultivated people. While they are pushing themselves into power amid the negroes of the interior, a Caucasian race, of higher civilization, has set its foot on the Mediterranean shores of Africa, and begun to push them out of their previous conquests. We refer to the occupation of the Algerine coast by the French. Strange how ceaselessly the round of substitutions seems to go on! From the immense extent to which they are spreading, one would say that the Caucasians seem destined to fill the earth. Certain it is, that they appear to have peculiar capabilities for successful colonization.

it already, for there can be little doubt that they once stretched to the Mediterranean. Benevolence at first shrinks from the idea of a consummation like this; but reflection soon reconciles us to it. The supplanting of one race by another does not imply the extensive destruction of individuals which it at first appears to do. It only, in the main, denotes a stronger principle of population in the one race than the other. The development of numbers in the one is repressed, in the other encouraged, till at length the first may be said to die out, leaving the intruding race in possession of the soil. Generally, where such changes take place, the soil becomes the means of supporting far greater numbers than formerly.

The Wahabees in modern times, and in past days the Phœnicians and Idumeans, whose respective capitals were Tyre and Petra, are further specimens of Arab tribes. The last two tribes sprung, it is probable, from the primitive Chaldean branch, settled at Babel or Babylon. Whatever be its ultimate destiny, we may anticipate that the Arab race will yet play a greater part on the scene of earthly affairs than it has hitherto done. The capacity of the race is high, and under favourable circumstances, as when settled in the cities of Spain, their native talents for poetry, music, and the fine arts, developed themselves in no ordinary degree. Planted in cities on the fertile banks of the Niger, of which they are rapidly assuming the mastery, they might in time renew there all the splendours of the Caliphate.

The *Nilotic* (Coptic or Egyptian) branch of the Caucasian family, is chiefly remarkable on account of its high distinction in past times, when the tribe founded the civilization of the world. The Nilotic branch consisted of the Egyptians, Nubians, and Abyssinians; and, though these nations have long been commingled with the Arabs, producing the mixed race of Fellahs, yet the pure Nilotic characteristics can still be traced among them. Slender persons, long limbs, and delicate feet, narrow oblong foreheads, eyes elongated in a peculiar manner, long noses, with swarthy brown complexions, seem to have been the main personal features of the old Egyptians. The pure Copts now-a-days exhibit various shades of colour, from a pale olive to a deep brown. The flat features and bushy hair of the Sphinx led the traveller Volney to form the hypothesis that the old Egyptians were Negroes; but his desire to arrive at a liberal conclusion carried him too far. The numberless paintings since discovered, in many of which negroes appear as captives, exhibiting features perfectly distinct from those of their Egyptian captors, prove incontestably that the Nilotic race were of the Caucasian variety of mankind. Even at this day, the Nubians, certainly the purest descendants, as a nation, of the old Egyptians, have in no case the woolly hair, flat features, or long heels of the Negro race, though sometimes nearly jet black in complexion. They have the Caucasian heads and forms most undeniably. At what time the banks of the Nile from the Abyssinian mountains to the seven-streamed Delta, were peopled by the Nilotic race, it would be vain to conjecture. It is only in the case of countries far more distant from the cradle of the race, that we can form any rational conclusions upon the date of immigration. It is scarcely necessary to add, that history proves the Coptic race to have possessed the highest intellectual capabilities.

The *Hindostanic* branch of the Caucasians presents an extraordinary variety of complexions, from a deepish black to a beautiful brunette. Shades of olive, however, are the predominant hues. Small, elongated, and narrow heads, oval faces, noses slightly aquiline, bright black eyes, and dark glossy hair, with very short slender persons, mark the pure Hindoo race. Passing by the claims which they themselves prefer to immense antiquity, there can be no doubt that they have been longer settled as a nation than almost any on the earth. They early attained to distinction in the sciences, and particularly in mathematics, poetry, and the drama. What was the precise place of their origin has been long a matter of dispute. From the great reverence borne by them for the north, and from the unquestionable intercourse existing between them and the Egyptians in the very earliest times, as well as from the numerous points of similarity between the two nations in many important respects, a common and intermediate spot might be regarded as likely to have produced both. But conjecture on this point would be fruitless.

We have now gone over the various prominent branches of the great Caucasian family. To them we owe nearly all that dignifies the name, and enhances the happiness of the human being. All that we possess of written literature—from the poetic, historical, and philosophic treasures of Greece and Rome, and the romantic creations of Arabian fancy, to the productions of the modern press—has emanated from the Caucasian variety of mankind. The Pelasgian branch in ancient times, and the Teutonic or Germanic in modern ages, have been most distinguished for their institutions, and the various productions of the higher intellectual powers.

The Germans, in an early age of their history, were the first who raised WOMAN from the condition of a slave to that of an equal with man, and made her a partner in his powers and rights. The importance of this change is best shown by the fact, that, to woman's condition among them at this hour, the Mongols and other varieties of men certainly owe much of their inferiority. Free political institutions, elective senates, and jury trials, came from the Germanic race. They were the discoverers of printing, of the compass, of the steam-engine, of gunpowder (a great invention, however abused), and of accurate time-measurers. To these discoveries numerous others might be added; but when we think how much the happiness of man now depends even on these few, we feel it unnecessary to extend the list. The Caucasians proper, and the Celtic family, have shown surprising genius in many departments of intellectual exertion, but, in all the industrial arts that bear practically on human comfort, they must yield the palm of merit to the Germanic family.

Mongolian Race.

2. The MONGOLIAN variety, as regards numbers, is a family of vast importance; the tribes of the Mongol-Tartars, the Turks, the Chinese, the Indo-Chinese, and the Polar races, being included in it. These tribes cover an immense portion of Asia, from the line of the Ural and Himmaleh mountains to Behring's Straits; and they are spread over more than one-half of North America, towards the Arctic Circle. They also occupy Greenland and a portion of the north of Europe, comprising the Finland and Lapland coasts.

The physical characters of the Mongolian race vary considerably, but the following general description will be found to apply extensively. The skin is commonly of a sallow or olive tint, and in some cases nearly yellow; the hair is black, long, and straight, seldom curling; the beard usually scanty; the iris black; the nose is broad and short, and the cheek-bones broad and flat, with salient zygomatic arches; the skull is oblong, but flattened at the sides, so as to give an appearance of squareness; and the forehead is low. In intellectual character, the Mongolians are by no means defective, but they are more distinguished for imitative than inventive genius. This faculty at the same time renders them highly susceptible of cultivation. In many cases, however, tribes of this variety have arrived at considerable proficiency in literature and the arts. Their moral character is decidedly low. China, Japan, Thibet, Boutan, and Indo-China, may be mentioned as locations where the best-marked specimens of the Mongolian variety are to be observed. The Turkish and Mongol-Tartar tribes have been great conquerors in past times, and have often even vanquished the Caucasians; but, in most cases, they have afterwards been repelled from their acquisitions by the Caucasians, succumbing to the apparent law of nature which gives these the ultimate superiority in all struggles with the other varieties of men. The Fins and Laplanders appear to be a remnant of some primitive Mongolian people, whom the Caucasians originally pushed to the extreme verge of the Arctic seas, and were content to leave there. The Esquimaux, as well as the people of Finland and Lapland, have some physical peculiarities distinguishing them from other Mongolians, but these seem to be the effect chiefly of local position, which undoubtedly exercises a *degree* of influence on the human frame.

Ethiopic, or Black Race.

3. The Ethiopic or Black variety of mankind are characterized by complexions of jetty hue, black woolly hair, eyes large and prominent, nose broad and flat, thick lips, and wide mouth; the head is long and narrow, the forehead low, the cheek-bones prominent, the jaws projecting, and the chin small. A long protruded heel, also, and a flat shin-bone, often distinguish this variety. The principal Ethiopic families are the Negroes of central Africa, the Caffres, the Hottentots, the natives of Australia, and some of the Islanders of the Indian Archipelago and the Pacific Ocean. The lands over which this variety is spread (numbers being left out of the question), are proportionally of somewhat smaller extent than those occupied by any of the other varieties of mankind, with the exception of the Malays. The Mongolians, to be more explicit, occupy the largest share of the globe; the Caucasians (their various colonial settlements being included) stand second in this respect; the Americans occupy a portion slightly less than that of the Caucasians; the Ethiopic variety stand next in the list; and the Malays are lowest of all in the scale. The following figures will further show the proportions of these territorial holdings in a rough manner:—Mongolians, 4; Caucasians, 3; the Americans, 2½; the Ethiopians, 2; and the Malays, 0-1-20th. The chief locations of the Ethiopic race are—Africa south of the desert of Sahara; New Holland; New Guinea; New Georgia; and a few other Polynesian islands. Most island Negroes are of a dingy brown hue. In disposition, this variety of mankind are easy, indolent, and cheerful; in intellect, the race varies much, though certainly the majority of its tribes stand low in this respect. This may be in part ascribed to want of cultivation, and opportunities for cultivation; but even while adopting this lenient view of the matter, it is impossible to shut our eyes to the fact, that the race have shown no inventive genius. They would otherwise have long ago originated the arts of civilization for themselves, as other varieties of men certainly did. At the same time, many of the Negro race have shown no mean degree of talent, and some of them have exhibited such address in the arts of politics and war, as indicated the capability of attaining to a high state of intellectual advancement, had their powers been properly fostered and directed.

American Race.

4. The American variety of mankind occupy well-defined territorial limits. They were originally spread over nearly the whole of the Americas, south of the sixtieth degree of north latitude, though their numbers are now thinned, and their territorial possessions curtailed, by the colonial incursions of the Caucasians. A reddish brown complexion, long black lank hair, deficient beard, eyes black and deep set, receding brow (sometimes from artificial compression), high cheek-bones, prominent aquiline nose, small skull, with the apex high and the back part flat, large mouth and tumid lips, with fine symmetrical frames of middle height, form the chief physical characteristics of this race. "In their mental character," says Professor Morton, by whom they have been thoroughly studied, "the Americans are averse to cultivation, and slow in acquiring knowledge; restless, revengeful, fond of war, and wholly destitute of maritime adventure." The same writer divides the Americans into two great classes, one of which (Toltecans) embraces certain semi-civilized nations, as the Mexicans, Peruvians, and Bogotese, while the other includes all the hunting tribes of North America, the Brazilians, the Patagonians, the Fuegians, and other minor tribes, none of whom have exhibited the same capacities for cultivation as the first-mentioned nations. The Americans differ much in colour of skin and stature. Some of them are not brown, but of a perfect copper tint. The Patagonians are of almost gigantic size, while the Fuegians are very short in stature. Yet there are characters common to all, which have led accurate inquirers to set them down as being throughout one and the same people. Their languages have certain peculiarities found to be of universal occurrence among them, from Cape Horn to the far north. By those who, like Cuvier, have not viewed the Americans as an indigenous race, the mode in which the New World was peopled has been curiously inquired into, and it has been conjectured that they either came by Behring's Straits from Asia, or that some small party, in ages long past, was wafted accidentally across the seas to these vast shores. Such an occurrence as the latter has been proved to be not impossible, to say the least of it. But assuredly the weight of evidence is in favour of the opinion that the Americans are, not a casual offshoot from some other human family, but a people so far indigenous, at least, and primitive, as to be derived from a common root, endowed with specific and unique physical characters. The manner in which they were planted in their destined

home, and received these peculiar characters fitting them for its inhabitation, must remain, according to this view of things, among the mysteries which the Creator has seen fit to leave in darkness. It is undeniable, it may be observed in conclusion, that the American race is tending to extinction

Malay Race.

5. The MALAY variety of mankind are characterized by tawny or dark brown skins, coarse black hair, large mouth, short broad noses, seeming as if broken at the root, flat expanded faces, with projecting upper jaws, and salient teeth. The skull in this race is high, and square or rounded, and the forehead low and broad. The moral character of the Malays, generally speaking, is of an inferior order. They are a race differing much, in some respects, from the Negro and Red Indian, being of peculiarly active temperaments, and fond of maritime enterprise. They exhibit considerable intellectual capacity, and are an ingenious people. Borneo, Java, Sumatra, the Phillipine Islands, New Zealand, part of Madagascar, and various Polynesian islands, are inhabited by this variety of men. It is extremely probable, from the fact of their being found in islands surrounded by others in the hands of the Ethiopic race, that the Malays have pushed out the less active variety from these isles, and, in short, annihilated them. It is but too likely, moreover, that the Malays will in turn suffer extinction at the hands of a superior variety, or a variety rendered superior by civilization, if not naturally so. Safely, indeed, may one prophesy that, in New Zealand, ere many years pass away, the natives will have disappeared before the European colonists. Not many months ago, the last native thus disappeared from Van Diemen's Land. So will it be ere long with New Holland, large as that continent is. Amalgamation of races is in these cases next to impossible, and no other preventive, as already stated, could be found.

DISTRIBUTION OF THE RACES—CHANGES AND AMALGAMATIONS.

This point, really one of the most curious and important connected with man's physical history, may be illustrated by further references to the changes in geographical position, undergone by the five great varieties of mankind now described, from the earliest periods. Very few portions of the earth have retained the inhabitants by whom they are known to have been first peopled. With respect to Europe, it seems extremely probable, as Dr. Prichard and others admit, that the Celtic and Germanic races were not the earliest settlers upon this territory. They pushed out, from some parts at least, a previous race, of which the Fins and Laplanders may perhaps be held to give us some idea. The Celtic population of the south of Europe were in a great measure overwhelmed by the Germanic tide from the north, and, though centuries of confusion followed the collision, the good ultimately effected by the intermixture was immense. It appeared, indeed, as if a savage people there crushed a civilized one, but the result, in reality, consisted in the infusion of healthy blood into a vitiated frame. At this day there is but one important part of Europe in the hands of the pure Mongolian race, namely, Turkey. But can we doubt that at this very hour the once formidable power of the Ottomans is verging to extinction! The Caucasian states around it have gradually seized province after province, and jealousy of each other alone prevents them from at this moment annihilating the petty remnant of the Mongols left in Europe. The power of the empire is not only going to decay, but, as M. Lamartine has lately shown, the Turks are in reality becoming extinct as a people. They are sinking beneath the pressure of the superior or superiorly cultivated nations around them.

In Africa, as has been said, the Negroes have already been stripped of one-half of their continent by the Caucasian Arabs, and are likely to be ultimately extinguished by them. If the climate of the same great country had been more favourable to the pure Caucasian whites than it is, they would assuredly have taken a larger share in the occupation of it than they have done. As the case stands their aggressions have been considerable. Not to speak of their coast stations, they have colonized the southern extremity of Africa, and the Caffres and Hottentots are falling before them, or are receding to the interior, to be finally crushed between the opposing forces of the Arabs and Europeans. The Arabs themselves are beginning to feel the retributive pressure of the French on the Mediterranean coast. In Egypt, again, we may trace striking proofs of the same grand movement. Altogether, what with the Arabs and the whites of Europe, Africa may be expected, ere many ages pass, to be in the hands of the Caucasians.

In Asia, the conquering Mongols long held extensive rule, but the semi-Caucasian power of Russia in the north, and the British in the south, have torn from them immense territories, and every few years behold additional losses on their part. Even at this time the great Mongol power of China, which, by a policy cautious to an extraordinary degree, maintained for ages its independence, has forgot itself so far as to provoke a struggle not likely to terminate until China becomes little else than a Caucasian colony. The Australian continent, and the Polynesian islands, are also on the direct way to the same consummation.

The truth of the view now taken is more remarkably borne out by the history of the Transatlantic Continent, than by that of any other country. Rapidly, indeed, have the red men of North America fallen before the march of Caucasian colonization. The numerous islands of the Mexican Gulf have been so completely cleared of all traces of native population, that it has become a matter of doubt whether, on several of these islands, any native population ever existed. South America has been largely subjected to the same influences, and would have suffered more from them, had the Caucasians who went thither been a branch specially adapted for the business of colonists, and had not a considerable admixture of races peculiarized that colonization. As it is, the natives have been thinned, though the amalgamation alluded to, arising from the *comparative* similarity between the races, renders the truth difficult of discovery. In short, if we look at the whole course of the past history of mankind, we shall find the Caucasian race everywhere gaining the ascendancy, and slowly but surely renovating the population of the world.

In those instances where an amalgamation of varieties of men has taken place to a considerable extent (and there are a few prominent cases of the kind to be observed at present on the face of the globe), a population of a most extraordinary and heterogeneous kind has been the result. In parts of South America and Mexico, not only Europeans and native Americans, but also Negroes and Malays, transported thither chiefly as slaves, have contributed to form the existing population. Europeans and Negroes produce a race called Mulattoes; the children of Europeans and native Indians are termed Mesti zoes; and those of Negroes and Indians are styled Zambos. Of course, the sub-varieties are numerous—indeed, almost numberless. The European and the Mulatto produce Tercerons; the children of the Terceron and the European are called Quarterons or Quadroons; and those of Quadroons and Europeans are Quinterons. In the Quadroon, little or no vestige of dark blood is visible; but in most countries where these admixtures take place, the rights of pure white blood are only assigned to the Quinteron. Mexico, and the greater part of the states of the South American continent, including Peru, Chili, and Brazil, with the colonies and islands of the West Indies, are the chief scenes of these amalgamations of blood. Undoubtedly their immediate consequences are pernicious. The white blood is everywhere haughtily disposed towards the dark, and all the jealousies and oppressions of *caste* are accordingly displayed to a dreadful extent. Whether, out of the numerous varieties and sub-varieties of species there at present to be beheld, *one* perfect and homogeneous race shall ever be formed, is rendered doubtful by the undiminished, if not increased, eagerness with which the purity of the white blood continues to be maintained. If we could suppose that the amalgamations of different varieties of mankind were never to produce happier consequences than in these instances, we might question whether such admixtures be desirable. The experiments of amalgamation and non-amalgamation may be said to have been tried, on great scales, in the two American continents, and it is of importance to notice the issue in the respective cases. In North America, we must ere long find the aborigines extinct; and in the place of hordes of savages, stationarily pursuing the wild and warring life led by their fathers from time immemorial, will be found a great and improving race, cultivating the arts of peace, carrying human civilization to the highest pitch, and extracting from their vast continent all the blessings with which the Creator has so liberally endowed it, and which he certainly meant not to lie unused.

The general characters of the great varieties or families of men, the mode of their distribution over the earth, and the causes which have affected, and are likely hereafter to affect, their future fate, have now occupied our attention; and our next duty is to advert to the most remarkable features of difference in the various branches of the human family.

VARIETIES OF SKIN IN MANKIND.

It has been already seen, that the Caucasians are generally distinguished by a white or fair skin, while the Mongolians are yellow, the Ethiopians black, and the Americans red or copper-coloured.

In former times, when only two varieties, the white and black, were recognised or thought of, it was supposed that complexion was simply a result of the action of the sun's rays. This idea would naturally arise from its being observed that exposure to the sun darkened a white person, while seclusion tended to bleach or whiten him; and that the black nations were those which chiefly occupied tropical countries, while the whites were placed in the temperate zone. The Greeks, who never doubted that they were the perfection and standard of human nature, and who entertained exaggerated notions of the heat of the African sun, were strongly impressed with the idea that the Negro nations had been originally white, and had been changed into black purely by the action of the solar rays. This notion continued to be set forward undoubtingly by naturalists down to the time of Buffon, and it is still the belief of the ignorant in most countries.

The views of naturalists on this subject have recently been considerably affected by the investigations of M. Flourens concerning the actual structure of the coloured skin.* The white, as is well known, has a skin composed of three integuments. First, is the outer or *scarf skin*, a thin transparent pellicle, seemingly secreted by the parts below, and devoid of recognisable vessels or nerves. Next below is the *rete mucosum*, a soft, pulpy net-work. Next, or undermost, is the *cutis* or true skin, a strong layer, abundantly vascular, and very sensible. It was formerly supposed that the colouring matter of the dark races lay in the *rete mucosum*, and that the only difference between the two races, in that respect, lay in the one having a mucous integument charged with globules of colouring matter, and the other a mucous integument in which there were no such globules. If the investigations of Flourens be correct, the difference is considerably greater. He states that, in a sufficient variety of experiments upon the skins of Negroes and red Americans, he has found, beneath the *rete mucosum*, two distinct additional layers, capable of being detached, and the outer of which is the true seat of the colour of those races. M. Flourens considers this as a difference much more important than any depending on form. Being a structural difference, he thinks it should be held as one of the first class, while differences of shape ought only to be considered as secondary. Without following him in these speculations, we may readily allow the importance of a peculiarity which consists in a distinct and additional *part*. M. Flourens, it may be remarked, has found the two layers also in Mulattoes. He had not had an opportunity of experimenting upon Mongolians or Malayans; but he infers, from the other cases, that in them also the extra integuments would be found.

M. Flourens adds, that, in the case of Europeans tinged by exposure to the sun's rays, the mucous web is what is affected, becoming, as it were, slightly dyed. No degree of exposure can, he thinks, confer the colouring layers of the Negro and other dark races. He remarks, that the African Moors, who have lived beside the Negroes for centuries, have never acquired the colouring apparatus of that race; and it has been observed by travellers (Captain Lyon among others) that the Tuariks, a race of African Caucasians, of a dark-brown complexion, are nearly as white on those parts of their bodies covered up from the sun, as most Europeans. It is also well known that the progeny of an European, however much he may have been tinged by the sun, is invariably as white as he himself was at first.

The black races are localized in the warmest regions of the globe, and their skin and general constitution seem to be fitted for their allotment. A black man can lie naked, exposed to the hottest sun, without injury, while the skin of the white man, if exposed to similar heat, breaks out in blisters. The black man can labour under a burning sun with impunity; but the white man sinks under exertion made in such circumstances, and this is well known to be the cause why slaves were introduced from Africa into the settlements of Europeans in tropical America. Sir Everard Home, who made some laborious investigations into this subject, was puzzled by the obvious physical fact that the black skin must absorb more heat than the white. But it has since been suggested by Dr John Davy that the black perspires most readily. "In the Negro," he says, "the blood flows more readily through the vessels, so as to promote perspiration, and by that means contributing to the cooling of the surface, it contributes again, when it flows back to the heart, to the cooling of the internal parts." After quoting this remark, Dr. Glover of Newcastle says—"Were the inhabitant of the tropic not possessed of this organization, his system could not respond to the stimulus of heat, by a determination of fluid to the surface of the body; and the heat absorbed by the skin being prevented from entering the system by the perspiratory process, the greater *radiating* power of a dark skin must be beneficial in cooling. Again, the dark skin places the Negro in the conditions of his climate, by causing him to radiate heat at night, and he

* On the Natural History of Man. By M. Flourens. Edinburgh New Philosophical Journal, July, 1839.

some at that time cooler than a white under the same circumstances." Hence the love of the Negroes for night dancing and exercise.

M. Flourens deems the difference of structure between the white and coloured races as sufficient to prove that they are of different stocks, and he accordingly speaks of them as "essentially distinct races." But there are some considerations which greatly confound all such conclusions, as drawn from differences of colour alone. Colours, it is to be observed, are not invariable characteristics of particular races. Most Caucasians, it is true, are white; but then there are also black Caucasians. The Hindoos are undoubted Caucasians, being proved to be so by many characters of form. Yet the Bengalese and Malabars, varieties of the Hindoos, are often as black as the generality of Negroes. Caucasians of similar colour are spread through Persia and Western Asia, into Northern Africa. It has indeed been said that the Hindoo branch of the Caucasians alone includes every variety of colour, from the deepest black to something very nearly white. There are similar variations in at least one of the other four races. "Although the Americans," says Dr. Morton, "possess a pervading and characteristic complexion [which he describes as more brown or cinnamon-coloured than red], there are occasional and very remarkable deviations, including all the tints from *a decided white to an unequivocally black skin*." The white tribes have been found chiefly in the high regions in the northern part of South America. With such facts before us, we cannot admit that the colouring apparatus of M. Flourens decides that the races are distinct.

DIFFERENCES IN HAIR AND EYES.

Dr. Prichard has endeavoured to class mankind, with a regard to the colour of their hair, into three varieties, the *Melanic*, the *Xanthous*, and the *Albino*. The Melanic, or black class, comprises all individuals or races who have black hair; the Xanthous includes all who have brown, auburn, or red hair; and the Albino all who are distinguished by white hair and red eyes. With all due deference for the able writer who proposed this arrangement, it seems one from which no distinct or useful conclusions are deducible. The hair, however, is certainly a strong individual characteristic in man. Its colouring principle is evidently the same, speaking comprehensively, with that of the skin. The hairs issue from bulbs or roots beneath the true skin, where vessels supply them with nourishment. An external horny covering, and an internal pith, constitute the body of each hair, and the pith is to some extent vascular, because liable to disease. It is, doubtless, in this vascular pith that the colouring principle lies. The fact of the pith being supplied both with vessels and nerves, is further proved by the effect which great grief can produce upon the colour of the hair. Dr. Prichard had personally observed one case in which the hair grew white in a single night through grief, and many similar cases are on record. One distinguished French anatomist went so far as to assert, that in the bulbs of the hair lay the whole colouring matter of the skin; but, admitting that minute hairs exist on the general frame, we could not thus explain the black hue of the inside of the Negro's lip, which is quite free from hair. However, when we consider that the woolly hair seems to be inseparable from the jetty skin of the Negro, and the lank straight hair from the red skin of the Indian, we must believe in the existence of some strong bond between these physical characteristics.

In like manner do we trace a general correspondence between the colour of the eye and the skin and hair. The hue of the eye depends on a pigment or dye, lining the choroid coat or membrane. According to the tint of this pigment, is the eye blue, gray, brown, hazel, or black. Generally speaking, light-coloured eyes are conjoined with fair complexion and light hair, and the converse holds as commonly good. To this rule, it is well known, there are exceptions; yet Mongols, Ethiopians, Malays, and Americans, in ninety-nine cases in the hundred, show the extent of its applicability. The Caucasians display, in this respect, greater variations.

The Albinoes are scarcely to be called a variety of mankind, being a race whose peculiarities depend on *defects*. Red eyes and white hair are their chief features, though these features vary a little according to the race to which the individual belongs; and there are Albinoes to be found in almost all countries. The redness of the eye depends on the absence of pigment on the choroid coat, permitting the red blood-vessels to be seen. From a deficiency in the power of absorbing the rays of light, which purpose is served by the pigment, the eyes of Albinoes are weak. The Albinoes of the black race are called white negroes, from the colour of their skin, and they have white woolly hair. Among the copper-coloured natives of the Darien isthmus, Albinoes are common. Their bodies are of a milk-white tint, covered with a short down; and they have white hair, with red eyes. They love such light as the moon gives, and by night are all life and activity, while by day they are miserable, the rays of the sun making their weak eyes stream with water. It is needless to dwell on this subject, however, as the Albino peculiarities are, in the main, much the same everywhere. Europeans of this description are sometimes exhibited in public. The connection between skin, hair, and eyes, and the unity of the source of colour for all these parts, is very strikingly exemplified by the peculiarities of the Albino race.

SKULLS OF MANKIND.

Amongst the external distinctions of races, the form of the skull calls for particular attention. In describing these varieties, the shape of the skull of each was noticed in a general manner, and it would be observed that great differences existed with respect to this feature. From observation of an immense number of heads, Blumenbach arranged the skulls of men into three great divisions, the Caucasian, Mongolian, and Ethiopic, holding these to stand at extremes from one another. The skulls of the American and Malay seemed to him to stand intermediately between these. As, beyond all doubt (without carrying our belief to extremes, as some have perhaps done), we ought to consider the form of the skull as indicative of the intellectual powers, the distinctions in this organ necessarily become of great importance. The most perfect type of the Caucasian skull is found, as might be anticipated, in the modern Caucasian-proper, such as as the Georgians. "The head [of a female Georgian, described by Blumenbach] is of the most symmetrical shape, almost round; the forehead of moderate extent; the cheek-bones rather narrow, without any projection, but having a direction downwards, from the malar process of the frontal bone; the alveolar edge well rounded; the front teeth of each jaw placed perpendicularly."

The head of the perfect Mongolian type is, says Blumenbach, "almost square; the cheek-bones projecting outwards; the nose flat; the nasal bones, and the space between the eyebrows, nearly on the same horizontal plane with the cheek-bones; the superciliary arches scarcely to be perceived; the nostrils narrow; the maxillary pit slightly marked; the alveolar edge in some degree rounded forwards; the chin slightly prominent."

In the Ethiopic variety of men, "the head is narrow, and compressed at the sides; the forehead very convex, vaulted; the cheek-bones projecting *forwards*; the nostrils wide; the maxillary pits deeply marked at points the jaws lengthened; the alveolar edge narrow, long and elliptical; the front teeth of the upper jaw turned obliquely forwards; the lower jaw strong and large."

In the American skull there is an approach in shape to that of the Mongol, with this difference, that the top is more rounded, and the sides less angular. The summit of the Malay head is narrow, the forehead a little arched, and the upper jaw pushed somewhat forward. It would be superfluous to enumerate here the particular tribes marked by these varieties of skulls, as this has been done with sufficient distinctness in the general classification of the races. Of course, among Caucasians, Mongols, and Negroes, there are considerable individual differences in the form of the head, but the preceding descriptions give the type of each division.

No mode of examination exhibits so strikingly the differences in shape between the skulls of different races, as that called by Blumenbach the *vertical* method, in which the various skulls are placed in a row, resting upon the lower jaws, and are then viewed from above and behind. Examined from above, the facial bones of the Caucasian skull are scarcely visible, both from their comparative smallness of size, and because they are hidden by the rounded and well developed forehead. A perpendicular line, falling from the middle of the brow, would barely touch the front of the upper jaw. The Negro head, in the same position, presents a strong contrast to the preceding one. The narrow slanting forehead here permits the *whole face* to come into view, the cheeks and jaws being somewhat compressed laterally, and greatly elongated in front. In the case of the Mongol, again, we find a contrast not less remarkable. The bones of the nose, cheeks, and jaws, are almost equally visible as in the negro, but are expanded on each side, not pushed angularly forward. The squareness of the Mongol head arises in a great degree from this lateral expansion of the facial bones. Dr. Prichard gives to these varieties of the skull the respective names of *mesobregmate*, *stenobregmate*, and *platybregmate*—words expressive of the characters which have here been assigned to them.

This remarkable contrast in the prominency of the facial bones, conjoined, as it commonly is, with an equally striking difference in the anterior development of the skull, has been deemed by some physiologists a feature of the highest importance. Camper founded on these physical characters a scheme for estimating the degrees of intellect and sagacity bestowed by nature on the whole members of the animal kingdom possessing a skull and brain. The *facial angle*, as he termed the degree of prominency in the facial bones, was measured by him in the following way. One straight line was drawn from the ear to the base of the nose, and another from the prominent centre of the forehead to the most advancing part of the upper jaw-bone, the head being viewed in profile. "In the angle produced by these two lines," says the physiologist, "may be said to consist, not only the distinction between the skulls of the several species of animals, but also those which are found to exist between different nations; and it might be concluded that nature has availed herself, at the same time, of this angle, to mark out the diversities of the animal kingdom, and to establish a sort of scale from the inferior tribes up to the most beautiful forms which are found in the human species. Thus it will be found that the heads of birds display the smallest angle, and that it always becomes of greater extent in proportion as the animal approaches most nearly to the human figure. Thus there is one species of the ape tribe, in which the head has a facial angle of forty-two degrees; in another animal of the same family, which is one of those *simiæ* approaching most closely to the human figure, the facial angle contains exactly fifty degrees. Next to this is the head of the African Negro, which, as well as that of the Kalmuc, forms an angle of seventy degrees, while the angle discovered in the heads of Europeans contains eighty degrees. On this difference of ten degrees in the facial angle the superior beauty of the European depends; while that high character of sublime beauty, which is so striking in some works of ancient statuary, as in the head of the Apollo, and in the Medusa of Tisocles, is given by an angle which amounts to *one hundred* degrees."

Dr. Prichard, in quoting this passage, remarks, that "the faculties of each race of animals seem to be perfect in relation to the sphere of existence for which they are destined;" and hence, in as far as the measurement of the facial angle is applied to the determination of the comparative intellectual characters of different tribes of the lower animals, he holds Camper's scheme to be imperfect and ineffective. As a method of distinguishing varieties in the shape of the actual cerebral case, moreover, the measurement of the facial angle is not always a safe guard. "I have now before me," says Blumenbach, "the skulls of a Lithuanian Pole and a Negro, in which the facial angles are nearly equal, but the difference between the shape of the two crania is otherwise prodigious." Nevertheless, as a general test of the mental capacity of individuals, "I think," says Prichard, "we must allow that experience is in favour of the position assumed by Camper. It is certain that every man is struck with the expression of dignity or elevation of mind and character in the ancient busts, which have a great facial angle, and that this expression would be lost if the facial angle were contracted. The fact seems, indeed, to be a general one, that men of great intellect have fully developed brains, as indicated by elevated and capacious foreheads." Since the time of Camper, it is scarcely necessary to tell the reader, the subject of craniology has been amply investigated by Dr. Gall and his followers, who have founded upon their inquiries a system of mental philosophy in a great measure new to the world, and of which the fundamental principle is, that the size and form of the skull, as depending on the size and form of the brain within, denote the intellectual and moral character.

Whatever may be thought of the phrenological doctrine in its details, it is at least scarcely possible to dissent from the moderate conclusion of Dr. Prichard, that "fully developed brains indicate great intellect." Hence, leaving out of the question the connection of the development of the skull with that of the facial bones, the simple *capacity* of the cerebral case becomes in itself a matter of the highest consequence. We happily have it in our power, from the experiments of a most accurate inquirer, Professor Morton, to determine the comparative capacity of the skulls of all the varieties of mankind. The following are Professor Morton's conclusions:—

Having obtained a considerable number of the skulls of the various races of men, Dr. Morton measured their internal capacity by means of white pepper seed, and found the following results:—

Races.	No. of skulls.	Mean internal capacity in cubic inches.	Largest in the series.	Smallest in the series
1. Caucasian,	52	87	109	75
2. Mongolian,	10	83	93	69
3. Malay,	18	81	89	64
4. Aboriginal American,	147	80	100	60
5. Ethiopian,	29	78	94	65

It thus appears that the aboriginal Americans rank fourth with respect to the size of their brains, the Ethiopians being lowest and the Caucasians highest.

This result is certainly the precise one to be expected, considering the capacity of the cranium as an index of intellectual power. The Caucasian race, which stands highest in the scale, is that which has produced the most civilized nations; while the Mongolian, the next in order of capacity of cranium, has produced a number of nations which remain at a fixed point in semi-civilization. The Malay is a degree more barbarous, and the American and Ethiopian the most barbarous of all.

Though thus compelled, both according to the views of Camper and those of other physiologists, to admit an inferiority of organization, accompanied by an inferiority of faculties, in certain races as they at present exist, there is yet an encouraging prospect to cheer us. Reasons exist for the belief, that cultivation, in the case of both races and individuals, is capable of modifying even the shape of the skull; and hence, whatever be the peculiarities attending this physical characteristic in any existing race, we are not left, in this view of things, to despair of the possibility of improvement. Without some such compensating prospect, it would be painful to admit that the protruded bones of the face, the proportionably small cerebrum, and the almost simious lowness of forehead in the Negro, indicated a natural inferiority in the race. Many writers will not, indeed, countenance this conclusion. "I have not met with an individual, out of a great number of intelligent West Indian planters and medical practitioners," says Dr. Prichard, "who has not given a most positive testimony as to the natural equality of the African Negro and the European." The same writer also points to instances in which Negroes became excellent scholars, and wrote elegant Latin verses. But, on the other hand, Mr. Lawrence, with many able physiologists, gives countenance to the supposition of a decided inferiority of cerebral organization in the Negro, attended with a corresponding inferiority of faculties. It is certainly one remarkable circumstance, that, in the majority, at least, of those cases in which Negroes exhibit striking talent, their heads are found to approach the Caucasian formation in respect of shape. Phillis Wheatley, for example, a coloured girl, who wrote very pretty verses at an early age, is represented, in the plate attached to her little book, as having not only a Caucasian brow and head, but these of the finest order.

The physical characteristic now under consideration varies considerably among the white nations of Europeans. The Turks, who, though originally a Mongol race, have had their primitive physical attributes modified by continual intermixtures with Greeks, Georgians, and Circassians, present a form of skull combining, apparently, the mingled characters of the two varieties. The square Mongolian head has been rounded off in their case, and we find it to be now almost a perfect globe. The Greek head approaches the same shape. It was long asserted that the globularity of the Turkish head resulted from artificial compression in infancy, but modern physiologists discredit this notion. "A single glance at the Turkish head," says Mr. Lawrence, "at the symmetrical and elegant formation of the whole fabric, the nice correspondence and adjustment of all parts, the perfect harmony between the cranium and face, in all the details of each, demonstrate most unequivocally that it is a natural formation, and a very fine work of nature, too." The writer now quoted proceeds also to remark, that, although no sufficiently extensive examinations have yet been made, the probability is, that between the European nations, such as the Germans, Swiss, Swedes, French, and others, distinct differences in the shape of the skull would certainly be found to exist on inquiry. Mr. George Lewis observed in travelling on the continent, that the French have the lower and anterior parts of the cranium large, while the upper and anterior region is more prominent in the Germans. The Italian head, though comparatively small for the most part, is marked by great elegance. The Jews have long been noted for the fine Caucasian shape of their heads.

It is worthy of remark, that, though the globularity of the Turkish skull is not to be deemed the result of art, there are certainly races of people who modify the shape of the head by compression in childhood, and the views of Camper, as well as of the phrenologists, must be applied with some reservation to the skulls of one great variety of mankind. Many, very many, of the tribes of North and South America are so partial to low and retreating foreheads, that they have long been in the habit of assisting nature in producing that form of head. The comparative softness of the osseous texture at birth, and the partially mobile state of the cranial sutures, enable them to effect this object. "The Caribbs," says Labat, in his account of a voyage to the isles of the Caribbean Sea, "are all well made and proportioned; their features are sufficiently agreeable, excepting their forehead, which appears rather extraordinary, being very flat, and as it were depressed. These people are not born so, but they force the head to assume that form, by placing on the forehead of the newly-born child a small plate, which they tie firmly behind. This remains until the bones have acquired their consistence; so that the forehead is flattened to that degree, that they can see almost perpendicularly above them without elevating the head." The consequence is, that the heads of these people, naturally somewhat depressed in front, become hideously so; and unnatural bulges behind show that the cerebral matter has been forced into new positions. The possibility of changing the form of the skull has been doubted by some physiologists, but the circumstance is authenticated beyond all question. In Morton's *Crania Americana* are delineated many specimens of skulls thus altered in form, some so greatly changed by a pressure which has been applied both before and behind, as to resemble half-moons. It is not necessarily to be inferred that injury results either to the mental constitution, or the general health, of those who submit to this process. Supposing the pressure to be slow and gentle, the ductile organs will easily accommodate themselves to it, and it is probable that the brain, as far as its size or volume is concerned, will remain unaffected. A skull in Dr. Leach's possession, bearing the marks of extraordinary compression, is known to have been that of a Caribb chief distinguished for intelligence and prudence.

TEETH OF MANKIND.

The general differences of features, accompanying these variations in the shape of the skull, were pointed out in going over the great divisions of the human race. The teeth of mankind differ very little in shape or position. "The oblique position," says Mr. Lawrence, "of the anterior incisors in the Negroes, and some other tribes who have prominent jaws, is the only *national* difference I know of in teeth. Their size and form exhibit merely individual differences." One of the most remarkable individual varieties in the teeth, it may be observed, consists in the phenomenon of a double set in the same mouth. This is of rather rare occurrence, but the writer is aware of one instance, in which both upper and under jaw are encircled by a double row of extraordinary beauty. In case of a colonial settlement being founded by such an individual, and the dental duplicity being perpetuated in numerous descendants, would we not be apt, seeing a peculiarity so striking, to entertain doubts of the descent of the parties from the ordinarily jawed race of men!

FIGURE—PROPORTIONS—WEIGHT AND STRENGTH

The differences which exist among the races of mankind, with respect to Figure, Proportions, and Strength, form a branch of the present subject not less interesting than any yet noticed. It has long been attempted, in the civilized regions of the world, to ascertain and fix a standard of physical perfection for the human body; and there certainly does seem to be a model, the closest approach to which combines the quality of pleasing the eye with the possession of the greatest degree of corporeal power and activity. Artists have usually looked to the model-figures of the Caucasians of Greece, or, in other words, to their ancient statues, as exemplifying the finest possible proportions of the human frame. But the taste of man varies so much, and habit modifies to such an extent his physical powers, that any standard of the kind alluded to must be open to numberless objections and exceptions. If judged of by the common artistical standard of the civilized world, certain races of men would be set down as out of proportion, and yet they possess physical powers of the most perfect kind. The Hottentot and the American savage will outrun wild animals, and hunt down the deer; the slim and "effeminate Hindoo," as we call him, will keep up with the horse for days; and the South Sea islander feels himself at home in the raging surf, which would whelm a boat or vessel. Yet these races depart widely, in many cases, from the Grecian model. Such facts show that physical power is at least not confined to men moulded after the Grecian artistical standard, though it may be that individuals so moulded would surpass in the exercises mentioned, with equal training, those otherwise fashioned.

STATURE.

Different races of men exhibit considerable diversities of stature, though there are no varieties of stature in different nations so remarkable as those which frequently occur in the same family. The tallest race of men, authentically known to exist, are the Patagonians, a tribe occupying the coast of South America, between the Rio de la Plata and the Straits of Magellan. The territory occupied by them is of immense extent, and they are probably migratory in habits; hence a considerable degree of discrepancy in the accounts given of them by different writers. Magellan's companions declared the Patagonians to be commonly about seven feet four inches in height, English measure. Commodore Byron saw and conversed with many companies of them, and states that few were under seven feet, while others were considerably above it. Nearly six feet high himself, he could barely touch the top of a chief's head, though standing on tip-toe. Captain Wallis, again, having probably examined a different tribe, says that the majority of the Patagonians seen by him averaged from five feet ten to six feet, and that he only saw one man so tall as six feet seven. By later and accurate measurements, made by the Spaniards, we learn positively, that there are at least Patagonian tribes, reaching the average height of from six and a half to seven feet. Were they even somewhat less, they would be decidedly the tallest *race* of men existing on the face of the earth. All voyagers admit them to be large and muscular in proportion to their height.

A people situated in the polar circles of the north, stand nearly at the other extreme of the scale as respects stature. The Esquimaux, or at least some tribes of them, are for the most part between four and five feet in height, and their congeners the Laps are also a dwarfish race. They are of the Mongolian variety of mankind. The Ethiopic variety also numbers some very small tribes, and in particular the Bosjesmans, a race said to be also very commonly deformed. Among the American nations, there are also dwarfish tribes, and in particular the natives of Terra del Fuego, near neighbours of the Patagonians.

These nations only present us with the extremes of the human race, as respects stature. The subject is worthy of much more minute investigation. It would be highly interesting, and indeed instructive, to know the comparative average stature of each of the ordinary varieties and sub-varieties of mankind. Unfortunately, the observations of naturalists respecting stature have not been carried far. Quetelet and others have attentively examined the relative heights of individuals of *single* nations, at different ages, with a view to determine the general phenomena of man's growth; but few observations have been made upon the respective heights of different races or nations. The stature of the Caucasian has not been fully compared with that of the Mongol, or the Negro, or the Red Indian; nor have single nations, belonging to any of these great varieties, been satisfactorily contrasted with one another, as respects height. No accurate comparisons, for example, have yet been made of German with Spaniard, of Briton with Frenchman, or, in fact, of any one European nation with another. The following table, exhibiting the comparative heights of a small number of Englishmen and Negroes, is given in the work of Mr. Lawrence, upon the Natural History of Man. The Negroes were from various regions.

	Stature. Feet.	In.		Stature. Feet.	In.
An Englishman,	6	4½	A Negro, -	5	10½
Ditto, - -	6	1	Ditto, - -	5	5½
Ditto, -	6	0	Ditto, -	5	8
Ditto, - -	5	9½	Ditto, - -	5	0
Ditto, -	5	7	Ditto, -	5	7½
Ditto, - -	5	4½			
Ditto, -	5	0			

The Caucasian here has considerably the advantage of the Negro, the average height of the former class being nearly 5 feet 9 inches, while the black averages little above 5 feet 6 inches; and the advantage would still be on the same side, were we to leave the first Englishman, certainly a man of uncommon height, entirely out of the reckoning. But it must be admitted, that from such an insignificant amount of examples, no satisfactory conclusions can be drawn. The accounts of recent travellers in Africa would lead one to imagine that the majority of the Negro nations, excepting in the case of a few particular tribes, such as the Bosjesmans, are not below the Europeans in average height. The Caucasians have indeed the advantage in one respect; no tribe or section of them sinks so low in the scale of altitude as some of the other races do.

The stature of the Chinese, who must be regarded as amongst the purest specimens of the Mongol variety, was accurately and extensively measured by Mr. Rollin, the surgeon who accompanied La Perouse. He found the ordinary height of the natives of the great Isle of Tchoka, on the east coast of China, to be *five French feet*.* The natives of the mainland, near the same region, measured 4 feet 10 inches (French). This examination places the pure Chinese below the average height of Europeans, and, we believe, correctly. Other Mongol races have not been accurately examined, with a view to the point under consideration. In that variety of mankind, however, as in the Ethiopic division, there are individual races which stand much lower in the scale of height than any Caucasian tribe. The Esquimaux and Fins prove this assertion.

The Americans also present great differences in height; so much so, that it would be vain to attempt to discover or strike an average for the whole variety—a variety which comprises the giant Patagonians and the dwarfs of Terra del Fuego. For determining the heights of individual tribes of Americans, we have at present no better authority than the loose reports of travellers. The same may be said of the Malays; and, such being the case, it would be a waste of time to attempt any comparative estimate, having reference to these races. One conclusion may be drawn

* The French foot slightly exceeds that of England, the proportions of the former to the latter being as 1·066 to 1·000.

from the little which we do know, and that is, that civilization equalizes the stature of mankind, and keeps it near a steady mean. All the less cultivated races present extremes not to be observed among the Caucasians.

Professor Forbes of Edinburgh (the able successor of Leslie, in the chair of Natural Philosophy) has recently made a series of experiments upon the physical differences between English, Scotch, Irish, and Belgians, the results of which constitute the most interesting information we are able to lay before the reader, with respect to the comparative heights of sub-varieties of the Caucasians. The following is a table drawn up by Professor Forbes, to exhibit the relative heights, at different ages, of the students attending his class, during a series of years, and belonging respectively to England, Scotland, and Ireland. The Belgian measurements were probably derived from other sources. The number of individuals subjected to examination was very considerable, so many as eighty Scotch and thirty English being occasionally measured at once.

*Heights—Full dimensions with shoes.**

Age.	English.	Scotch.	Irish.	Belgians.
	Inches.	Inches.	Inches.	Inches.
15	64·4	64·7	...	61·8
16	66·5	66·8	...	64·2
17	67·5	67·9	...	66·1
18	68·1	68·5	68·7	67·2
19	68·5	68·9	69·4	67·7
20	68·7	69·1	69·8	67·9
21	68·8	69·2	70·0	68·0
22	68·9	69·2	70·1	68·1
23	68·9	69·3	70·2	68·2
24	68·9	69·3	70·2	68·2
25	68·9	69·3	70·2	68·3

This table places the Irishman uppermost in the scale of stature, the Scotsman second, the Englishman next, and the Belgian lowest. The comparison seems to be fair as regards the parties taken, for, if there were any peculiarity in their condition as students, it must have been common to all. As a comparison of national heights, therefore, the table perhaps exhibits conclusions pretty generally applicable, and we shall find it borne out by similar comparisons of *weight* and *strength*. Professor Forbes's observations are confirmed, in one point at least, by the following passage in Quetelet's work upon Man:—"When in England, we chose the terms of comparison from rather higher classes of society [he has been speaking of English factory *children*]; we find the stature of man rather *higher* than in France or the Low Countries, at least for young persons between eighteen and twenty-three years of age." Quetelet then alludes to eighty different measurements of Cambridge students, taken in groups of ten each. The average height of every ten was 58 feet, or 5 feet 9 inches and 3-5ths to each man. This is above Professor Forbes's average; but, as the English universities are only attended by the aristocracy, who are undeniably a section of the people above the average national stature, it is probable that, as a national comparison, Professor Forbes's table approaches nearest to the truth.

The table alluded to indicates the cessation of growth to take place at twenty-two, the case of the Belgians being the only exception. This exception may be accidental, but it is remarkable that Quetelet, a Belgian writer, and whose observations were chiefly drawn from Brussels and Brabant, lays down the following as one of his conclusions:—"It does not appear that the growth of man is entirely completed at twenty-five years of age." One can scarcely doubt the accuracy of this conclusion, which was founded on an examination of 900 individuals at the ages of nineteen, twenty-five, and thirty. It is perfectly possible, however, that climate and other circumstances may cause a difference in this respect between the Belgians and British. We learn from another of the valuable inferences made by Quetelet from his investigations, that the stature is materially influenced by residence in town or country. "The stature of the inhabitants of towns, at the age of nineteen, is greater than that of the country resident by 2 or 3 centimeters." An examination, accompanied with vast labour, of not less than 3500 individuals living in towns, and 6000 residing in the country, brought Quetelet to this conclusion, which is therefore in all probability correct, and will be found to hold good in all situations. It was only at the age of nineteen, however, that the stature of the townsman was found by Quetelet to exceed that of the rustic; and he conceives it possible, though it was not in his power to obtain full proof on the subject, that, "the inhabitant of the country may attain to a greater height than the inhabitant of the town, before the completion of the full growth." The truth is, that circumstances greatly modify the rate at which the growth is developed. The law of nature on the subject is thus stated by Quetelet:—"The growth of the human being, from several months before birth up till the period of complete development, follows such a law of continuity, that the accessions of growth diminish regularly in amount, in proportion to the age." Here, of course, each successive addition of growth is considered relatively to the growth previously acquired. "We shall find," he says, "that the child increases in size 2·5ths from birth to the end of the first year; 1-7th during the second year; 1-11th during the third year; 1-14th during the fourth year; 1-15th during the fifth year; 1-18th during the sixth year, and so on; the relative growth always decreasing from the time of birth." This simple law of nature, however, is liable to be greatly affected in its operation by circumstances. "Dr. Villermé remarks," says Quetelet, "that the height of man becomes greater, and the growth takes place more rapidly, other circumstances being equal, in proportion as the country inhabited is richer, the comfort more general, houses, clothes, and nourishment better, and labour, fatigue, and privations less during infancy and youth; or, in other words, the circumstances accompanying misery put off the period of the complete development of the body, and stint human stature. There can be no doubt of the accuracy of these remarks. The simple exposure to the action of cold, not to speak of toil, materially influences the growth of man; and we see this proved, conversely as well as otherwise, in all the extreme climates of the world. The warmth and luxury of cities develop rapidly the growth of all but the lowest classes. Our British gentry bear out fully the conclusion of Quetelet, that "individuals who enjoy affluence generally exceed the mean height; hard labour appears to be an obstacle to growth."

Two other conclusions, of those which Quetelet gives as the result of his patient and cautious investigations, are as follow:—"The limits of growth in the *sexes* are unequal; first, because woman is born smaller than man; secondly, because she sooner reaches her complete development; thirdly, because the annual increase of bulk which her frame receives is smaller than that of man." The seventh and last deduction is, that, "from the fiftieth year, the human body undergoes a diminution of stature, which becomes more and more marked towards the close of life." The writer does not assert that the declension is more than in appearance, and it probably is nothing more, though not less palpable to measurement than if real. On the other points it is unnecessary to make any remark. The present treatise cannot be ca

* Half an inch may be reckoned as equivalent to the shoe

ried beyond generalities, and we must be content, in many particulars, to regard the sexes only under the common title of mankind.

WEIGHT OF THE HUMAN BEING.

The stature, weight, and strength of the human body, form but parts of one and the same subject. Each of these properties or characteristics, if not dependent on, is at least closely related to, both the others. As the object here is to make the view of the species comprehensive rather than minute, it were to be wished that the *weight* of the body, among the various races of men, had been inquired into with some attention by naturalists. But, as in the case of the stature, this has yet been done only to a very imperfect extent. Quetelet has fully examined the comparative weight of the human body at different ages, and of differently placed individuals in a single nation; but no attempts have been made to determine the comparative weights of Mongol and Caucasian, or American and Negro. The endeavour to do so would be attended undeniably with vast trouble, and some may think the matter not worthy of it. This, however, is not a correct view of things. In all undertakings that require the exertion of physical energy, and more particularly in war, bodily weight, it has now been clearly shown, is a most important element; and, wherever the superiority in this respect lies, thither will success, other circumstances being equal, almost infallibly tend. An observation of the various collisions of troops on the field of Waterloo, whether of horse or foot, has been found to substantiate this proposition.

Professor Forbes extended his inquiries among his students, English, Scotch, and Irish, to bodily weight, adding examinations of similar, and also of mixed classes of Belgians. The results were as follow:—

Weight in Pounds, including Clothes.

Age.	English.	Scotch.	Irish.	Belgians (not mixed classes.)
	lbs.	lbs.	lbs.	lbs.
15	114·5	112	...	102
16	127	125·5	129	117.5
17	133·5	133·5	136	127
18	138	139	141·5	134
19	141	143	145·5	139·5
20	144	146·5	142	143
21	146	142·5	151	145·5
22	147·5	150	153	147
23	149	151	154	148.5
24	150	152	155	149.5
25	151	152·5	155	150

Here, again, the superiority lies with the Irish, the others holding the same relative positions as in the case of stature. The mixed classes of Belgians, in whose case the weight of clothes was deducted, ranked exceedingly low—134 lbs. being about the average. We have it in our power, fortunately, to compare the conclusions of Professor Forbes with those of other inquirers, in as far as the English and Belgians are concerned. The eighty students of Cambridge, weighed (with the clothes) in groups of ten, gave an average, as we are informed by Quetelet, of 151 lbs.—the precise mean, it will be observed, of the Englishmen of twenty-five years of age weighed by Professor Forbes. The Cambridge students, however, were between eighteen and twenty-three years old, and therefore the Cambridge estimate is a little higher than that of Professor Forbes, as it also was in the case of stature. With respect to the weight of the Belgians, as examined by Quetelet, he states that the mean weight of the Cambridge students of eighteen and twenty-three much exceeds that of Belgians of the same age, being nearly the same as that of men of *thirty* in Brabant and the other departments of Flanders.

The superiority of the Irish in point of stature and weight is remarkable. We shall find it borne out by a corresponding superiority in physical power, as shown in the table of Professor Forbes having reference to that characteristic.

Quetelet's conclusions respecting the weight of the human being at various ages, and the general laws regulating his growth in this particular, are nearly as follows:—The mean weight of male children at birth is 3·20 kilogrammes.* The weight of female infants is less, being 2·91 k. A child loses weight for the first three days after birth, and does not make any decided increase until about the seventh day. Ages being equal, man generally weighs more than woman; but at the age of twelve this is not the case. The sexes are then nearly equal in this respect. The period of complete development in man, as respects weight, is the age of forty. Woman again does not attain her maximum till the age of fifty. According to observations made on the most extensive scale in Belgium, the mean weight of man at twenty-five is 62·93 k.; at the age of forty (the maximum period), it is 63·7 k. The mean weight of woman at twenty-five is 53·2 k.; at fifty (the maximum period), it is 56·16 k.† The maximum weight of the human being is nearly twenty times the sum of his weight at birth. The mean weight of the human being, neither sex nor age being taken into account, is 45·7 k. From the ages of forty and fifty, men and women begin respectively to sustain a decrease of weight, from six to seven kilogrammes being the usual loss before the close of life.

STRENGTH OF MAN.

The strength of the human frame is a subject which has received much more attention than has been paid either to its weight or proportions. It is obviously, indeed, a subject of the utmost moment, whether we view it with reference to the comparative physical powers of different races, or simply as a question interesting to civilized man from its bearing on practical mechanics. Various methods have been proposed for determining accurately the strength resident in the loins and arms of the human frame; and the instrument called the *dynamometer*, invented by Regnier, is that most generally approved of and employed to the purpose. The dynamometer, however, though used by Quetelet, Professor Forbes, and others, in their experiments, is allowed to be far from perfect, and it is only by uncommon care and caution, that results can be obtained from it worthy of being depended on. It is an instrument which cannot well be described in mere words, and all that may be said of it here is, that it is so contrived as to indicate to the experimenter, on a dial-plate, the physical power resident in the loins and arms of the parties subjected to trial.

Observing the extraordinary displays of physical power and energy frequently made by savages, scientific men were long of opinion that civilization diminished the strength of the human frame. Other circumstances tended to foster this belief. The Negro is possessed of longer arms, or at least forearms, than the Caucasian, holding in this respect, it is worthy of remark, a middle place between the white and the ape, which latter creature has arms of great length. "I measured," says Mr. White, "the arms of about fifty Negroes, men, women, and children, born in very different climes, and found the lower arm longer than in Europeans, in proportion to the upper arm and height of the body." The same writer says that whites of 6 feet 4 inches, whom he measured had shorter arms than Negroes of middle size. Similar sources of physical superiority appeared to voyagers to be possessed by the Pacific Islanders, the Malays, and many other uncultivated races. But more attentive ob-

* A kilogramme is as nearly as possible 2 1-5 lbs. English.

† The mean weight, therefore, of man in Belgium at the maximum period, is little more than 140 lbs. English. This is much below the average of man in Britain.

servation has disproved the supposition. The voyager Peron took with him to the southern hemisphere a dynamometer, with which he experimented on the following number of individuals: twelve natives of Van Diemen's Land, seventeen of New Holland, fifty-six of the island of Timor (a fine race of men), seventeen Frenchmen, and fourteen Englishmen. The following numbers express the mean result in each case, the strength of the arms and loins being respectively put to the test. It is by lifting a weight that the strength of the loins is tested with the dynamometer.

Mean strength.

	Arms. Kilogrammes.	Loins. Myriogrammes.
1. Van Diemen natives,	50·6	...
2. New Hollanders,	50·8	10·2
3. Timorians,	58·7	11·6
4. Frenchmen,	69·2	15·2
5. Englishmen,	71·4	16·3*

The highest power of arm shown by any of the Van Diemen natives, was 60; by the New Hollanders, 62; while the lowest in the English trials was 63, and the highest 83. In *lumbar* power, or that of the loins, the highest point reached by a New Hollander was 13; the lowest of the English was 12·7, and the highest 21·3.

"These results," says Mr. Lawrence, "offer the best answer to the declamations on the degeneracy of man. The attribute of superior strength, so boldly assumed by the eulogists of the savage state, has never been questioned or doubted. Although we have been consoled for this inferiority by an enumeration of the many precious benefits derived from civilization, it has always been felt as a somewhat degrading disadvantage. Bodily strength is a concomitant of good health, which is produced and supported by a regular supply of wholesome and nutritious food, and by active occupation. The industrious and well-fed middle classes of a civilized community, may be reasonably expected to surpass, in this endowment, the miserable savages, who are never well-fed, and too frequently depressed by absolute want and all other privations." Such is the case, as Peron's experiments show. But indeed the same thing is shown by a hundred historical facts. The Spaniards, on their first visits to the New World, found the natives much weaker than themselves, and this was proved not only by hand to hand struggles, but by the labour of the mines, in which the Indians were far deficient. The backwoodsmen of the States have always shown themselves stronger, in single combats, than the Indians. The Russians of Europe, also, are said by Pallas to excel the Mongol tribes of the empire, to a remarkable extent, in physical power.

Proper and extended comparisons are yet to be made of the relative physical power of the various Caucasian nations. The following table of Professor Forbes gives us at least a glimpse at the comparative strengths of English, Scotch, Irish, and Belgians:—

Lumbar Strength in Pounds.

Age.	English.	Scotch	Irish.	Belgians.
15	...	280	...	201
16	33[illegible]	314	...	236
17	352	340	369	260
18	364	360	389	280
19	378	378	404	296
20	385	392	416	310
21	392	402	423	322
22	397	410	427	330
23	401	417	430	335
24	402	421	431	337
25	403	423	432	339

* Peron—Corrected Edition of his Voyages. (The myriogramme is nearly 23 lbs. English.)

The same relations are here preserved as in the previous tables, and as, with respect to weight and height at least, there could be no mistake, the probability that the last table is correct is much strengthened by the conformity in question. The difference between the Irish and Belgians is immense, the former exceeding the latter in strength by nearly one-fourth; while between the English and Belgians there is also a great difference, amounting to 62 pounds. The English, in Peron's table, showed a lumbar strength equal to about 376 lbs., a point considerably below that of the English in Professor Forbes's table. But we might expect such a difference between students and sailors, or stout colonists, which latter classes were those examined by Peron. Between the Scotch and Irish the difference is small comparatively. It is much to be wished that the example of the Edinburgh professor were extensively followed, both abroad and at home, so as to give us satisfactory views of the relative physical powers of the different European nations. Such questions, as already hinted, will be found to bear more directly on the prosperity of nations than has hitherto been commonly imagined.*

Regnier, the inventor of the common dynamometer, was led to the conclusion, after many experiments, that, between the ages of twenty-five and thirty, man is at the maximum of his strength, and that he is then able, by pressing strongly with both hands, to make an effort equal to 50 kilogrammes, and to raise a weight of 13 myriogrammes. Man preserves (says the same observer) much of his physical power nearly till the age of fifty, when it diminishes progressively. The experiments of another Frenchman, M. Ransonnet, made upon 345 of his countrymen, sailors of the port of Havre, give results somewhat different from those of Regnier. Ransonnet found the mean manual power of these men to equal 46·3 kilogrammes; and the lumbar power, or that of the loins, to amount to 14·2 myriogrammes. There is every reason to believe, however, that the particular mode of using the instrument employed by each experimenter, is the cause of such differences in its results. Quetelet's observations led to the following conclusions:—

Lumbar Power of Men and Women.

Age.	Men. Myriogrammes.	Women. Myriogrammes
9	4·0	3·0
15	8·8	5·3
20	13·8	6·8
25	15·5	7·7
30	15·4	...
50	10·1	5·9

The highest point which the dynamometer here gave, for the power of the loins in Belgian men, was 15·5, twenty-five being the age when the power reached this maximum point. The conclusion agrees very closely with those made by Peron on the French sailors of his party, who exhibited a lumbar power equivalent to 15·2 myriogrammes, falling below that of the English, which was 16·3. Other observations, however, would lead us to suppose that the difference is more in favour of the British, when compared with the Belgians, than this cultivation would indicate; and this would probably have appeared, had Britons been tested under Quetelet's own eye, and by his directions.

The difference in lumbar strength between men and women is remarkable, as shown in Quetelet's table. At the age of twenty-five, when both attain the maximum of lumbar strength, the woman is deficient by more than one-half. "The difference," says Quetelet, "is commonly less in early youth than at the period of complete

* We have been informed that the mere physical power of the different companies of men to whom the Duke of Wellington was opposed in his campaigns, was always with him an object of serious consideration.

development, the ratio being at first as 3 to 2, and becoming afterwards as 9 to 5. The power of the right hand, when tried separately from that of the left, exceeds that of the latter by nearly a sixth. If the results which I have attained be compared with those of MM. Regnier and Ransonnet, differences of a remarkable kind will be observed, which I ascribe to the manner in which the hands were laid upon the instrument, and to the distance left between them. According to the researches, however, of the gentlemen mentioned, the mean strength of man is estimated at about 46·3 and 50 kilogrammes, a weight not equalling that of man himself. Hence a man should not be capable of supporting himself with his hands. Now, experience tells us the very opposite of this. Among the sailors examined by Ransonnet, there would not probably have been found a single man who could not sustain himself for some instants at the end of a rope. Peron, who estimates the manual force at 69·2 kilogrammes, approaches nearer to the truth, but my own experiments carry the estimate considerably higher."

These conflicting results cannot but lead us to look with suspicion on the dynamometer, when in the hands of *different* experimenters. But the conclusions of single experimenters, who have compared a variety of individuals, are still to be held of value, since they would cause the different subjects of experiment to operate on the instrument in the same way. The conclusions of Peron respecting civilized and uncivilized men, as well as Englishmen and Frenchmen, are by no means to be deemed unworthy of credit, because Quetelet arrived at different general conclusions; and the same may be said of the observations of Quetelet upon the comparative strength of man and woman at different ages. To the observations of Professor Forbes the same remark applies, and we believe, with reference to them, that the conclusions which they indicate will hold extensively good. The Belgians partake largely of the Celtic blood, and the Celtic race will probably be found inferior to the Germanic, in almost all cases, in height, weight, and strength of frame. The superiority of the Irish, it may be thought, does not countenance this view of things, as they are in the main a Celtic people. But it is the English portion of the Irish population, chiefly, who are in circumstances to quit their country in quest of academical education, and such was, in all likelihood, the character of the majority of those who became the subjects of experiment to Professor Forbes. The peasantry, in some of the more retired districts of Ireland, present characters very different from those of the parties settled within what was called the English "pale." They are pure Celts, unquestionably, with short, spare, wiry frames, and features strikingly Celtic. Not to these, but to the English portion of the nation, must the conclusions of Professor Forbes be held chiefly to apply; and the people of the Scottish Lowlands, who encircle and attend the Edinburgh University, are, in like manner, a Germanized race. It is in this light that English, Scotch, and Irish, are to be ranked together, and collectively contrasted, as being all of them branches of a Germanized population, with the continental Celts. In height, weight, and stature, the superiority, we repeat, seems to lie with the former, and their national career may have been more affected by the circumstances than has hitherto been dreamed of. Future inquiries are likely to give to such physical characteristics a degree of weight not ascribed to them in time past.

Leaving the question of comparative degrees of strength, whether in varieties or sub-varieties of mankind, a word may be said respecting the extraordinary physical powers which *individual* men, of various nations, have occasionally evinced. We learn from history, that Milo, a Greek, could fell an ox with his fist, and afterwards carry it home on his shoulders. Firmus, a man who lived in later times, being born in Seleucia about the reign of the Emperor Aurelian, could suffer iron to be forged on an anvil placed on his breast, his body being then in the position of an arch, with only the two extremities resting on supports. He exhibited other feats of muscular strength, nearly all of which were successfully imitated, during the past century, by a German named Van Eckeburg. This man sat down on an inclined board, with his feet stretched out against a fixed support, and two strong horses were unable to move him from his position. In imitation of Firmus, he lay down, with his body in the form of an arch, and allowed a stone, one foot and a half long and one foot broad, to be broken on his abdomen with a sledge hammer. He also stood on an elevated platform, and, by means of a rope round his waist, sustained the weight of a large cannon, a burden for several horses. A flat piece of iron was likewise twisted by him into the form of a screw.

Dr. Desaguliers, a scientific gentleman who witnessed the German's feats, showed, however, that skill was more concerned in the matter than mere strength. With the aid of some friends, the doctor actually performed many of the same feats, on the very night on which he witnessed them. The simple sustaining of the stone, it seems, was the chief difficulty in the most striking of the experiments, as the breaking of it caused little additional annoyance; and, in place of increasing, the arched position of the body greatly diminished the shock of the blows. In the case of many of the other feats, in like manner, a skilful application of ordinary physical powers was found competent to their accomplishment. There appeared, nevertheless, about the same time with the German, an Englishman, named Topham, who performed equally wonderful feats by sheer strength, unaided by skill. He out-pulled a strong horse by main force, though in attempting to pull against two, he ultimately got himself hurt, being totally ignorant of the contrivances which his German predecessor used in aidance of his muscular powers. Topham rolled up pewter plates with ease, and unrolled them; he struck an iron poker, three inches in circumference and three feet long, against his bare right arm, till he bent it to a right angle; he placed a similar poker against the back of his neck, and, with a hand on each end, twisted it round, till the points met in front; after which he pulled it nearly straight again, his arms acting in a most unfavourable condition while he did so; and, finally, among other feats, he lifted with his teeth, and held out for a time, a strong table six feet long, with half a hundred weight hanging at the farther extremity.

We have accounts of men performing more wonderful feats than these of Topham, but they are either ill authenticated, or seem to have resulted as much from skill as strength, as in the case of the German. Topham appears, on the whole, to have been gifted with physical powers as remarkable as any that we can believe any human being ever to have naturally possessed, judging from the details on such matters given in merely secular history.

MENTAL CHARACTER.

It is only a recapitulation of much which has been stated in the earlier sections of this treatise, that great differences of mental character are exhibited by the various races of mankind. The black intertropical nations, generally, are decidedly the lowest in the intellectual scale. They are generally characterized by great indolence, as well as by gross barbarism and superstition. The idea of a social community has made but a small advance among them, though more among some tribes than others. The lowest of the class are to be found in Australia and some of the islands of the Pacific. Yet there is scarcely any tribe of blacks so mean, but they possess certain traits of mind calculated to produce respect, being in some instances surprisingly ingenious in fabricating particular articles, or in the management of canoes and the use of warlike implements.

The red races of North America are a considerably superior race to the Negroes. Their associations for war and other purposes are upon a more complicated scale; they show many remarkable traits of ingenuity; and in many tribes we find kindness and courtesy approaching to our ideas of the chivalric character.

The Mongolians, and the Indian branch of the Caucasians, must be considered next in the scale. They have formed great states, and made advances in the arts and in science; but a stationary character appears to be impressed on them all, and ages pass without their manifesting the slightest moral or physical improvement. The Malayan variety exhibits a somewhat inferior character to the Mongolians, but not so different as to call for special notice.

The Caucasian variety, as a whole, stands greatly above all the rest. It is characterized by superior sagacity and sentiment, and, above all, by a progressive character which other races have only shown in a very limited degree. The social arrangements formed by some branches of this race, are the most calculated to insure the general happiness which have ever been known. Their industry and perseverance, aided by the lights which they have deduced from science, have led to the production of an amount of wealth beyond the dreams of Orientals. Their benevolence has led them not only to found institutions calculated to succour the poor and afflicted in their own country, but to exert themselves for the benefit of other nations in every region of the globe. Wherever this race sets its foot, it makes itself master—a result directly flowing from its superior energy, skill, and perseverance. Amongst the branches of the Caucasian variety, considerable differences prevail. The Indian branch approaches to the Mongolian variety, and it is in the Pelasgian branch in ancient, and the Teutonic or German in modern times, that we find the utmost development of the finest faculties of the species.

PERMANENCY OF TYPES.

This subject has been already touched upon; but it calls for some special consideration. We find some interesting light thrown upon it in a work entitled "The Physiological Characters of the Races of Mankind considered in their Relations to History," by Dr. W. F. Edwards.

This writer cites the Jews as an example of a race who, for nearly two thousand years, have been spread throughout a variety of climes, yet have everywhere preserved their original features. In Leonardo da Vinci's picture of the last Supper, painted three hundred years ago, the figures are represented with countenances exactly resembling those of the Jews of the present day. That the present well-known type of this people has undergone no change at any time, is proved by the paintings found by Belzoni in the tomb of an Egyptian king, probably not less than three thousand years old. These paintings represent four different races in procession—1. The natives, of a dark-brown tint; 2. Negroes, with black skins, thick lips, and woolly hair; 3. Persians; 4. Israelites, distinguished by their complexion and physiognomy. The paintings were exhibited in London, where Dr. Edwards particularly examined them: he says, "I had seen, on the previous day, Jews in the streets of London; I thought that I now saw their portraits."

Dr. Edwards shows that there is much error in our ordinary ideas respecting the effect of conquests in changing population. There is a tendency in savage races to sink under a superior intruding race, as the Guanches have done in the Canary Islands, the Caribbs in the West Indies, [illegible] a particular Indian race in New [illegible] but [illegible] the original people are to a certain [illegible] ized [illegible] therefore numerous in proportion to [illegible] law seems to be, that they continue to form [illegible] of the population, while the conquerors become [illegible] progenitors of an aristocratic class. Even when the cruel Genghis Khan deliberated as to the propriety of massacring the people whom he had subdued in the north of China, it was shown to him, and he yielded to the suggestion, that they were better spared, as being useful for producing victual and paying taxes. We see the Hindoos continuing to occupy their country on this principle, after being subjugated; and the British, though they have exterminated the intractable savages of Van Diemen's Land, seem to contemplate encouraging into their service the more docile races of New Zealand. Reason is shown by Dr. Edwards for concluding that, in several European countries which have passed through the hands of various masters, the bulk of the people are still the same as in very remote times. Rome, and the Papal states, yet show a people of exactly the same type of visage with the ancient Romans as represented in busts and upon bas-reliefs. A people of one type, supposed to be that of the ancient Gauls, were distinctly traced by Dr. Edwards in eastern France and in northern Italy. [illegible] also adduces reasons for believing that the early Britons still form a large portion of the present population of England. History itself, rightly read, bears out these propositions. The Franks, who acquired the mastery in Gaul in the 5th century, were rather an army than a migratory nation. The Lombards, who overran and seized the northern half of Italy, are supposed to have only been about 100,000 in number. The immigration of the Saxons into England seems to have been upon a greater scale; but the Normans, led by the Conqueror, were only 60,000 soldiers.

The sterility of the people on their original ground, and the permanency of their original character, are both shown in a striking manner by the description which Tacitus gives of the Gauls, Britons, and Germans. The Gauls he speaks of as "gay, volatile, and precipitate, prone to rush to action, but without the power of sustaining adversity and the tug of strife; and this is the character of the Celtic portion of the French people down to the present day. He represents the Britons as cool, considerate, and sedate, possessed of intellectual talent, and says that he prefers their aptitude to the livelier manners of the Gauls. The same mental qualities characterize the English of the nineteenth century, and they and the French may still be contrasted in similar terms. He describes the Germans, allowing for the state of their civilization, as a bold, prudent, self-denying, and virtuous people, possessed of great force of character; and the same features distinguish them still."* It is scarcely necessary to remark, that the blue eyes and fair hair which the Roman historian attributes to the Germans, are still widely-prevailing features of their external physiognomy.

The perseverance of national types is supported by circumstances favouring the same conclusion with regard to individual families. It has been repeatedly observed, in galleries of family portraits, that a particular style of face, or some shape of feature, is handed down from one generation to another, or, passing perhaps over one or two generations, revives in a third. A certain thickness in the under lip has been thus hereditary in the royal family of Austria for several centuries. The face of the British royal family has experienced nothing but minor changes since the Electress Sophia, if not from earlier generations. Mr. William Howitt, in his work entitled "Visits to Remarkable Places," gives a portrait of a school-boy who was pointed out to him at Stratford-upon-Avon as a descendant of Shakspeare, and it is unquestionable that the face has a considerable resemblance to that of the great dramatist. The present writer may be allowed to state, that he has seen a claimant of the Wintoun peerage in humble life, bearing precisely the peculiar physiognomy of two or three of the children

* Essay by Mr. Combe, in Morton's *Crania Americana.*

of the baron of Queen Mary's time, as represented in a family group painted by Antony More, and engraved in Pinkerton's Scottish Gallery. The likeness in this case was as great as is ever seen between brothers. Another circumstance, in which the writer was personally concerned, will perhaps be considered as a curious illustration of the same point. He was one day, while walking in the country, struck by the appearance of a middle-aged gentleman who passed in a carriage, and who strongly reminded him of the common portrait of Sir William Wallace. He had previously, as might be supposed, no inclination to attach any credit to that portrait, but he could not help being greatly surprised when, upon inquiry, he learned that the gentleman who had just passed was General Dunlop of Dunlop, whose mother he well knew to have been the daughter of Sir Thomas Wallace, of Craigie, the last lineal descendant of a branch of the family of the Scottish hero. It may be added that the rencontre took place sixty miles from the seat of General Dunlop. As Wallace is now known to have visited France, it is not impossible that his visage may have been painted; or, supposing the portrait not his, it is likely to be that of some early member of the Wallace-Craigie family, in which case the anecdote would be not much less valuable as a proof of the long descent of a family face.

EFFECTS OF LOCAL CIRCUMSTANCES IN PRODUCING CHANGES.

On the other hand, there are proofs of considerable alterations having been produced in the external features of races by peculiar local circumstances. The descendants of the English settlers in the American states display a considerable variation, in general form and aspect, from the parent nation. The children of European settlers in New South Wales are tall, thin, and weaker than their progenitors. In the West Indies, some distinct new peculiarities of structure have been observed in the descendants of English settlers. Their cheek-bones are higher, and their eyes deeper set in the head, than those of the English nation generally. In these respects, they approximate to the form of the aboriginal races of the American continent and islands; and it has been pointed out that such a form is useful in protecting the eye-sight from the glare of the tropical sun. The Creoles have also cooler skins, and are keener of sight, and more supple in the joints, than the English. It has been remarked of the descendants of Africans in the United States, that, after three or four generations, their features lose much of the native African cast, and approximate to those of the white people, the mouth becoming smaller, the eyes lively and sparkling, the nose higher in the ridge, and the hair considerably longer and less crisp.

Analogous circumstances are observed among the lower animals. For example, the woolly sheep, brought into a tropical climate, loses its fleece, and retains only a thin coat of hair. The hogs of Cuba, all of which are descended from a European stock, are twice as large as modern European hogs. The horses which run wild in Paraguay, though all descended from variegated European races, are now of one peculiar colour, which we cannot doubt is the effect of some peculiar local circumstances.

Dr. Prichard says—"On considering these and analogous phenomena, we can hardly avoid concluding that the variations of animals proceed according to certain laws, by which the structure is adapted to the necessity of local circumstances." If such be the case, it must be held as a circumstance favourable to the supposition that all the races are sprung from one stock. The variations might, in that case, be regarded as altogether produced by local circumstances operating during a long course of time.

It is certain that the Negro skin, and, indeed, the whole Negro constitution, are better adapted for a tropical climate than those of the white man. It is also true that intertropical countries all round the globe are inhabited by black races, excepting only those in tropical America, which are so much elevated as to enjoy a temperate climate. We here see much reason for believing that the Negro is a being adapted, in a special manner, to live in a high temperature; and this seems the more likely, when we consider that blacks, on settling in northern latitudes, become the victims of several severe ailments, which seem to forbid that they should ever multiply in such countries. Blacks, indeed, and whites, appear to be respectively adapted to tropical and to temperate latitudes; and their attempts to interchange their proper situations are not in general attended with good effects, although, as we have seen, there is reason to believe that nature makes an effort, to a certain extent, to accommodate them to the changed circumstances.

CONCLUSION.

From all that has been written or learned on the subject of man's physical and social history, it appears evident that the constitutional character of the human being admits of a very high degree of culture and improvement. Nature ushers him into existence more weak and helpless than any of the lower animals, and, left uncultivated, he grows up an ignorant savage. In the most debased condition, however, in which he can be found, he possesses the rude elements of intelligence, and aspires to a destiny altogether beyond the reach of the creatures over which he has acquired dominion. His pre-eminence in the scale of being may be proximately traced to the structure of his brain, or organ of thought, which greatly exceeds in relative magnitude that of any of the lower animals; likewise to the capacity for speech, and to his upright posture; his superior mental development, when operated upon by a combination of happy circumstances, usually classed under the name of education, enables him to trace effects to causes, to convey an account of his experience to his fellows, and, above all, to put not only this experience, but his numerous and varied thoughts, on record for the benefit of future generations. In this manner, the savage, which man originally is, is gradually improved. Each new generation enjoys the benefit of an accumulated experience; and at last, as cultivation advances, man is found to be a highly intellectual being, with a frame more elegant and powerful than he possessed when his race was in a state of heathen darkness.

Indian Savage.

Under an all-wise Providence, man has assuredly been placed on this earthly scene to perform a part immeasurably more dignified than that assigned to the lower orders of animals, each of whose generations is in no respect advanced, and cannot possibly advance beyond the precise and humble station which was first occupied by its race. "In this point of view," to use the language of Lawrence, "man stands alone: his faculties, and what he has effected by them, place him at a wide interval from all other animals—at an interval which no animal hitherto known to us can fill up. The man-like monkey, the almost reasonable elephant, the docile dog, the sagacious beaver, the industrious bee, cannot be compared to him. In none of these instances is there any progress either in the individuals or the species."

Elevated, however, as is the meanest among human beings above the higher of the animal tribes, it is evident that for the proper performance of his part he must employ means for advancement, else he rests in a condition of ignorance and barbarism most deplorable to contemplate. Placed in a large and beautiful world, abounding with animal and vegetable existences at his command, and accountable for his conduct, it behoves him to pursue such a course of activity as will enable him to enjoy the full benefits of his situation. By pursuing that line of policy which leads to social melioration, he rises step by step to a high degree of civilization, and bequeaths to posterity almost imperishable monuments of his greatness. Attaining this enviable height, should he pursue or be the victim of a contrary line of policy, he sinks in the same ratio, and perhaps with greater speed, down to the original and humble level from which he had formerly arisen.

To be assured that these are not merely conjectural speculations, we have only to direct our attention to history, wherein examples are offered of the gradual rise, the eminence, the decline, and the ultimate extinction, of civilization. Again, like the growth of a new order of plants on the soil of an exterminated forest, we find on the spot once consecrated by deeds of human greatness, a different branch of the family of mankind, pursuing by toilsome steps a similar rise from barbarism, and asserting, in their turn, the exalted capacity for improvement common to all varieties of our race.

Although it is established both by scriptural record and geological discoveries, that man was placed on earth last in the series of animal existences, his race possesses a sufficient antiquity to embrace various instances of the rise and decay of nations at a period so remote as to be beyond the reach of ordinary record, and only known by the wrecks of man's inventive genius. Thus, in the east, are found remains of architecture and sculpture, of the origin or meaning of which the oldest known nations were altogether ignorant, and which are a puzzle to modern archæologists.* Thus, also, throughout North and Central America, there are found vast monuments of antiquity and objects of art, of a date long anterior to that of the earliest recorded nations, and which these nations looked upon with awe and wonder. The valley of the Mississippi, in particular, abounds in an immense quantity of artificial mounds of various shapes and sizes, and forts of different kinds, the origin of which is altogether unknown, but which are doubtless the remains of an extinct civilized race. This country, as is well known, was found, in the earlier periods of American discovery, in the possession of those red races usually called Indians, who are now retiring before the advance of the whites. These red races manifest no symptom of possessing, or of ever having possessed, either the power or the inclination to erect such works: they disclaim having erected them, and in their traditions speak of them as the productions of a people who were their predecessors in the country, and have long been extinct.

* See article, Arabia Petræa.

To close this imperfect sketch of man's physical history we have only to add, that from all the existing remains of antiquity, both in the eastern and western hemisphere, and from all written history, it conclusively appears that mankind, taken in the mass, have in no respect degenerated in physical structure, but that individually they are as tall, bulky, and powerful, as they were in the earliest periods of their progress, while, as respects mental qualifications, they now, in all enlightened societies, occupy a station in the scale of being which it is reasonable to conclude was never before enjoyed.

Enlightened Englishman.

[BOOKS ON THE PHYSICAL HISTORY OF MAN

It is surprising that, when so much has been written on the natural history of all the inferior animals, so little has been written on that of Man. There are probably at this moment twenty books extant on the varieties of butterflies, for every one on the varieties of the human race. With respect to the anatomy and physiology of man, there are abundance of books, because the medical profession demands them; but his external appearance in different parts of the world, and the influence of climate, customs, &c., on his configuration, have been little studied by scientific men. The most complete general work on the natural history of man is that of Dr. Prichard, with coloured plates, of which a new edition was recently issued.

Dr. Morton's *Crania Americana* and *Crania Egyptiaca* are by far the most accurate scientific and important works connected with this subject which have ever appeared, as they not only discuss the present state, but the past history of the races to which they relate.

It is understood to be the intention of the United States government to publish a complete natural history of man, as a portion of the scientific result of the late Exploring Expedition; and a gentleman of profound science, who accompanied the expedition, has, since its return, visited Asia and Africa, in order to render the observations and researches required by so extensive an undertaking complete. Whenever this work shall appear, a most important addition will be made to the stock of information on natural science at present within the student's reach.

It begins to be understood that the distinctions of *race* have a most important bearing on national character and history; and under this impression inquiries into this branch of science will hereafter be prosecuted with great vigour and effect.—*Am. Ed.*]

CHINA AND THE TEA TRADE.

The Chinese Boodh.

GEOGRAPHICAL POSITION—BOUNDARIES AND DIVISIONS.

China—called by the inhabitants Tchong-Kouo, or the Middle Kingdom, from an idea that it is the centre or heart of the universe, around which all the other nations of the world lie scattered like minor provinces—is an immense country of Asia, extending from the 18th to the 41st parallel of north latitude, and from the 98th to the 123d degree of east longitude. The length has been estimated at 2000 miles, and the breadth at 1500; and, according to M. Gutzlaff, it contains an area of 1,298,000 square miles. It is conterminous with Asiatic Russia on the north-west; bounded on the south and east by the Pacific Ocean (that part of it being commonly called the Chinese Sea); on the west by huge mountains and sterile deserts, separating it from the great body of Asia; and on the north by the regions of Tartary, from which it is separated by the stupendous erection known by the name of the Chinese Wall, which extends 1500 miles in length. The Tartars call China, Catay and Nicancarou; the Japanese, Thau; and the natives of Siam and Cochin-China, Cin (pronounced Chin or Tsin). From the latter countries, lying nearest (nautically) to the Hindostan dominions, it is conjectured, with much probability, that the last-named appellation first gave rise to the European name of China. Some theorists, however, set down its derivation from the patronymic of the first imperial family Tsin, or Tai-tsin. The country is divided into eighteen provinces according to M. Gutzlaff; but other geographers enumerate only fifteen, and some fourteen. These provinces, as given by M. Gutzlaff, are—Chih-le, Shan-tung, Shan-se, and Ho-nan on the north; Këang-soo, Ganhwuy, Che-këang, and Fuh-keën on the east; Shen-se, Kan-suh, and Sze-chuen on the west; Kwang-tung, Kwang-se, Yun-nan, and Kwei-chow on the south; Hoo-pih, Hoo-nan, and Këang-se in the centre. These are again subdivided into portions corresponding to our counties, shires, and districts. Of these provinces, a survey was made by some Jesuit missionaries, employed by the Chinese government, nearly a century ago, the execution of which occupied about ten years. A manuscript map, by a Chinese, constructed according to this survey, is now preserved among the archives of the Royal Library of Britain. Po-cheli is now the principal province in the empire, from its capital Pekin being the residence of the emperor, and the seat of government. Its name signifies the northern court, in contradistinction to Nankin, or the southern court, where the emperor formerly resided.

INTERNAL APPEARANCE AND CLIMATE.

From its immense extent, it may easily be imagined that China presents almost every variety of scenery. It is intersected by three large rivers, one of which, the Yang-tsze-keang, is described as perhaps the largest in the world, and is connected with all the others by canals. There are also many other streams, and several large lakes in the interior; but nothing is known as to their actual extent. "In the long line of internal navigation," says Mr. Barrow, "between the capital (Pekin) and Canton, of 1200 miles, with but one short interruption, the traveller will observe every variety of surface, but disposed in a very remarkable manner, in great masses. For many days he will see nothing but one uniform extended plain, without the smallest variety; again, for as many days, he will be hemmed in between precipitous mountains of the same naked character, and as unvaried in their appearance as the plains; and, lastly, ten or twelve days' sail among lakes, swamps, and morasses, will complete the catalogue of monotonous uniformity. There is a constant succession of large villages, towns, and cities, with high walls, lofty gates, and more lofty pagodas; large navigable rivers, communicating by artificial canals, both crowded with barges for passengers and barks for burden, as different from each other, in every river and every canal, as they are all different from any thing of the kind in the rest of the world." One general feature, however, pervades the empire—the utter nakedness of the country as respects trees and hedges.

The climate of China embraces almost every degree of the thermometer. In Canton it ranges from 80 to 90 degrees during the summer, but the winter months are so cool that many of the inhabitants use fires. There can be no more certain criterion of the climate of any country than its vegetable productions, and we may therefore mention here generally, that within the bounds of China are all the varieties of tree, shrub, flower, and herb, to be found growing in every other country of the world. The temperature, however, may be generally described as rather warm than cold; but it is much affected by the direction of the winds, which may be literally said to "box the compass," with uniform regularity, during the various seasons of the year. They blow from the north and north-east in October, November, December, January, February, and March, during which months the weather is rather cold; in April and May, from east and south-east, when it is milder, but still cool; in June and July, from the south and south-west, when it is hot; and in August and September, from the west, when the temperature is oppressively sultry and hot. Speaking summarily, the coldest months are November, December, and January; the warmest, July, August, and September. Canton, although situated in the same parallel of latitude as Calcutta, is so much cooler during the winter months, that fires are generally used; nay, ice has frequently been found at Canton of the thickness of a dollar, but snow is never or rarely seen. The air is generally dry during the north, moist during the south, and clear during the west winds. The north winds are the most violent, and the south the most feeble. In the months of July, August, and September, the hurricanes, called by the inhabitants *Tay-fun*, usually occur, which, although extremely violent, and coming in sudden gusts, seldom occasion much disaster, owing to the inhabitants being prepared for them. The climate of China is, on the whole, highly salubrious; and many of the complaints common to the whole of Europe are there unknown. The Chinese profess to be free from stone, gout, and gravel complaints; and they are at all events seldom affected with cutaneous diseases. Much, doubtless, is owing to their uncommonly temperate mode of living, of which we will have occasion to say more hereafter. Epidemic fevers, however, are very frequent and fatal, arising from the crowded state of the towns and numerous swamps. The small-pox, too, was formerly very [illegible] the characteristic prejudice of the Chinese against [illegible] foreign innovations, however beneficial in the mode of treatment. Their physicians pretended to distinguish *forty* different kinds of small-pox; and when a favourable sort appeared, they endeavoured to propagate it, not by inoculation in the usual mode of incision, but by inserting into the nostrils a little cotton wool dipped in the *virus*, or putting on the clothes of the infected. Of late years, however, the European mode of vaccination has generally been adopted, and at [illegible] present moment has entirely superseded the ancient practice. Sore eyes, and even total blindness, are very common, and are undoubtedly to be ascribed to their low, crowded, and smoky habitations, conjoined with their practice of bathing the face in warm water even in the hottest of the summer months.

Several parts of China have suffered much from earthquakes; but there is no appearance of volcanic eruptions throughout the country, though various substances of that description are found in some of the islands along the western and southern coasts.

HISTORY.

From the grossly fabulous and exaggerated nature of the Chinese records, an air of doubt has been thrown over all their early annals. Pretending, as they do, to trace the foundation of their empire not only as far back as the time of the Deluge (of which, it is well worthy of remark, their traditions bear attestation), but even to a period long antecedent to it, it can scarcely be wondered at that a disposition should prevail to reject the whole as purely fictitious. There may be as much error in too great disbelief, however, as in too ready acceptance. The early annals of every nation are mingled up with much that is absurd, and obscured by the suggestions of ignorance and superstition. Nor are those Chinese historians, who trace the origin of their kingdom back through ninety millions of years before the Christian era, a whit more deserving of ridicule than the Romans themselves, who, with all their enlightenment, believed that the gods of their barbarous mythology took an immediate and active share in sublunary matters. The only substantial ground for wonder, in regard to China, is, that many modern writers, some even of our own country, should have given in their adhesion to the fabulous records of the native historians, and pretended to have established beyond doubt that the Chinese empire was founded more than 2000 years before the Christian era! The following may be given as an abstract of the res[illegible] of their veracious theories:—They suppose th[illegible] Moses, by Mount Ararat, does not mean to particul[illegible]ny individual mountain, but merely the first land [illegible] showe[illegible] itself upon the subsiding of the deluge, which they conjectured to be the elevated parts of Asia: That Noah followed the track of the large rivers of China which flow southward, as leading to a fertile and open country, and became the founder of the Chinese monarchy—identifying him with the Fo-nee or Foo-shee of their history: That, becoming offended with the impiety of his rebel offspring, he separated himself from them shortly before their presumptuous erection of the Tower of Babel; and, steering his course eastward, after 200 years' peregrination, settled himself in one of the northern provinces of China (2114 years before Christ). Here, having settled his colony, and established the religion, laws, and government, which he had received from his antediluvian ancestors, he died in the 115th year of his reign, and 950th of his life (1999 years before Christ). He was succeeded by Shin-nong or Zing-nung, who reigned 140 years, and at his death (1859 years before Christ) left the crown to Whang-tee or Hoang-tee the inventor of Chinese arithmetic and other arts, who reigned 100 years; and at his death left the crown to Shau-hau (1759 years before Christ).

But it were a mere waste of room to complete the enumeration of this genealogical succession of princes. Suffice it to say, that these theoretical historians trace it, with painful accuracy, down to the reign of Yau (1452 years before Christ), in the 67th year of whose monarchy happened the remarkable solstice mentioned in the book of Joshua, and which is actually noticed in the old Chinese annals, although without the specification of any year. From this time downward, the national records have undoubtedly some appearance of veracity, being principally contained in the *Shoo-King* (or history) written by Confucius, who lived about 500 years before the birth of Christ. Mr. Barrow, to whose researches the present age is chiefly indebted for the information most deserving of belief respecting this singular nation, suggests a much more moderate and rational supposition, of which the following is the substance:—He observes, that although the Chinese may be admitted to have been among the first nations of the world, after the Flood, yet they do not appear to have made such progress in arts and learning as the Chaldeans or Assyrians; that it is only from the time of Confucius that they seem to have advanced in civilization; that previous to his time, the country was divided into a number of petty kingdoms, under separate chiefs, with a recital of whose reciprocal wars and struggles for superiority the Chinese annals are chiefly filled; that their historical records are sufficiently abundant and complete during the last 2000 years, and the transactions of each reign fully detailed without interruption, down to the present time; and that, during this time, the empire of China has been less disturbed by [illegible]reign wars or intestine commotions than any other po[illegible] of the world of which we possess any accounts.

Even from this view of the subject very great deductions must be made. We are, however, compelled to walk according to our lights, and to offer the following summary of the Chinese dynasties, from the period when their chronicles begin to assume an air of probability:—

From the reign of Yau (mentioned above) until the final succession of the present royal family of Tching, or Tai-tsin, in 1644 (A. D.), the Chinese annals enumerate twenty-two imperial dynasties. Three royal families are mentioned as having possessed the throne from 1767 till 258 before Christ—Kia, Shang, and Chew. About the latter year appeared a Chinese hero, Chi-hoang-ti, who overran the empire, extirpating all the petty chiefs and rulers, and uniting the whole of China. He also built the great Tartar or Mongolian wall, and reigned until the year 207 before Christ. This prince was the first of the present family of Tai-tsin, who of course are justly proud of their great claims to antiquity.

The empire was, however, again dismembered, after his death, under his son Ul-shi, but was re-united, ten years later, by Lieu-pang. He adopted the new name of *Hang*, and founded the dynasty of Hang. The princes of this dynasty extended their conquests considerably to the west, and took part in the affairs of Central Asia. The religion of Tao-tse prevailed during their ascendency; and in the same period Judaism was introduced into China. In the course of time, the princes degenerated, and, under Hien-ti, China was divided into three kingdoms (220), which were again united by Wu-ti (280). Whilst the whole aspect of Europe was changed by the general migration of nations, two empires were formed in China, with the extinction of the dynasty of Tsin—one in the north (386), and the other in the south (420). After this, China was torn by internal commotions, and almost every province had a separate ruler, when, in 990, the people elected the able Shao-Quang-Yu emperor. He was the founder of the dynasty Sing, or Song, which reigned till 1279. His immediate successors resembled him, yet the country suffered considerably by the devastations of the Tartars. Under Yin-tsong (1012), the Chinese were forced to pay tribute to the Tartar Leao-tsang. Whey-tsong overthrew the empire of Leao-tsang (1101); but the Tartars possessed themselves of the whole of the north of China (Pe-cheli), 1125. Kaot-song II. was their tributary, and reigned over the southern provinces only. Under the emperor Ning-tsong, the Chinese formed an alliance with Genghis-Khan, and the Niu-cheng submitted to this great conqueror (1181). But the Mongols themselves turned their arms against China, and Kublai-Khan subjected them, after the death of the last emperor, Ti-ping (1260). Under the Tang dynasty, arts and sciences flourished in China; several of the emperors themselves were learned men. The Chinese authors call the Mongolian dynasty of emperors *Yuen* (from 1279 till 1368), and Kublai-Khan is by them called *Shi-tsu*. This was the first time that the whole of China was subjected by foreign princes. But the conquerors conformed themselves entirely to the Chinese customs, and left the laws, manners, and religion of the country unchanged. Most of the emperors of this line were able princes. But after the death of Timur-Khan, or Tsing-Tsang (Tamerlane), 1307, and still more after that of Yeson-Timur-Khan, or Tai-ting (1318), divisions in the imperial family frequently occasioned internal wars, which weakened the strength of the Mongols. The Chinese Chu took up arms against the voluptuous Toka-mur-Khan or Shunti, and the Mongolian grandees became divided among themselves. Toka-mur-Khan fled into Mongolia (1368), where he died (1379). His son Bisurdar fixed his residence in the ancient Mongolian capital Karakorum, and was the founder of the empire of the Kalkas, or northern Yuen. This state did not remain long united; but, after the death of Tokoz-Timur (1460), each horde, under its own khan, became independent; in consequence of which, they were, with few exceptions, constantly kept in subjection to China after this period. Chu, afterwards called Tai-tsoo IV., a private individual, but worthy of the throne, delivered his country from the foreign yoke, and founded the dynasty of Ming (1368 till 1644), which gave the empire sixteen sovereigns, most of whom were men of merit. On the frontiers of the empire, the remains of the Niudshee Tartars, now called Mantchoos, still existed. The emperor Shin-tsong II. gave them lands in the province of Leao-tong; and when an attempt was made soon after to expel them, they resisted successfully, under their prince Tai-tsu, and obtained possession of Leao-tong, upon which their chief assumed the title of emperor. He continued the war during the reigns of the Chinese emperors Huan-tsong and Hi-tsong, until his death. His son Ta-tsong succeeded him, and Hoai-tsong, a good but weak prince, was the successor of Hi-tsong on the throne of China. On the death of Ta-tsong, the Tartars did not appoint any one to succeed him, and discontinued the war. But in China, Li-tching excited an insurrection, during which Hong-Puan put an end to his life (1644). Li-tching's opponents called in the Mantchoos to their assistance. They got possession of Pekin, and of the whole empire, over which they still reign. Under Thum-chi, a child of six years old, the conquest of China was completed (1646–47), and the present dynasty of Tsing was finally established. He was succeeded, in 1662, by his son Kang-hi, who subdued the khan of the Mongols, took Formosa, and made several other additions to his empire. During the reign of this prince the Christian religion was tolerated, but his son Yong-ching prohibited it in 1724. The son of the latter, Kien-Lung, continued the persecution against the Christians (1746–73). He conquered Cashgar, Yarkand, the greatest part of Songaria, the north-eastern part of Thibet and Lassa, the empires of Miao-tse and Siao-Kin-tshuen, and extended his territories to Hindostan and Bucharia. He peopled the Calmuck country, which the expulsion of the Songarians had rendered almost a desert, with the fugitive Torgots and Songarians from Russia. In 1768, he was totally defeated by the Burmese of Ava: nevertheless, the Chinese took possession of a town in Ava in 1770, and returned to their country with the loss of half their army. They were more successful against the Miao-tse (mountaineers). Towards the end of his reign, his minister, favourite, and son-in-law, Ho-Tching-tou, abused his influence over him. Kien-Lung was succeeded, in 1799, by his 15th son, Kia-King. His reign was frequently disturbed by internal commotions. The Catholics, whom he favoured, have lost most of their privileges by their inconsiderate zeal; and at Pekin, the preaching of the Christian religion has been strictly prohibited. Kia-King was succeeded, in 1820, by his second son, Tara-Kwong, whom the Russians call *Daoguan*.

Such is a brief summary of the historical annals of this singular people. Throughout their chronicles occur many periods which are completely blank, and these chasms having been filled up, as usual, with gross fables, which throw an air of doubt over the whole; but it is worthy of remark, that many of the leading facts recorded in their more veritable histories, have been confirmed by contemporary travellers and historians of other nations.

On the whole, however, it appears, that, instead of having existed as a great and united nation from a period of 3000 years before Christ, as the natives pretend, China was not formed into one state until between 200 and 300 years before Christ. Since the establishment of the Mogul dynasty, the empire has not been again divided, but has experienced two great revolutions, at the accession of the Chinese dynasty of Ming, and the re-accession of the Mantchoo Tartar dynasty (Tsing) in 1644; and has scarcely in any reign been free from revolts, wars, and domestic seditions. Instead, therefore, of having a right to be regarded as a privileged country, governed from time immemorial by the same constitution, exempt from foreign conquest and intestine commotions, the only peculiarity it possesses, distinct from the other empires which have been swept from the earth, is—that owing perhaps to its peninsular situation, at the extremity of the habitable world, and its consequent exemptions from the destructive sweep of those conquering nations who supplanted those whom they overthrew, it has preserved its usages and manners in a great measure unaltered, amid the many internal revolutions it has undergone. Still, the fact of this, the greatest mass of population which was ever united under one government, being kept together in one bond of union for a period of time far exceeding that at which the earliest European nation may be said to commence, presents a moral phenomenon of the greatest interest, and seems altogether inexplicable by any of the usual principles which are supposed to bind society together. That it has neither been owing to the nature of the government, nor the virtue of the princes, nor the morality and peaceable disposition of the people, is certain; and we can only conjecture that the system of strict exclusion from all communication with foreign nations, and the national habit of appealing to ancient usage as the universal rule of conduct in all matters of life, have served to preserve their primitive habits and ideas in a great measure unchanged, and left unstimulated those energies invariably called into action by the free intercourse of mankind.

GOVERNMENT.

The government of China is not so much what is usually understood by an "absolute monarchy," as a specimen of what we learn from history to have been the social arrangement of a patriarchal family. The emperor, like the "head of a house" in those times, is perfectly unlimited in his power over all under him. He can dispose of the lives of his subjects at pleasure; can make or abrogate whatever laws he chooses; all offices and emoluments emanate from him alone; in short, he is equally the source of all power, honour, and mercy in the state. He can even appoint his own successor to the throne, either from his own family, or whatever class of his subjects he pleases. One of the leading principles in the Chinese constitution is to place as great a distance as possible between this universal autocrat and his subjects, and to hold him up as a demigod, a sort of *dragoman* betwixt heaven and mortals, alternately communicating the decrees of the one and the petitions of the other. He is altogether exalted above the common gross sphere of humanity. He is styled the "Holy Son of Heaven, sole guardian of the earth, and father and mother of his people." In fact, he is *believed* to be of heavenly origin; and this superstitious notion appeared sufficiently obvious by the obstacles opposed to the succession of the present Mantchoo dynasty, on account of their family not being able to trace its descent through more than eight generations. The new monarch, aware of the danger of this stigma to the stability of his throne, caused his genealogy to be drawn out and published, wherein it was given out that the daughter of heaven, descending on the borders of the lake Poulkouri, at the foot of the White Mountain, and eating some red fruit, conceived and bore a son, partaking of her nature, and endowed with wisdom, strength, and beauty; that the people of that nation chose him for their sovereign, and that from him was descended the present Son of Heaven, who filled the throne of China. This explanation at once satisfied all the scruples of his celestial subjects. Offerings are made to his person and throne, and he is worshipped by prostration, not merely in his presence, but in places where he is *supposed to be present*—as our sailors lift their hats on coming upon the quarterdeck of a man-of-war. When Lord Amherst, in his ill-starred mission to Pekin in 1816, stopped at one of the stages towards that capital, a repast was found prepared by orders of the emperor, and he and his suite were ordered to prostrate themselves nine times before the *table*, as if the descendant of the red fruit of Lake Poulkouri had been personally present. It is, of course, only in keeping with such superstitious notions, that the emperor should be reckoned not only the sovereign of China, but of all the world besides, the other royal personages being merely his vassals. "Heaven has not two sons; earth has not two kings; a family has not two masters; sovereign power has not two directors: only one God and one emperor." Such were the precepts of the learned Confucius, 500 years before Christ; and such is the doctrine of the Chinese at this hour.

This irresponsible autocrat bears two distinct characters: first, that of high priest; and, secondly, that of the sovereign of the empire, or "father and mother of the people." In the first character, he is sole mediator with Heaven for the sins of the nation; the sole officiator at all solemn rites and sacrifices for propitiating the favour of God. He has thus the exclusive credit of all the blessings the people enjoy—such as plentiful crops, favourable weather, &c.; and although occasions of public calamity, storms, inundations, and such matters, are also laid to his charge, yet such is the infatuation of the people, that they forgive his faults in consideration of the proof thus afforded of the attention of Heaven to his conduct! But care is always taken to present his character in the most amiable light possible to his subjects, who only hear of him as practising all the Utopian virtues of his station—remitting taxes and punishments, protecting virtue, punishing oppression, relieving the poor. So much for the head of the executive. What may be called the administrative government, consists of the emperor's council and the great public tribunals. The council is composed of the ministers of state, taken from the first order of mandarins, and presidents of the supreme tribunals, but is never assembled except upon occasions of extreme public importance; every thing being in general directed by an inner council, where the emperor sits in presence. There are six superior tribunals at Pekin. The first, named Lü-poo, watches over the training of mandarins, or persons to fill official situations, as well as over their conduct after being appointed to office; reports their proceedings and character to the emperor, and, in short, has them entirely under its surveillance. The second tribunal, called Ho-poo, may be designated the court of finance, where all the revenues of the empire, the royal treasures and domains, and every branch of public expenditure, are managed. The third tribunal, Lee-poo, or the court of ceremonies, superintends the observance of ancient customs and religious ceremonies; examines the public schools, and reports the progress of the sciences; receives foreign embassies; (a great tax on their time!) and regulates all matters of etiquette about the court. The fourth tribunal, Ping-poo, is something akin to our war-office, in having the management of all the military concerns of the empire. Fifth, Hong-poo is the police department, directing every thing relating to the detection and punishment of crimes. The sixth tribunal, Kong-poo, is the tribunal of public works, having charge of the palaces, public buildings, canals, mines, manufactories, &c. All these tribunals have under them a great number of subordinate tribunals scattered throughout the empire, subservient to their various objects of institution. Each of the six supreme tribunals has two presidents, one of whom must be a Tartar by birth, and the other a Chinese. They have, also, twenty-four assessors, who are half Chinese, half Tartars.

There is also another tribunal, the nature of which sufficiently demonstrates of itself the grand principle upon which the Chinese government is based—namely, of making every thing depend upon the emperor. This is a board of *censors*, who send an inspector to watch over the proceedings of each of the tribunals—both the supreme and subordinate. These functionaries take no part in the proceedings of the tribunals, but merely sit and attend to all the proceedings, which they report to their principals, and these again to the emperor. These agents are, in short, his spies; and by them he indirectly governs his empire. The mandarins are changed from one situation to another every three years, to prevent their acquiring too much influence with the people, at which times they are obliged to appear regularly at court—to resign the seals of office, we suppose, and kiss *the ground*, upon entering on a new one.

The beautifully complicated machinery of government just described, might be supposed, if properly regulated, well adapted for accomplishing its object; but it is only by that very elaborateness of construction rendered the more liable to be abused. The emperor being the prime source of all power, it would be requisite for him to manage the whole machinery with his own hands, or under his own inspection at least—a task which would require him to possess as many hands, heads, and eyes, as Briareus and Argus had between them. The necessity, therefore, of relying upon the fidelity of so many thousand agents for his information and the execution of his will, is in every department of his government taken advantage of; and the whole may be generally described as a uniform system of corruption, plunder, and oppression, from the prince to the beggar. As soon as the censors (or spies) visit the provinces, they are instantly waited upon by the mandarins, who attempt to purchase their favour with rich presents, the value of which has of course been raised by the most grinding exactions from the poor inhabitants. Every mandarin intrusted with any temporary lucrative commission from the court, makes all he can of it by the most unscrupulous means; and, by bribing the higher officers about the court, is allowed to sit down in quiet with his ill-got gains. As all complaints must pass through the hands of these officers, of course no remonstrance ever reaches the throne against such oppressions. It is true, frequent examples happen of a guilty mandarin, who is sometimes imprisoned, and his riches confiscated to the state; but it is well known that these examples of punishment do not originate in motives of justice. "The emperor," says M. de Guignes, one of the most intelligent of our modern travellers, "makes use of his grandees, as of a sponge, to suck up the riches of his subjects. When the sponge is full, he squeezes it, and sends it elsewhere to be filled anew." One mandarin, complained of by Lord Macartney, was dismissed by the emperor to the government of Quang-ton and Quang-see, with the following observation:—"I place you in a city where there are many European curiosities, but from which nothing is ever sent to me." The hint was not lost. Upon entering on his government, the inhabitants found it impossible to obtain an audience of him for less than a present of 15,000 or 20,000 piastres (£4500). "I have lived a long time in China," observes M. de Guignes: "I have traversed that vast empire in all its extent. I have everywhere seen the strong oppress the weak, and every man who possessed any portion of wealth, employ it to harass, to burden, and to crush the people." In fact the jealousy and suspicion which prevail between all the members of the government, from the emperor to the lowest of the magistrates, sufficiently evince how little they trust between themselves to their fine moral maxims, by the influence of which they pretend the throne is upheld, and the happiness of the people secured.

The great basis of the Chinese government is the strict inculcation of the sacred nature of filial obedience into the hearts of the young. The parent is understood to possess unlimited power over his offspring as long as they live—a maxim which has been for ages interwoven with their earliest feelings and ideas. The child stands in the same relation to the father as the father does to the sovereign. No wickedness or unnatural treatment by the father can relieve a son from his subjection. The merit of every good action performed by the son is ascribed to the father, but the son bears his own disgrace. In like manner, as already mentioned, the sovereign receives all the merit of the country's prosperity, but incurs no disgrace for its misfortunes. To be consistent, in thus placing the young and vigorous at the mercy of the old and feeble, the emperor sets an example, by prostrating himself, at the commencement of every year, before the empress-dowager, before receiving the prostrations of his officers and attendants. This same principle pervades all the branches of authority; the governor of a province or city being held as the father of all under his jurisdiction. The effect of this state-morality is, while it must certainly be viewed as the cause of the long stability of the government, to deteriorate the principles and feelings of the people, and destroy all genuine sentiment among them. From the beggar upwards to the sovereign, each individual is the slave of him immediately above himself; and, what is worse, all are aware of the hypocrisy of each other, and there are no other bonds to hold society together save the chains of tyranny

LAWS.

The laws of this singular nation may be described as those of the bamboo, the cord, and the scimitar. "This great nation," says Mr. Barrow, "may be aptly enough compared to a great school, of which the magistrates are the masters and the people the scholars. The bamboo is the ferula, and care is taken that the child shall not be spoiled for sparing the rod. The bamboo, however, is not used merely as an instrument for flogging the people. In the fundamental laws of the empire, it forms the scale by which all punishments are supposed to be proportioned to the crimes committed, and which are carefully dealt out by weight and measure. Punishment, as an example to deter others from the commission of crimes, would seem, indeed, to be less the object of Chinese legislation, than that of satisfying the claims of rigid justice—to wipe off a certain degree of crime by the infliction of a proportionate degree of suffering."

The laws are embraced in a code called the Leu-lee, which has generally undergone some modifications under each new dynasty, but has continued fundamentally the same from time immemorial. It is one of the duties of the mandarins to instruct the people in the provisions of these laws, and they are likewise promulgated in all the schools and public seminaries. The code of the present family, called Tai-tsin Leu-lee, consists of six great heads, to correspond to the functions of the six supreme tribunals, and embraces an epitome of the whole system of government. Our readers would not, we believe, thank us for an exposition of this institute of Asiatic jurisprudence; but the fifth division, relative to crimes and punishments, contains matter sufficiently curious and interesting. Treason—which, besides the crime of rebellion, comprehends nine other species of offence, among which are parricide, impiety, and desertion to a foreign power—is invariably punished with death, in the former case with the most lingering tortures. But it is not merely upon the criminal himself that the penalty for treason falls. All the male relations of such persons are indiscriminately beheaded, the females sold into slavery, and all their connections relentlessly put to death. And it is well did the vengeance of the law always terminate here; but it too frequently happens that whole villages, nay, sometimes entire districts, are [illegible]discriminately slaughtered for the crime of one indivi[illegible]. To intrude into the line of the imperial retinue while [illegible]eror is travelling, subjects the offender to [illegible] of the most extraordinary decrees is, that [illegible] physician is discovered compounding [illegible] manner not sanctioned by establi[illegible] with 100 blows. If any [illegible] majesty's food, the cook receive[illegible] [illegible] he mixes any unusual ingredient or [illegible] majesty's palate does not agree with, he rec[illegible] blows, and is compelled to swallow the article himself! All cases of deliberate murder are punishable by death; and death, with the most lingering torture, is denounced against parricides. The penalty of death is also awarded against a slave who shall strike his master; a son who shall strike his father or mother; a grandson who shall strike his grandfather or grandmother; a wife who shall strike her husband's father, mother, grandfather, or grand mother. But if a father kill a son, grandson, or slave, even designedly, the punishment is no more than sixty blows of the bamboo, and a year's imprisonment. Even this lenient punishment is generally remitted for a fine, as the law presumes the cause of the act to be the disobedience of the child, which is held as a crime of the deepest dye, as affecting the principle of the whole system of government. The jealousy of the Chinese law on this important point is further illustrated by the following decree—"That a child or grandchild, who is guilty of addressing abusive language to his or her father or mother, paternal grandfather or grandmother; a *wife* who is guilty of the same to her husband's father or mother, paternal grandfather or grandmother—shall in every case *suffer death by being strangled!*"

There are five degrees of punishment for offenders:—The first is inflicted by the lesser bamboo,* and is said merely to be in the way of reproof and admonition. The correction extends from four to twenty blows. The second degree extends from twenty to forty of the larger bamboo. The third is temporary banishment to the distance of 150 miles, extending from one to three years. The fourth degree is perpetual banishment, with one hundred blows of the bamboo. The fifth and ultimate punishment is death, either by strangulation or decollation. There are also various kinds of torture to extort confession and evidence. The punishment by the bamboo, however, is, in the case of offences committed by the officers of government, commuted to fine or degradation, and, under peculiar circumstances, the benefit of commutation by fine is extended also to private individuals. In fact, there is a regular scale of charges for those not legally excluded from the degradation of flogging, of which all who are rich enough may avail themselves. The motive of this regulation is evidently to fill the coffers of the royal treasury.

REVENUES.

No correct estimate, for want of the necessary data, has ever been ascertained of the actual amount of the revenues of this immense empire, and the most different statements have been put forth on the subject by various writers and travellers. The Chinese themselves, of course, attempt to impress foreigners with a most exaggerated idea of its magnitude. A Chinese minister represented it to Lord Macartney as amounting to a sum exceeding sixty millions sterling, of which, after defraying all the civil and military expenses, about twelve millions were supposed to remain for the emperor's private support. Mr. Barrow reckons "that fifty millions, in an economical government like this, where the officers and magistrates are so shamefully paid that they could not live without robbing the people, may be considered as an ample revenue for all the necessities of the state." Some late writers have reduced the estimate as low as twelve millions; but such a calculation is evidently absurd. Perhaps the nearest to the truth is that of the intelligent M. de Guignes, who accompanied the Dutch embassy in 1794. He drew up a minute summary of each individual tax and branch of expenditure, and their amount, and the result was as follows:—

Revenues, - - -	£31,555,554
Expenditure, - - -	22,222,221
Surplus,	£9,333,333

—the surplus, after the emperor takes what he immediately requires, being deposited in the public treasury. If this calculation be correct, it is evident that enormous sums must thus sometimes be accumulated. Mr. Barrow, it is true, says, "that the immense treasures said to have been amassed by the reigning dynasty, exist only in the imagination of the Chinese." But he seems to have forgotten what he himself states in another place, where, speaking of the various means adopted to preserve the emperor's popularity, he tells us that the sovereign sometimes remits a whole year's taxes to his people—a proceeding which could not easily be put in practice with an empty exchequer. The emperor has also private domains, the revenue of which was estimated by M. de Guignes at upwards of four millions.

The revenue is raised from a land-tax, amounting to about a tenth of its produce, one half of which is paid in money, and the other half in kind. There is, besides this, a tax on salt, coals, and manufactures; and a capitation-tax upon merchants, artisans, &c., who are held lowest in the scale of society. It is a curious fact, that the regulations for collecting the duties on manufactures, and preventing smuggling, resemble exactly the British system of permits, excise-officers, licenses, &c. In addition to these revenues is the large amount raised by the duties on foreign shipping and merchandise, of which we will have further to speak when we come to treat of the trade of China.

ROYAL FAMILY—COURT DRESS AND CEREMONIALS.

As may be imagined, the emperor is domiciliated in a style suited to his immense wealth, high rank, and pretensions to unlimited sway. His train of courtiers, officers of state, and other attendants, when he appears in public, which is exceedingly seldom, is inconceivably numerous; and being all apparelled in gorgeous silks and satins of the brightest dyes, garnished with gold and silver, their appearance is inexpressibly magnificent. But it is only while going through this public exhibition that all this show of wealth and magnificence has any reality. When released from duty, they retire to their mean and solitary cells in the outskirts of the palace, where they devour their rice out of wooden bowls with their chop-sticks, and then lie down on their mats on the uncovered floor, to slumber away the hours till their services are again required; for to enter into conversation with his fellow-slaves, would, as being so strange a departure from the national taciturnity, subject the parties to the suspicion of conspiracy.

The emperor has three classes of wives. The first consists of one who has the rank of empress; the second of two queens and their attendants; and the third, of six queens and their attendants. The emperor's wives and women are doomed to reside for ever within the walls of the palace, and are, after his death, imprisoned for life in a prison called the "Palace of Chastity."

The princes of the blood who are descended in a direct line from the reigning family, have their names and dates of birth registered in a yellow book, and have the privilege of wearing a yellow girdle; but those who are only of collateral descent, have their names enrolled in a red book, and wear a red girdle. So inimical is the spirit of the government, however, to a multitudinous nobility, that even the princes of the blood beyond the third generation, unless they have talents and learning to recommend them to some honourable employment to which rank is attached, gradually merge into the common mass. The princes have the privilege of being tried only by their peers, and may procure exemption from any corporeal punishment by a fine. The persons of those who wear the yellow girdle are held so sacred, that any one insulting them incurs death. Those who hold no office, only receive a salary equal to the pay of a common soldier in the Tartar bands, and receive 100 taels (about 30 guineas sterling) at their marriage. The emperor and his children wear robes of satin of a bright yellow colour, while all the other branches of the royal family, like the mandarins, wear robes of a violet colour. The emperor, his sons, and those of the first rank, are also distinguished by figures of dragons with five claws embroidered on their vestments; princes of the second rank have dragons with four claws: those of the third rank, as well as the mandarins, have, instead of dragons, serpents with four claws. The *button of ceremony* on the head-dress of the emperor consists of three dragons of gold, placed one above the other, encircled and studded with pearls. His upper robe has four circles embroidered

* This instrument, which makes so conspicuous a figure in the Chinese code, is of two sizes: the larger is five feet eight inches long, and two and three-fourth inches broad, and two inches thick, weighing two and two-third pounds; the smaller is the same length, two inches broad, one and one-fifth thick, and weighs one and five-sixths of a pound. The infliction is applied in open court, immediately upon sentence being passed.

with dragons. His necklace, which in his case alone is composed of pearls, consists of 1?2 pearls, and other ornaments of rubies, sapphires, and amber. His girdle is of a bright yellow, with four circles of gold, studded with rubies, sapphires, and pearls. The oldest son of the emperor, called Hoang-tay-tse has a similar button with his father, only with fewer pearls. His necklace is of coral, and he has a bright yellow girdle like his father, but unadorned. The bonnets of the sovereign and heir-apparent have also a figure of the idol *Fo*. The other sons of the emperor are adorned in much the same fashion as the eldest, but with fewer ornaments. All these distinctions of dress in the royal household—as indeed the apparel of every class in the kingdom—are expressly regulated by law.

The public exhibitions of the royal person, amid all the pomp and circumstance of his household, are limited to certain fixed festivals, such as the anniversary of his birth, beginning of the year, &c. "Those on the former occasion are the most splendid, all the principal officers of the government, tributary chiefs, and Tartar princes, being in attendance. As the ceremonies observed on such occasions—like every thing else in China—never vary, the following description of one in 1793, given by Lord Macartney, may be taken as an equally faithful account of the exhibitions of the present day:—'The 17th September being the emperor's birthday, we set out for the court at three o'clock in the morning. We reposed ourselves about two hours in a saloon, at the entrance of the palace enclosure, where fruit, tea, warm milk, and other refreshments, were brought to us. At last, notice was given that the festival was about to begin, and we immediately descended into the garden, where we found all the great men and mandarins in their robes of state, drawn up before the imperial pavilion. The emperor did not show himself, but remained concealed behind a screen, from whence, I presume, he could see and enjoy the ceremonies without inconvenience or interruption. All eyes were turned to the place where his majesty was imagined to be enthroned, and seemed to express an impatience to begin the devotions of the day. Slow, solemn music, muffled drums, and deep-toned bells, were heard in the distance. On a sudden the sound ceased, and all was still. Again they were renewed, and then intermitted, with short pauses; during which, several persons passed backwards and forwards in the *proscenium*, or foreground of the tent, as if engaged in preparing some grand *coup de theatre*. At length the great band, vocal and instrumental, struck up with all their powers of harmony; and instantly the whole court fell flat upon their faces before this invisible Nebuchadnezzar. The music might be considered as a sort of birth-day ode or state-anthem, the burden of which was, 'Bow down your heads, all ye dwellers on the Earth! Bow down your heads before the great Kien-long! the great Kien-long!' And then all the dwellers upon China-earth there present, except ourselves, bowed down their heads, and prostrated themselves upon the ground, at every renewal of the chorus. Indeed, in no religion, either ancient or modern, has the Divinity ever been addressed, I believe, with stronger exterior marks of worship and adoration than were this morning paid to the phantom of his Chinese majesty. Such is the mode of celebrating the emperor's anniversary festival, according to the court ritual. We saw nothing of him the whole day; nor did any of his ministers, I presume, approach him, for they all seemed to retire at the same moment we did."

All who are admitted to the honour of an audience of his "celestial majesty," are compelled to perform the ceremony of prostration, or *koutou*, which consists in prostrating themselves nine times on the ground, and beating it as often with their foreheads. This humiliating ceremony is exacted from foreign ambassadors as well as natives, as typical of the emperor's dominion over all the earth, and has been hitherto complied with by all the European plenipotentiaries who have visited the Chinese court, with the exception of the British; of which more hereafter. Of the other internal regulations of the royal household, nothing is known.

CLASSES OF POPULATION—OCCUPATIONS.

The population of China, under the emperor himself and his family, may be divided into eight distinct classes. And one of the most striking circumstances in the social system in this great despotism is, the want of that which has almost universally been reckoned indispensable to the stability of a monarchy—*a nobility*. With the exception of the princes of the blood, whose persons are in some degree held sacred, there is no rank but what is derived from the holding of some office in the state. But although those thus favoured are, by courtesy, esteemed noble, and even some families are, by the emperor's favour (such as the descendants of Confucius), allowed to retain a title of honour, they derive no power, privilege, or emolument therefrom. The sons of the highest mandarins derive no dignity or advantage from the rank of their fathers. As the possessions of the parent, too, are all equally divided among his sons, the riches of the greatest families diminish in proportion to the number of heirs; and if these are no way distinguished by talent, they soon sink back into the common mass of the people.

The great body of the people may be divided into the following classes:—The Mandarins, the Military, the Literati, the Bonzes (or priests), the Husbandmen, who are the most favoured class in the state, the Artisans and the Merchants, who are the *least respected, especially those who traffic with foreign nations!* It is one of the most curious features of this singular government, that, being so essentially despotic in itself, both in principle and practice, it possesses one feature generally reckoned the main principle of a democracy—namely, that *the highest honours and offices in the state are alike open to all classes of the people*. The meanest origin is no bar, and the proudest rank is no recommendation to the individual. This system, no doubt, soothes the public mind, and induces the people to bear with greater patience that insolence of office and stretch of power which they themselves have the prospect of exercising in turn. The result, however, is exactly in the inverse ratio to the plausibility of the system. "Where the offices of state," says Mr. Barrow, "are open to the very lowest of the people, when possessed of the requisite qualifications, the candidates for employment become so numerous, that every trifling fault is laid hold of to create a vacancy; and these frequent removals and degradations fall in precisely with the system of government, which is to break down all connection between the officers and the people, and to turn the respect and veneration of the latter exclusively to the sovereign." It is found, that the more mean the original condition of a mandarin has been, the more oppressive and extortionate is his conduct to those under him, not only with the view of making his origin be forgotten in his present elevation, but, knowing the insecurity of his situation, of making the most of it while it is in his power. The people, however, submit patiently to his exactions, assured that his dismissal (of which they are certain) will open the way for one of themselves to enjoy the same opportunities of robbery and oppression.

In accordance with the national system, however, the office of mandarin, to which all ranks eagerly aspire, is almost wholly engrossed by individuals selected from the three humblest classes—the husbandmen, the artisans, and the merchants. Those who have acquired wealth, by whatever means, generally enter into some of these occupations to render them more eligible for the office, in order that, by attaining it, they may enjoy the possessions in more security. Others purchase the office with their whole fortune, secure of finding the means of recruiting their finances during their three years' administration.

The mandarins consist of two classes, the civil and the military. The former, however, are the chief officers who govern the empire, although they are placed under such restrictions as to prevent their ever becoming dangerous to the emperor. They cannot marry in the province or city they govern, nor hold office in a province within fifty leagues of that where they were born, until they are sixty years old; with many other despotic regulations of the same nature. A mandarin has unlimited power in his district, but his conduct is watched by those above him, as it is the policy of the Chinese government to make every department responsible for the one immediately inferior to it. Notwithstanding this surveillance, however, and although their salary is barely sufficient for simple maintenance, it is regarded as a phenomenon by the Chinese to see a mandarin leave office without amassing great riches. Their means of accomplishing this we have already explained under the head of Government. Notwithstanding their infamous exactions, the people observe towards them the greatest reverence. They are saluted with the title of "Great Lord," and every one bends the knee while addressing them. The two chief classes of mandarins are divided into nine different orders, who are all minutely distinguished by particular parts of their dress. The most marked, however, is the button on the bonnet, which, among those of the first order, consists of a red ruby; others of a meaner order have a rock crystal; and the most inferior, one of gold. The number of civil and military mandarins is calculated at between 20,000 and 30,000.

The *literati* form the most distinguished part of the Chinese nation, as it is from amongst these that the individuals necessary for discharging all the higher duties in the state are recruited. To insure the adequate accomplishment of these learned statesmen, there is, as before stated (under the head of Government), a board of censors, named *Lü-poo*, to direct their studies, and examine into the progress of their erudition; and government has fixed for every city of the first, second, and third class, the number of literati allowed to qualify themselves annually in each, by taking out a diploma, corresponding to the degree of Bachelor of Arts in Britain. There are, then, in China, upwards of 24,700 individuals annually added to the qualified literati; and it is therefore conjectured, that there are never less than 495,000 of this body. These are all exempt from taxes of every description; and as soon as they have taken out their degrees, their names are enrolled in the lists of the *Lü-poo*, who choose from amongst them the higher orders of mandarins.

It is, however, in productive labour that perhaps two-thirds of the Chinese are employed; the remaining third, amounting, after deducting the civil and military officers, students, literati, &c., to about ten millions, being engaged in trading and manufactures. It is the great maxim of the Chinese government, that agriculture is the true source of national prosperity and wealth; and they have in every age honoured and protected the cultivators of the soil. This class, indeed, may be considered much the happiest and most independent of the nation; for although they pay to the amount of a tenth annually to the emperor, they have neither priesthood nor poor to support—unless the poor of their own families, whom all classes are bound to provide for. The monarch is the universal proprietor of the soil, and the tithe exacted from it is the whole rent paid by the farmer. But though the cultivator is thus in a manner a tenant at will, he is never disturbed in his possession so long as he continues to pay his land-tax, and has the power of letting out any part, or the whole, if he pleases, to another. As there are no public funds in which to vest capital, and commercial speculations are reckoned degrading, all classes are eager to lay out their capital in land. It is for this reason that even the princes and nobility vie with each other in countenancing agriculture. Yet, notwithstanding all this encouragement, the amount of land cultivated is trifling in comparison to the extent of the empire. By a report made to Kien-long in 1745, it appeared that there were only about 6,000,000 of acres under cultivation, out of the 640,000,000 calculated to be capable of tillage. From the want of enterprise, but still more from the want of skill and suitable implements, immense tracts of land are allowed to lie waste; and it is estimated that a fourth of the whole country consists of lakes and swamps, most of which are capable of being drained. It will easily be seen how inadequate the produce of the soil is to insure a regular supply of food to the inhabitants, in seasons of scarcity, occasioned by long droughts, which frequently occur; and when it is considered that there is no foreign supply of grain to make up for deficiencies, little wonder need be expressed at the terrific famines which often afflict the nation. To provide against these scarcities, a year's produce of the land is always kept stored up in public granaries; but this provision is never found sufficient to prevent the frequent recurrence of the most dreadful scenes of starvation.

We are somewhat puzzled what to say regarding the amount of the population of China; for although all accounts agree that it is something enormous, there is a difference of millions between the statements proceeding from what may be termed the most authentic sources known. The mandarins attendant on Lord Macartney, in the year 1793, gave out the population at 333 millions; and by a census taken in 1813, by order of the Chinese government, this enormous mass is swelled up to 367,821,647, which gives about 268 to the square mile. According to a statement in a Chinese official document which is quoted with approbation by Dr. Morrison, the population at present is 352,866,012. Of the truth of this statement nothing can be said, and, considering the small extent of cultivated land in the empire, it appears to be greatly exaggerated. The supposition is, that it not only includes China Proper, but all the surrounding states, which are either dependant upon, or pay tribute to the empire. According to Thom, the population is 181,788,163, which he divides into the following religious sects:—

Followers of Confucius, Laou-tsze, and Taou,	159,220,163
Worshippers of Lama,	18,000,000
Mohammedans,	1,600,000
Roman Catholics,	88,000
Jews,	50,000
Boodhists and others,	2,830,000
	181,788,163

This table is perhaps as near an approximation to the truth as can be made, although the calculation is thought by some to be too high for the extent of cultivated ground. According to a parliamentary paper published in 1830, the population of China Proper, exclusive of Tartary and the other dependencies, is 111,170,000 souls. In the German Statistical Almanac, published at Weimar in 1838, the population of China Proper is estimated at 118,000,000. From the same authority we learn that the army in 1835 was 1,250,000 strong; comprehending 830,000 infantry, and 420,000 cavalry; and the naval force is calculated at 32,440 men.

PRODUCTIONS—AGRICULTURE—TEA CROP.

The staple productions of China are rice, tea, silk, cotton, sugar, salt, porcelain, tin, lead, musk, rhubarb, quicksilver, saltpetre, wines, fruits, and various manufactures.

Rice is the great staple article of food, and so much is its importance regarded, that a high festival is held at the commencement of each seed-time. The emperor performs in person, and prepares himself for the solemn occasion by three days' fast and prayer. He then goes forth in great pomp, takes the plough in his own hands, opens a furrow, and throws in the first seed of the season. The same is done in every part of the empire, on the same day, by the viceroys and governors. The grain reaped from this seed is preserved in granaries, and reserved for sacrifices. The cultivation of this grain, of which there are two crops annually, requires little or no labour; water supplies every purpose, and for the most part this element is abundant in every part of the empire. The growers display great ingenuity in their various contrivances for raising the water from the rivers, by means of wheels, levers, swinging buckets, &c. The first crop of rice is sown in March, and the second in July, the grain being ready for the sickle three months after it is sown. Exclusive of rice, there is a great deal of barley grown in some districts, besides wheat, maize, peas, and beans. Oats, which spring up spontaneously, are pulled up as a useless weed. The implements of husbandry are extremely simple. The plough is held by one hand, and consists but of a single piece of crooked timber, the lower extremity of which is armed with a hook, and the superior guided by the hand; while a perpendicular piece of wood rises from the middle of the beam, across the top of which another piece is placed lengthways, one end of which is fixed to the handle, while the other is connected with the traces. This implement does not turn up the earth to the depth of more than six inches, so that new earth is never reached; and being thus exhausted, the ground requires often to be left fallow for want of manure.

Agricultural improvement in China has in all ages been encouraged and honoured. The husbandman is considered an honourable and useful member of society, and ranks next to men of letters and officers of state. The soldiers and the priests alike cultivate the soil; the latter generally having land attached to their convents. The empire, however, is not so generally cultivated as has been asserted by many travellers: some districts are almost entirely under cultivation, but many contain extensive tracts of waste ground. Dr. Abel is of opinion, that, "as horticulturists, the Chinese may perhaps be allowed some merit, but on the great scale of agriculture, they are not to be mentioned with any European nation." The productions extend to every useful vegetable, there being scarcely a grain, a fruit, a tree, or a culinary vegetable of Europe, that they do not cultivate.

The Chinese excel in gardening more than in agriculture, and especially in the art of laying out garden grounds; and this may be considered the only one of the elegant arts in which they display genius or taste. Their style, indeed, strongly resembles that of England. The most magnificent and extensive of the emperor's gardens are those of Yuen-min-yuen, at Pekin, and of Gehol in Tartary; the latter of which is described in glowing terms by Lord Macartney, who says it reminded him of the pleasure-grounds at Lowther-Hall in Westmoreland. They are, however, on a somewhat larger scale, being ten English miles in diameter, or 60,000 acres, containing within their precincts thirty separate habitations for the emperor, each resembling a village of considerable size.

Landed property is considered the absolute right of the emperor; the land being held by a sub-proprietor, or first holder, who is allowed to keep possession so long as he continues to pay a tenth of what his farm is supposed capable of yielding. If one person holds more land than his family can conveniently cultivate, he lets it to another, on condition of receiving half the produce, from which he pays the emperor's tax. There are no extensive estates or farms in the country. The whole ingenuity of the inhabitants seems to be exercised on the cultivation of small spots, rather than in cultivating large tracts.

The Tcha, Tha, or Tea-tree, grows equally in the mountainous and level districts, but prefers a light and rocky soil. It is sown by putting seven or eight seeds into a hole, two or three of which only spring up, and these are afterwards transplanted into rows. They begin to yield leaves three years after being planted, but require to be renewed every five or six years, as the leaves then begin to grow hard and harsh. The appearance of the tea-shrub resembles that of the broad-leafed myrtle, with a flower like that of the wild white rose. There are different modes of cultivating the tea-crop in different provinces; but there are in fact only two distinct species of it, the green and the black. All the rest are mere combinations of these two in different proportions, or are simple varieties produced by difference of soil, culture, gathering, or curing.

The black tea is grown in the maritime province of Fo-kien, with the exception of about one-third of the bohea, which is produced in the north-east corner of Canton province, in a district called Wo-ping. Green tea is all grown in the maritime provinces of Kiaguan, Kiang-si, and Che-Kiang, but chiefly in the two former. Some of the buds of the plant in Fo-kien are picked in the early part of the spring, before they have burst, and a small portion of these is mixed with the best parcels of congou, to give them a flavour. Pekoe is also brought to Canton unmixed with other leaves.

In the beginning of April, the leaves are stripped off the plant; a new crop is then thrown out, and picked about six weeks afterwards, and a third crop about the end of May: the two first pickings are the best, and nearly equal in quality. The third crop of leaves yields tea of little strength and inferior flavour: hence the best crops are composed wholly of the choice leaves of the two first gatherings, with a small sprinkling of the buds or pekoe. The inferior crops contain a larger share of the third pickings, and none of the pekoe. The black tea in Fo-kien is cultivated largely by cottagers in small plots of ground or gardens. The leaves are picked by the family, and immediately sold to persons whose business it is to collect quantities of them, and manufacture them in parts, that is, expose them to be dried by the wind under the shade, and afterwards to be further dried in a heated warehouse. The tea-merchants and the agents of the Hong merchants come to the tea districts, and purchase quantities of the dried leaves of the first, second, and third gatherings, discriminating the leaves of the young and old plants, and those grown in well-known favourable spots. They then complete the drying or roasting process, and employ women and children to select the hard, the best leaves, with more or less discrimination, according to the object of making very fine, middling, or common tea. The green tea is less highly dried than the black; and Mr. Barrow supposes that it is from the former thus retaining much of its natural juices, that its nervous properties (generally ascribed to its being dried in copper vessels) are to be imputed. The green tea is usually pressed into chests while hot, to give it a finer flavour. The tea is made into parcels of from 100 to 600 chests each, with a distinctive name to each parcel, and conformity of equality, where the tea-merchant acts honestly; hence those parcels of tea, which, under certain Chinese names, have proved, in a series of years, of excellent quality and similar characters, and which are greatly sought after at the London sales, are not the produce of any particular farm, but owe their character to the skill and good faith with which the tea-merchant or the Hong merchant's agent have executed their commissions in selecting only superior parcels of leaves in the markets of Woo-y-shan. Like the black tea, the different classes are formed by selecting the better from the inferior leaves after they have been dried; the light leaves separated by a winnowing machine from the heavier, the latter of which constitute the gunpowder tea; the lighter are of inferior quality, and only used by the common people. The blooming appearance of hyson, gunpowder, &c., is said to arise from the effects of carefully roasting the leaves in iron vases placed over a fire, and by rubbing them against the sides of the vessel; in this process, with the green teas, much skill is requisite, and there is a class of persons hired by some of the tea-merchants to superintend their respective manufactories. The bohea tea is composed partly of the lower grades of the Woo-y-shan tea, which has been left unsold after the departure of the last ships of the season, and partly of the tea grown in the district of Canton called Wo-ping.

The tea-chests undergo severe scrutiny in Canton, previously to being purchased; and if, when finally examined at the period of their shipment, they are found superior to the quality which has been attached to them, their price is raised; if inferior, they are rejected, or their price lowered. The scientific mode of proving the finer teas is to put a small quantity into a cup; pour on it pure spring water at full boiling heat; place the saucer above the cup, filling it also with boiling water to increase the heat: after a sufficient time has elapsed for the leaves to unfold themselves, to examine the appearance, flavour, but particularly the *Colour* of the infusion. The latter quality is of course only known to the initiated.

Tea is the universal beverage of China. It is drunk at all meals, and is almost the only liquor used at feasts, and while visiting each other. But it is a general rule amongst them never to drink tea immediately after a long fast, it being apt to affect the nerves, and create giddiness. The tea-shrub is cultivated only in China and Japan, and is supposed to be indigenous to one or both of these countries. All attempts to introduce it into Europe have hitherto failed.

The quantity of tea annually plucked in China, it is impossible to calculate, unless we also knew the quantity consumed by the natives. About 54,000,000 of lbs. are annually exported from Canton to all parts of the globe; and it is a remarkable fact, that of this quantity Great Britain and Ireland alone consume nearly 32,000,000 lbs.—being about 10,000,000 lbs. more than all the nations of the civilized world put together!

As substitutes for tea, the Chinese use a species of moss common to the mountains of Shan-tung; an infusion of different sorts of ferns, and the leaves of the common cammelia.

A plant called the oil-bearing tea, is much cultivated for its seeds, from which an oil is expressed, in very general use in the domestic economy of China. The seeds are ground to a coarse powder, boiled in bags, and then pressed, when the oil is yielded. There is also cultivated a tree of considerable height, called the tallow-tree, from the seeds of which a substance is prepared, having all the properties of animal tallow. A species of white cabbage is in very general use, and is considered to be to the Chinese what the potato is to the Irish. Fruits of every kind abound, but they are not considered good, except the orange, and a species called lee-tchee.

MANUFACTURES.

From the inveterate adherence of the Chinese to ancient customs and practices of every description, they have been left comparatively behind by almost every civilized nation in all useful mechanical arts, even those which originated with themselves. Every thing seems to have stood still in China but time. Nothing can be more illustrative of this fact than the case of the silk-manufacture, of which they were undoubtedly the inventors, and the knowledge of which, as their annals boast, they possessed 3000 years before Christ. The native reeler and weaver still continue to labour on by the same tardy process, and with the very same materials, as were used by their ancestors; while in England, where the manufacture was totally unknown until the fourteenth century of the Christian era, Sir Thomas Lombe, so far back as 1718 erected at Derby a machine driven by a water-wheel, by every revolution of which wheel 73,726 yards of organized silk-thread were thrown off, and amounting per day to 318,504,960 yards! At this day, the silks of China will not bear comparison with those of Lyons, Spitalfields, and Edinburgh; the first for light fabrics, the second for the more substantial, and the last for shawls. Again, in the article of porcelain (from the Portuguese *porcella*, a cup, they being the first who introduced it into Europe), which, until a very late period, continued to be the admiration of the world, we have been enabled, through the researches of Reaumur and other chemists, to compound earths matching that with which nature voluntarily furnishes the Chinese, and not only equal them in the fineness and durability of the ware, but infinitely excel them in elegance of manufacture. For nearly a century, the clumsy fabrics of the Chinese, with their daubs of blue paint, which formerly were the principal ornaments of the mansions of the wealthy, have been driven out of the market by the beautiful wares of Dresden, Staffordshire, and Severs.

The same remarks may be applied to all the other manufactures of China, the principal of which, besides the two above mentioned, are those of cloth, nankeen (or cotton), linen, paper, and ink. In whatever department of art the Chinese continue to maintain a superiority over, or equality with, the rest of the world, the cause is to be found in the bounty of nature, not their own ingenuity. Thus, the beautiful yellow which distinguishes the nankeen cloth, is a natural quality of the cotton grown in the province of Kiang-nan (of which Nankin is the capital), and is to be found in no other district of China. The Chinese still pertinaciously adhere to their ancient practice of fabricating their paper from the bark of the bamboo and koo-tchoo (by the latter of which names they term it), notwithstanding their being perfectly well aware of the superiority of that made from rags, and the infinitely greater cheapness and simplicity of the manufacture.

The Chinese ink is obtained from the soot produced by the smoke of pines and the oil in lamps, mixed with the isinglass of asses' skin and musk, to correct the odour of the oil. It is principally made in the province of Kiang-nan.

ARTS AND SCIENCES.

What we have said respecting the stationary condition of the manufactures, applies equally to the arts and sciences of China. The process of printing continues the same as when originally invented by themselves about 1700 years since. The characters are first written on paper, which is glued upon boards of hard wood, and the engraver carves the characters upon the wood, hollowing out the intermediate parts. When an impression is to be taken off, the printer lays on the ink with a brush, applies the sheet of paper, which he presses down with a softer brush than the other, and with a greater or less degree of pressure, according to the quantity of ink laid on. Such is the primitive mode of printing still persevered in throughout the interior of China, although movable types are of course necessary in printing the Royal Gazette of Pekin, which is issued daily, and other documents.

One of the most singular features of Chinese genius is developed in their attempts at painting. They display extraordinary powers of minute imitation, and will copy with the utmost exactness the number of petals, thorns, spots, &c. of a flower, and the scales of a fish; but they are, utterly unable to mix and soften their tints, and copy every defect as well as excellence in the object of their imitation. They have not the slightest idea of perspective, considering the diminished and faded appearance of distant objects as the consequence of a defect of vision; and they therefore insist upon placing every object in the foreground. When one of their ministers of state beheld a portrait of his Britannic majesty, he remarked that it was a pity it should have been spoiled by the dirt on the face —meaning the shading of the nose. When they draw a picture of the emperor, they consider it would be almost impious to represent him of the ordinary human proportions, and therefore make him twice as large as any of his attendants—the head particularly. But this self-conceited people consider themselves in this, as in every other art, pre-eminent over all other nations, and reject with disdain the remonstrances of European artists.

In sculpture, as in painting, the Chinese have no conception of order, attitude, or proportion; and there can be nothing more monstrously grotesque than the figures which *adorn* their temples, bridges, and tombs. It is affirmed, indeed, by recent travellers, that there is not a statue or column in the whole empire worth not .e.

The Chinese music remains in that state of primitive simplicity in which it has been observed to exis in all barbarous nations. Dr. Burney says, that "all the melodies of this nation have a strong analogy to the old Scottish tunes;" that "both resemble the songs of ancient Greece;" and that "the music of all three ought to be considered as *natural* music." Their gamut, like that of the Greeks, consists of five natural tones, and two semitones; but they use neither lines nor spaces in noting down their music, which they do in a column confusedly, without any attempt at marking time, key, or expression. They always endeavour to play in unison, having no idea of counterpoint or parts in music. Their musical instruments are extremely rude, consisting chiefly of drums, bells, triangles, &c.; and the only kinds resembling those of Europe are a species of lyres or harps, with strings of silk, and a small organ, or rather Pan's pipe, made of unequal reeds, struck into a hollow cup of wood, and blown by a pipe for the mouth, which conveys the wind to all the reeds. Dr. Burney tried in vain, however, to adapt a scale to this instrument. The great delight of Chinese taste, in short, is in the commingled sounds of all sorts of instruments at once. An anecdote is told of a Chinese of rank, who, being in London, was carried by a friend to one of the theatres. When the orchestra at first commenced, he appeared inexpressibly pleased, but listened with the utmost indifference to the beautiful overture that followed, asking impatiently if the musicians were not going to play again the fine air they did at first? His friend was puzzled to imagine what the air could be; until upon the performers proceeding to re-tune their various instruments after the first ac. was over, the Chinese exclaimed, in rapture at the medley of sounds, "There it is —that's it now!" The affected gravity and unsocial life of the Chinese, indeed, are unfavourable to the cultivation of music. They like to see dancing, but not to practise it—like the Turks, considering it a species of labour, not of pleasure. It is told of a Turkish ambassador that when he saw, at a ball given by some nobleman in London, all the n bility and gentry of both sexes capering about on the floor, he expressed unfeigned wonder at their giving themselves so much trouble, and observed contemptuously, "We make our slaves do all these things for us!" And thus it is with the Chinese.

In almost all the mechanical arts, however, the Chinese are wonderfully expert, and in some have attained a degree of perfection unrivalled by any other nation. No people have carried the art of dyeing, or of extracting dyeing materials from animal, mineral, and vegetable substances, so far as the Chinese have done, and this without any scientific chemical knowledge. They show particular dexterity in fashioning ivory fans, baskets, nests of eight or nine movable balls one within another: "yet it does not appear," says Mr. Barrow, "that they practise any other means than that of working in water with small saws. As little can Europeans pretend to rival their large horn lanterns, of several feet in diameter, perfectly transparent in every part, without an opaque spot, and without a seam; yet a small portable stove or furnace, an iron boiler, and a pair of common pincers, are all the tools required for the manufacture of those extraordinary machines. Their expertness in cutting tortoise-shell, mother-of-pearl, and all kinds of stones and gems, is extraordinary, and in all the metals they work with extreme neatness."

Respecting the state of science in China, Mr. Barrow says, "Nothing has yet appeared in Europe, from an authentic source, to warrant any other conclusion than that of the utter ignorance of the Chinese in the pure, speculative, and abstract science of mathematics. Their knowledge of arithmetic and geometry is bounded by mere practical rules. Their numerical notation is marked down by symbols of the language, as that of the Greeks and Romans was by letters of the alphabet. The common operations of arithmetic are generally performed by a few balls strung on wires (called the *swam-pan*), somewhat resembling the Roman abacus, and sometimes by joints of the fingers. The measure of quantity is usually determined by reducing all surfaces and sides to the dimensions of squares and cubes; and with those few practical operations they contrive to manage all the common purposes of life." All other recent observers concur with Mr. Barrow in attesting the defective knowledge of the Chinese in the science of astronomy, for their proficiency in which they have hitherto enjoyed a great reputation. Their high pretensions in this department turn out to be founded fully as much on superstition as scientific observation. So sensible are the Chinese monarchs of this fact, that for many generations the construction of their vaunted Imperial Almanac has been intrusted to foreigners, the native astronomers only contributing the important department of fixing the lucky and unlucky days, days of festivals, &c. "The Chinese system, if system it can be called," says Mr. Barrow, "resembles so closely that which remains of the Hindoos, that both must have been derived from the same source. The period, or cycle of sixty years, by which their chronology is regulated—the period of 10,800 years observed by the Tao-tse, which is the sum of the first three Hindoo ages, with their intermediate periods—the division of the zodiac into twelve signs, and also into twenty-eight constellations, or habitations of the moon, corresponding with the twenty-eight Hindoo maschatras—are so many signs of a common origin; and both may perhaps have derived the remains of this science from some third nation, more ancient than either; as the little which both nations do possess appears to be the remains rather than the elements of the science." There is, nevertheless, a board of astronomers and mathematicians maintained at Pekin, which is, in fact, one of the official departments of government; and a committee is annually appointed with great ceremony to superintend the compilation of the national calendar. It is curious to see this ostentatious show of a love of learning kept up by a people who are still so ignorant as to reckon that the firmament is a body encircling the earth, the latter of which is a solid fixed square, and round which the sun revolves, as well as the moon; that all the stars are stuck into the sky at an equal distance from the earth:—who gravely decide, by the state of the planetary system, the days proper for taking medicine, marrying a wife, setting out on a journey, laying the foundation of a house, &c. Their geographical is on a par with their astronomical knowledge, as may be imagined from their supposing China to be the middle region of the globe, and termin one m[illegible]tain, which is reckoned the centre of the empire, the "[illegible]vel of the Earth." The more educated are at this day well acquainted with the fallacy of such doctrines, but they are still propagated amongst the mass of the people, as it would be equally impolitic and dangerous to expose the delusions which have obtained credence amongst them from time immemorial, and the gross ignorance of their idolized sages. The fact is, that the pretended knowledge of the literati, and ostentatious patronage of learning by the government, is a mere state-trick, for the purpose of exciting the veneration of the ignorant multitude.

Of natural philosophy, or chemistry, the Chinese know literally nothing, except from a prac cal acquaintance with the result of certain causes. Of medicine, as a science, their whole stock of knowledge is a combination of quackery and empiricism; and it is a remarkable fact, that the healing art, which, in almost every other quarter of the known world, whether savage or civilized, justly obtains for its professors the highest respect, honours, and emoluments, is in China so little estimated, that all classes are allowed to practise it *ad libitum*. There are no schools for medical instruction; the theory of the human frame is wholly unknown to them; and they even reject the doctrine of the circulation of the blood. Their remedies are chiefly of a vegetable nature, and consist almost solely of *ginseng* (a native root, which they pretend to prepare in seventy-seven different ways), rhubarb, China-root, and tea. Their surgical knowledge is equally defective, as may be judged by the fact, that the practice of it is limited almost entirely to the honourable fraternity of barbers. Their operations consist in setting a fracture, reducing a dislocation, letting blood, by scarifying, cupping, or acupunctuation (for they entertain a sentimental horror of the lancet and scalping-knife), cutting corns, cleaning the ears, tweaking the nose, beating the back, pulling the joints till they crack; in short, we may sum up our account of Chinese knowledge of the healing art with the remark of the late Dr. Gregory of Edinburgh, that "the emperor of China could not command in all his dominions such medical aid as a smart boy of sixteen, who had been apprentice for one year to a well-employed Edinburgh surgeon, would be able to afford."

LANGUAGE AND LITERATURE.

The language of the Chinese is another branch of their history, respecting which the rest of the world has been impressed with the most preposterous and exaggerated ideas. It has been represented as consisting of millions of characters—as being perfectly unattainable by foreigners, and so forth; and thus has this truly barbarous nation acquired a reputation for philological science as spurious as that which they have enjoyed for other branches of antique erudition. "It is true," as Mr. Barrow says, "that their language, more than any thing else, stamps them as an original people. It has no resemblance whatever to any other language living or dead, ancient or modern. It has neither borrowed nor lent any thing to any other nation or people, excepting to those who are unquestionably of Chinese origin. The written character is just now as distinct from any alphabetical arrangement as it was some thousands of years ago; and the spoken language has not proceeded a single step beyond the original meagre and inflexible monosyllable." All this certainly goes to prove the Chinese to be a primitive people, and so far the circumstance is a moral curiosity; but at the same time it shows their inveterate and immovable obstinacy in adhering to a system of characters so utterly unreducible to any kind of intelligible vocabulary. The foundation of the language is purely hieroglyphic and symbolical, including all the remarkable objects of nature, such as the sun, moon, earth, fire, water, wood, stone, a horse, a cow, a dragon, &c.; the utensils most commonly in use—a knife, a spoon, a box, &c. the primary relations of life—a father, mother, brother, son, &c.; some of the most obvious qualities of bodies, as straightness, crookedness, &c., &c. To give a detail of the history of the Chinese language, through its various modifications and arrangements, would occupy a space of volumes, and to no purpose beyond the amusement it might afford to those antiquarians who delight in the investigation of matters as frivolous as they are obsolete. Suffice it to say, that the Chinese language, which has hitherto proved such a mystery to all the rest of the world, has at length been fathomed and rendered clear by the industry of British genius. In fact, the difficulties attending the acquisition of it have proved almost altogether visionary. The industry of Mr. Marshalman and Dr. Morrison has supplied us with grammars and dictionaries of this singular language, and placed within our reach all the supposed treasures it contained. "Europeans," says Mr. Barrow, "have been deceived as to the vast number of characters in this language, which was supposed to create its difficulty. In the great Dictionary of Kaung-hee there are not more than 40,000 characters, of which about 30,000 only are in use. The Lexicon of Scapula contains about 44,000 words. Ainsworth's Dictionary 45,000, and Johnson's about the same number. The whole works of Confucius contain only about 3000 different characters. The *Leu-lee* may have, on the whole, about 100,000 characters, but not more than 1860 different ones throughout the whole work. Where, then, can there possibly be any difficulty?" The same writer also adduces numerous instances of Europeans acquiring the Chinese language in a comparatively short time.

From all that has yet been seen, the trouble of learning the Chinese language will be very inadequately compensated by the literary "treasures" of which Mr. Barrow speaks. There are no doubt a profusion of poems (so called), novels, histories, and dramas, &c.; but of what character are they? From the translations which we have yet been favoured with, the poems, like some of Ossian's sublime passages, consist of unintelligible imagery; their novels of silly and pointless stories; their histories, as we have already seen, of fables; and their dramas, although for the most part true to nature, yet exhibiting nature in her most revolting forms. M. de Guignes, Mr. Barrow, and other visiters of Pekin, assure us, that the theatrical exhibitions are beyond every thing abominable and disgusting.

It has furnished matter of surprise to all writers, how a government so despotic as that of China should make the cultivation of letters a subject of such special anxiety Even the intelligent Mr. Barrow makes a marvel of this fact, notwithstanding that his own writings (had we no other authority) furnish a sufficient explanation of the seeming anomaly. It is true, there is a school to be found in every village of China, and that the instruction of the pupils forms one of the most anxious concerns of the government: but what is the nature or purpose of their education? To instruct them in all the erroneous doctrines of their parents—to confine their knowledge to the native productions of Chinese writers—to make, in short, Chinese politicians of them. The boasted system of education in China is not for the purpose of enlightening the people, but of keeping them in darkness. They are allowed to know nothing of other nations, and cannot therefore comprehend their own degraded and enslaved condition.

RELIGION.

The religion of the Chinese is allied in character to the Boodhism of the Birman empire, Japan, Siam, and other parts of Eastern Asia; and, under whatever name, it may be defined as a superstition intimately associated with ceremonial observances in pagodas and temples. According to Howard Malcom, the latest authority on the subject,* the Chinese are divided into three sects, namely, those of Ju-kea-su, Taou, and Boodh.

"The Jukeasuists are the followers of Kong-foo-tze, or, as the Jesuits Latinize it, Confucius, who flourished about 560 years before Christ, and was therefore contemporary with Pythagoras. He was of royal decent, and a mandarin, but early resigned official life, and devoted himself to literature, morals, and political economy. Reducing the maxims of former sages to order, he added valuable extracts from current works, and prudent sayings of his own, and produced a digest which continues to be the *ultima thule* of Chinese piety. Travelling extensively as a popular lecturer, and sustained, not less by his high birth and eloquent address, than by the excellence of his doctrines, he soon founded a sect which became virtually the state religion. It is, however, much less intolerantly maintained than either Popery or Protestantism, where united with the state. The other religions are allowed, and sometimes fostered. Great officers, and even the emperor himself, build and endow Boodhist and Taouist temples.

"The system of Confucius is highly extolled by European writers, and most extravagantly by Chinese. As accounts of it are accessible to all readers, I need not stop to describe it. He seems to have regarded religion less than politics, and the burden of his works relates to social virtues, civil government, and adherence to ancestral habits.

"The sect of Taou (literally *reason*) was founded by Laou-Keum, a contemporary and rival of Confucius. His followers may be called the mystics of China. They profess alchemy, assume mysterious airs, read destinies on the palms, and make great pretensions to deep research and superior light. Their practical works contain, in general, the same laudable precepts which distinguish the system of the Ju-kea-su.

"The third sect follow Fo-e, sometimes spelled *Fohi*. Foe is said to be the old orthography of *Fuh*, which is the Chinese abbreviation of *Fuh-ta*, or Boodha. The Boodhism of China is the same as that of Birmah," (for an account of which we refer to the article PAGAN RELIGIONS, in the present series of papers.) "The system is certainly far older than either of the others. It is generally supposed to have been introduced about A. D. 70. Kempfer dates the introduction about A. D. 518, when 'Darma, a great saint, came from the west, and laid the foundation,' &c. Chinese historians agree that the worship of Fohi was originally brought from India. Sir William Jones says confidently, 'Boodh was unquestionably the Fo-e of China.'

"This sect probably embraces one-third of the entire population. The government acts with indecision towards it, at one time denouncing it as dangerous, and at another contributing to its support. M. Gutzlaff saw at Pooto some placards calling on the people, in the name of the emperor, to repair to the Boodhist temple of that place, in order to propitiate Heaven for a fruitful spring. The priests are numerous, but not greatly respected. I saw some of them in the streets daily. A few were exceedingly well-dressed, but generally they were both shabby and dirty, sometimes quite ragged."

Mr. Malcom gives the following account of a visit to a Boodhist temple at Canton:—"There are 124 temples in Canton, besides the numerous public altars seen in the streets. I saw the principal ones without the walls, which are said not to be inferior, on the whole, to those within. They strikingly resemble the monasteries of Europe. The handsomest is one of the Boodhists, in the suburb of Ho-nan, on the opposite side of the river. Being accompanied by Messrs. Bridgman, Parker, and Morrison, who were acquainted with the superior, I was not only shown every part by his order, but had the pleasure of his society for an hour. Cloisters, corridors, courtyards, chapels, image-houses, and various offices, are scattered with little regard to order, over a space of five or six acres. Priests, with shaven crowns and rosaries, loitered about; but I never saw common people come to worship either at this or other establishments. Some of the priests occupied small and mean apartments; but those of the superior are spacious, and furnished not only with the ordinary conveniences, but with chandeliers, mirrors, pictures, &c., and with an extensive library. The buildings are chiefly of brick, one story high, the walks handsomely flagged, and the courtyard ornamented with large trees, or beautiful parterres of flowers. The printing-office contains stereotype plates enough to load a small vessel, so arranged as that every work is readily accessible. The principal apartment or temple is about 100 feet square, with the usual images, &c. We attended here to witness the regular evening service. It seemed to create little interest, for out of 160 resident priests, there were but fifty present; and these uttered their repetitions with the most obvious indifference. Their prayers are in Pali ostensibly, but I am told not truly, as their mode of writing renders it utterly unintelligible to any one. They keep time by striking a wooden drum, and occasionally a bell. At a certain stage of the process, the whole company formed into single file, and marched round the hall, without ceasing their repetitions. This gave us a full view of their countenances; and so far as these indicated, a more stupid set could not be picked out in all Canton. I have already remarked this characteristic of the Boodhist priesthood in other countries, and am confirmed in the belief of its being attributable to the character of their religion, and the nature of their duties.

"Instead of the humble dress of Birman and Siam priests, these were as handsome as they can get, with shoes and stockings. What is worse, some are in rags, barefoot, and squalid, with apparent poverty. They have, however, a common refectory, where I presume all fare alike. The buildings were erected at different times by the munificence of individuals, and by the revenues of the establishment, which amount to about 8000 dollars per annum.

"While we walked over the premises, the superior had prepared us a repast of sweetmeats and fruits, to which he sat down with us. His manners are easy and elegant, his dress unostentatious, and his countenance full of intelligence and mildness. His age is but thirty-eight. We of course endeavoured to make the visit profitable to him. My heart yearned over him; and when he assured me that he meant to visit America in a year or two, I was happy to promise him a most cordial reception. Priests may leave the country and return, without the restraints which make it dangerous to others.

"The whole number of priests in Canton is estimated at 2000; of nuns, 1000. The annual expense of the 124 temples is 250,000 dollars. An equal sum is required for the periodical festivals. Half a million, annually paid in one city for religion, by pagans! And the whole amount which all Christendom gives for pagans in a year, is but six times as much!"

For many years, Christian missionaries of different denominations have been established at Canton, Macao, and other parts of China; but they make little progress in proselytizing the population, on account of the difficulties of the language and the rigorous adherence of the natives to ancient customs. China likewise contains some Mohammedans and Jews; and these, with the Christians, seem to be tolerated merely on account of the public usefulness and learning of the missionaries of these sects. The Christians, for the same reason, are the most generally respected, but have been treated, from time to time, with the most arbitrary capriciousness, being persecuted by one emperor and encouraged by another. In the year 1747

* Travels in Hindustan and China. (People's Editions.)

five missionaries were beheaded in Fo-kien, and two Jesuits strangled in the same year in Kiang-nang, all of which was done "according to law," which says, that the chief of any sect who seduces the people from their duties under religious pretences, shall be strangled.

REVIEW OF MANNERS, CHARACTER, AND CONDITION.

From all we have said, it will be evident that civilization has as yet advanced but little beyond the infancy of what may be called agricultural society in China. It may be readily admitted that they were among the first of existing nations who arrived at a certain degree of excellence; but it is not less evident that they have long remained stationary, and have even in some points retrograded. "They can only be said," observes Mr. Barrow, "to be great in trifles, whilst they are really trifling in every thing that is great." The following assertion of Sir William Jones may almost be literally adopted:—"Their letters, if we may so call them, are merely the symbols of ideas: their philosophy is in so rude a state as hardly to deserve the appellation; they have no ancient monuments from which their origin may be traced, even by plausible conjecture; their sciences are wholly exotic; and their mechanical arts have nothing in them characteristic of a particular family—nothing which any set of men in a country so highly favoured might not have discovered and improved."

In their moral qualities, the Chinese are a strange compound of vanity and meanness, affected gravity and real frivolity—an utter want of all manly judgment and sense, combined with the most insidious art and cunning, the usual accompaniments of vulgar ignorance. The Tartar race are distinguished by a blunt and unstudied frankness of manner and openness of disposition; but the true Chinese betray the most debasing servility of tone and manner—plausible, sly, and artful. They have not the slightest regard to truth, and will assert and deny any thing with the most unblushing effrontery, being also entirely destitute of shame. The pain inflicted by the bamboo is the only consideration they attach to public and disgraceful corporal punishment. They have neither sense of honour nor self-respect. "A Chinese prince, or powerful mandarin," says a recent traveller, "will commit extortion or oppression whenever he can do it with impunity, and regards it as a matter of right attached to his station. A Chinese trader will cheat and defraud whenever it is in his power, and even piques himself upon his skill in overreaching, as a proof of his talent. A Chinese peasant will pilfer and steal whatever is within his reach, whenever he can hope to escape detection; and the whole nation may be affirmed to have almost nothing in view but their own self-interest and security. Their general character, in short, in point of morals, compared with the minute enforcement of duty by the penal laws, affords an irresistible proof of the utter incompetency of legislation, without the aid of religious principle, to reach beyond the mere external conduct of individuals, or to produce any thing like real social virtue among human beings." In their feelings, the Chinese are cruel, sensual, and vindictive. Mr. Barrow, M. de Guignes, and other travellers, all agree in their representations of the inhuman conduct of those in authority. One of the arbitrary laws of China is the compelling of the natives to pull the imperial barges along the canals; and Mr. Barrow had several opportunities of witnessing the merciless exercise of this authority on the part of the military. The impressed labourers took, of course, every opportunity of deserting; and whenever there was a deficiency of hands, the despotic officials set off to the nearest hamlet, roused the natives out of bed with the whip, made them jump into the water to assist the towing operations, lashing them with long cart-whips all the while with the most ruthless barbarity. Mr. Barrow also relates another specimen of Chinese indifference to human life, which he witnessed in passing down the great canal betwixt Canton and Pekin. Several persons who had crowded to the brink of the canal, had posted themselves upon the high projecting stern of an old vessel, which broke down with their weight, and precipitated the whole group into the water. Although numbers of boats were plying about at the very spot, not one was observed to go to the assistance of the drowning wretches, whose shrieks and cries were totally disregarded.

Nothing is so significant of the moral condition of a people as their treatment of the female sex, and nowhere are the women so inhumanly used as in China. They are not permitted to stir out of doors, excepting the wives of the lower orders, who are to be seen toiling at all kinds of laborious tasks, while their indolent husbands are sitting quietly smoking their pipes. In the country they are even to be seen drawing the plough and harrow, while their lazy helpmate drives them on.

The practice of deforming the feet of females of the better classes has long been prevalent. While still children, the feet are bound or compressed in such a manner as completely to prevent their growth. "At five, the rich man's daughter has her foot so firmly bound, that, in the native phrase, the whole is *killed*. The foot below the instep is pressed into a line with the leg, to add to the height of the little sufferer, while two of the toes are bent under the sole, that its breadth may be only of the least dimensions. The agony of such a process it would be hard to estimate; but it is said to last about six weeks, when I suppose the wasting of all the parts, and the cessation of many of the functions, have rendered the whole insensible to pain. The development of the muscles which form the calf of the leg being checked, the limb consequently tapers from its socket down to the foot, without any risings or inflections. This is regarded as the perfection of beauty by the Chinese, who say that the knee of the female is not protuberant, like the knee of the male, and is so well covered, that she can remain kneeling a long time without inconvenience. It is perhaps less throughout its length than when the foot is allowed to retain its natural size; but whether this be from the want of exercise, which ever acts as a stimulus to muscular deformity, or from the lack of nutriment through functional disturbance, I cannot take upon me to say; but I suspect the former is the real cause; otherwise the matter would grow from bad to worse, till the whole was destroyed by atrophy. A foot two inches in length is the idol of a Chinaman, on which he lavishes the most precious epithets which nature and language can supply. But its beauties are altogether ideal; for when stripped of its gay investments, it is a piteous mass of lifeless integuments, which resembles the skin of a washerwoman's hand after it has undergone a long maceration in soap and water. The sight of it is well fitted to excite our compassion, not our commendation—a beautiful limb crushed into a heap of deformity! It was the custom in former ages for the dames to wear long robes, which swept upon the ground, and kept the feet out of sight: it would be an ingenious device for the ladies to restore them again to use, and allow the instruments of progression to retain their natural size in the asylum of a long train. Poets might still celebrate the little 'golden lilies' in conformity with hoary custom; and it would be indifferent as to the morality of the thing, whether he said a foot was only two inches long, which was thrice that length; or called that the perfection of beauty which is, in truth, only a mass of deformity."*

Amongst the other moral iniquities of the Chinese, is the crime of infanticide; and from the contempt in which females are generally held, parents expose their female children without the slightest remorse. It is a part of the duty of the Pekin police to go their rounds with carts

* Lay's "Chinese as they are."

an early hour of the morning, to pick up the bodies of the infants that have been thrown out into the streets in the course of the night, and to carry them, without inquiry, to a common pit without the city walls, where they are thrown in promiscuously. It has been calculated that there are between 20,000 and 30,000 female infants thus yearly sacrificed in China!

In comparison with the lower orders of the Chinese, the condition of the slaves in our West India colonies was that of princes. They have scarcely an article of furniture, besides two or three jars, a few basins of coarse earthenware, a large iron pot, a frying-pan, and a portable stove. They use neither tables nor chairs, but at meals all the family sit upon their heels round a large pot, with a bowl in each of their hands. After taking the rice from the pot with a spoon, they then take their chop-sticks, which consist of two small pieces of wood, or generally of porcupines' quills, and are held between the two first fingers of the right hand. With this strange utensil they throw their food into their mouths with remarkable expedition. Boiled rice is their staple food, with the addition of millet or barley; but they likewise eat all sorts of animal and vegetable putrescent substances. The dead hogs thrown overboard the ships in the river at Canton, are greedily picked up by the natives; ... in the public market, dogs, cats, and rats, are exhibited for sale. The most degrading social vice of the Chinese is that of opium-smoking, the effects of which are much worse than those from an indulgence in intoxicating liquors.

INTERCOURSE WITH FOREIGN NATIONS—BRITISH TEA-TRADE.

The systematic discouragement which the Chinese government offers to all intercourse with foreign nations, explains the trifling amount of commerce carried on in a country adapted better than any other in the world for its prosecution, whether we consider its geographical situation, its productions, or the genius of the people. The innumerable rivers and canals with which the country is intersected, present facilities for internal communication possessed by no other country; yet there is no regular system of trade among them: it consists almost solely of barter, there being no circulating medium, excepting a small copper coin, the value of which is almost too minute for calculation. It is reckoned, that on the grand Pekin canal there are upwards of 10,000 boats and barges of various descriptions continually employed in the interchange of national produce. Of the commercial capabilities of China, indeed, we have ample evidence in the immense number and crowded state of the cities. These are divided by the Chinese into three classes, according to the number of leagues which they occupy; and of the first class alone—or *imperial* cities, as they term them—the natives enumerate upwards of 4000. There is much exaggeration here, no doubt; but even estimating the number of social communities at a third, or even a fourth, of what is set down by a Chinese, what an enormous source of consumption for all the necessaries of life is here shown! What an unbounded mart for all kinds of British manufactures would be thrown open by the removal of the government restrictions upon commerce! That the people of China are anxious for this free intercourse with other nations, has been abundantly shown; and in fact their greedy and peculatory disposition sufficiently guaranties the readiness with which they would engage in foreign traffic. But the all-powerful constraints of the government hang like a millstone round their necks. Whatever be the ignorance of the lower classes, there is no want of enlightenment in the executive, which is conscious that a free trade would inevitably lead to the breaking up of the whole despotic system of ruling. Their jealousy, indeed, is not so much to be wondered at, considering the precedent before them in the rise of the British power in the neighbouring peninsula of India; the only wonder is, that amid all the turmoils of war which have disturbed the world during so many ages, this country, so fertile in every thing which can make a country desirable, should have remained comparatively unmolested.

It is well known that the foreign trade of China is confined exclusively to one port—that of Canton. The overland trade with Russia and India has now almost entirely ceased. So great is their jealousy of the Russians, indeed, that the latter are the only people interdicted from even visiting Canton.

Tea does not appear to have been known in Britain previous to 1650; and it is evident, from the following note in Mr. Pepys' Diary, that many years elapsed previously to its coming into general use:—"September 25, 1661. I sent for a cup of tea (a China drink), of which I had never drunk before." And in 1664, there is mention made of the East India Company commissioning their foreign agent to purchase 2 lbs. 2 oz. of tea as a present to his majesty! From this time forward, however, the consumption of tea increased with a rapidity scarcely less wonderful than the progress of the British cotton manufacture.

Canton, at which the principal foreign commerce is carried on by the Chinese, and at which all the exports of tea take place, is situated on the eastern bank of the river Pekiang, a beautiful placid stream, as wide as the Thames at London. This great outlet of Chinese trade is about 400 miles in length, and Canton stands at the distance of 80 miles from its mouth. Canton consists of two descriptions of towns—that which is enclosed by walls, and the suburbs; both together, they are said to contain from seven to eight hundred thousand inhabitants. The circuit of the walls, which are of a moderate height, and furnished with a few cannon, is estimated by some at five, and by others at nine miles. Only about a third part, however, of the space enclosed is covered with buildings; the rest is occupied with pleasure-grounds and fish-ponds. The neighbouring country is very charming—hilly towards the east, and presenting in that quarter a beautiful prospect. The streets are long and narrow; the houses generally low, and towering above them may be seen temples and pagodas. At night the gates are closed, and bars thrown across the entrance to the streets. From this enclosed city, as well as from every other town in China, all foreigners are rigorously excluded; and these, if they obtain permission, must take up their abode in the suburbs, which contain a very miscellaneous population, though not therefore inferior in point of accommodation or appearance. But the most curious particular regarding Canton is the existence of a floating town on the river, consisting of perhaps forty or fifty thousand barks, junks, and vessels of various kinds, arranged close to each other in regular rows, with passages between them to allow other vessels to pass. This floating town extends several miles in length. For what reason we know not, the owners of these vessels and their families are not allowed to come ashore, and so they spend the whole of their lives on the water.

Foreigners are not permitted to go ashore and reside at pleasure at Canton. Their only land establishment consists of *hongs* or factories, which extend in a line along the banks of the river, from which they are distant about a hundred yards. They are built on a broad quay, with a spacious promenade in front. The hongs or factories individually consist of courts or lanes, admitting of no thoroughfare, and solely dedicated to the accommodation of the foreign residents. Large warehouses for the reception of goods are adjacent. The place of the Chinese suburbs which is most frequented by foreigners, is termed China Street, consisting entirely of shops, in which the native dealers are to be seen seated from morning till night. Their tricks in entrapping British seamen into purchasing their commodities, have long been matter of notoriety. Their signs uniformly exhibit an English name as well as a Chinese one; and having picked up an acquaintance with the most familiar of Jack's expressions, their mode of addressing their rough customers evinces at once the crafty and unscrupulous disposition of the natives.

The manner in which foreigners have heretofore conducted business at Canton is as follows:—When a ship arrives, it is necessary immediately to get a native merchant (or, as he is called, a hong merchant) to become security for the import and export dues, as well as for the good behaviour of the crew. In this there is never found the slightest difficulty, there being, on the contrary, always a competition amongst the natives for the honour of a consignment. The import duties consist of a tax upon the different species of goods, as well as a tonnage upon the vessel. In addition to the tonnage and cargo charges, there is also levied what is called a *kumshaw*, or present to government, exigible from ships of every burden alike. It has been estimated that all these various port-charges, including the expenses of victualling a ship, &c., amount to about 7000 dollars on a ship of 400 tons register.

The foreign merchants of Canton consist of British, American, French, Dutch, Danish, Swedish, Spanish, Portuguese, and Indian British subjects, who in 1832 amounted to 110. There are eight British establishments, seven American, and one joint Dutch and French establishment. Two English newspapers are published in Canton: the Canton Register once a fortnight, and the Chinese Courier once a week.

The personal intercourse of Europeans with the Chinese at Canton is chiefly carried on by means of a gibberish (for it cannot be called a language) composed of English, Portuguese, Chinese, and other words, but the whole greatly broken or altered in sound, and possessing no sort of grammatical construction.

At the entrance to an estuary of the river on which Canton is situated, is the island of Macao, containing a town of the same name, part of which forms a settlement or tenancy of the Portuguese, and here also the families of European merchants at Canton have been suffered to reside. The Portuguese privileges have been latterly much circumscribed, and their trade greatly diminished. "From Macao to the Boca Tigris or true entrance of the river (proceeding upwards) is just forty miles, affording a very safe channel for the largest ships. As far as the Boca or Bogue, the whole is a broad estuary of the sea, interspersed with islands, of which the well-known Lintin lies just midway between Macao and the Bogue. Lintin is on the right of the channel for ships, and abreast of it on the left is Lankeet Island, forming behind it the harbour of Kumsing-moon, where the opium ships of late years were accustomed to lie at anchor in safety. There is no entrance to the Canton river to the eastward of the Boca Tigris; but on the west the case is widely different; and it is there that the principal difficulties of a blockading squadron exist. The main part of the river flows through the Bogue; but to the westward there stretches a great delta, which has been gradually formed by depositions of soil from the turbid waters, and is crossed in all directions by shallow channels communicating with each other and with Canton. Some of these channels form the *inner passage*, by which the British traders used generally to proceed between Canton and Macao, passing a town called Heang-shan, the residence of the chief magistrate of the Macao district. These shallow channels to the westward, though they are impassable by English ships, present no obstacle to the flat-bottomed trading craft of the Chinese, below the size of the larger junks."*

It has been by means of the navigable inlet thus described, that nearly all intercourse with the Chinese has taken place; all the other ports which lie to the northward being shut against European commerce. The greatest possible care has at least been taken to prevent any intercourse by the river Yang-tse-Keang, which, by its connection with the great canal, leads to Pekin and the chief northern districts.

The principal traders with the Chinese have latterly been the Americans and British. "The American intercourse with China," says M'Culloch, "commenced shortly after the termination of the revolutionary war, and has since gone on rapidly increasing, so as to constitute one of the most valuable branches of the trade of the United States." Mr M'Culloch gives a table showing the extent of the exports from Canton to America from 1804 to 1826–7, by which, in the last-mentioned year, it is seen that the Americans had twenty-six ships in the tea-trade, and that the total value of exports from China was 4,363,788 dollars. "The principal articles," continues this most accurate authority, "carried by the Americans to China, are bullion, furs, Turkey opium, English woollens and cottons, and ginseng. The commodities exported by the Americans from China are tea, nankeens, raw and wrought silk, sugar, cassia, and camphor, with minor articles." The Americans are exceedingly enterprising in this, as in every other trade in which they engage.

The British trade with Canton was formerly carried on by the East India Company, but by an act of parliament which came into operation in April, 1834, the trade was thrown open to all classes of British subjects. From enjoying a monopoly, the East India Company were the only sellers of tea in this country, and could therefore regulate the price as they thought proper. It is but fair to say, that the Company did not abuse this monopoly; but, from the expensive manner in which the trade was carried on at Canton, the price of tea was greater in this country than it has been since competition was allowed. The duty on tea, down to the 22d April, 1834, was 96 per cent. on all teas sold under two shillings a pound, and 100 per cent. on all that were sold at or above two shillings. A discriminating scale of duties was afterwards established, with a view to allow the introduction of the cheapest kind of tea at the lowest duty; but it was found that merchants did not scruple to introduce better qualities of the article under inferior denominations; and to put an end to this impropriety, as well as stop all clamour on the subject, a statute was passed (1836), enacting that 2s. 1d. per lb. should be charged on all teas without exception, entered for home consumption in the United Kingdom. In 1835, the first year of open trade in tea, the imports to the United Kingdom amounted to 43,000,000 lbs., being more than 10,000,000 above what had ever been imported in any single year by the East India Company. In 1837, the imports were 36,973,981 lbs. (of which 30,625,206 were retained for home consumption), and the duties produced a revenue of £3,223,840. In exchange for the tea brought from China, there is imported into that country woollen and cotton articles, copper, iron, lead, glass, earthenware, and jewelry, the value of which in 1831 was £593,755. Bullion used formerly to be sent to China; but of late years it has been imported from China into England, instead of the contrary.

The preceding details refer to that condition of affairs which prevailed previously to 1838–9, when British intercourse with China was suddenly brought to a close by events consequent on the forcible suppression of the "opium trade." As already mentioned, the Chinese indulge in opium-smoking, but from the injurious effects of the practice, it is ostensibly prohibited, and the introduction of the article is legally declared to be contraband. Notwithstanding the illegality of the traffic, however, it

* Davis's Sketches of China: 1841.

has ever been extensively carried on, [illegible] in a secret, but open manner, by smuggling-vessels on the coast. Remonstrances against it by the Chinese government were generally disregarded, because the mandarins and others sanctioned it for private reasons; and it was observed that all menaces on the subject were merely empty threats, apparently put forward for the sake of external decency. Lulled into fancied security, and feeling that they were more encouraged than discouraged, the British continued to pour in opium from India, till, by a sudden outbreak, the whole stock in the vessels at Canton was seized and publicly burnt, causing a loss of from two to three millions of pounds sterling to the parties interested. It is here necessary to mention, that the chief promoters of the opium trade were the East India Company, and the stoppage of it was likely to prove most disastrous to British interests in that great empire. The rajahs and petty princes of Hindostan are the chief growers of the poppy, and it is important to conciliate their favour. The best opium is produced in Malwa, a district of India. From that quarter it pays at Bombay a [illegible] of 125 rupees (£12 10s.) per chest, fetching in [illegible] from 400 to 500 rupees (£40 to £50). This [illegible] ells on the Chinese coast for 700 dollars (£15[illegible]), and perhaps much more. The temptation [illegible] large a profit, sets all plans for stopping the [illegible] nce. "The opium trade (observes Lord Jocely[illegible] ver hateful it may appear in the eyes of many, [illegible] be recollected, a source of great benefit to the Indian government, returning, I have heard, a revenue of upwards of two millions and a half yearly. It therefore becomes those who are so eager for its suppression, to point out some method of making up the serious defalcation of revenue that must necessarily accrue to the Indian government, whose expenses already outrun its present income."

The seizure and destruction of the opium, as is well known, precipitated a quarrel with China, which is still (May, 1841), far from being settled to the satisfaction of the British people and government. The contemptuous manner in which the Chinese have always treated the English as well as other Europeans, has tended greatly to aggravate the dispute. Puffed up with a singular degree of vanity, the Chinese government has been in the habit of treating and speaking of the English as *barbarians*, and has on no account allowed the settlement of a consul or ambassador to watch over British interests. The only channel of communication has been by a Chinese commissioner at Canton and a commissioner or envoy from Britain, who in late times was not allowed to land. Added to this, the mean cunning and deceit of the Chinese have proved an obstacle to every kind of fair negotiation. The depreciatory view taken of the English power, having frustrated the peaceful adjustment of the dispute, nothing was left the British but to compel attention to their claims for compensation, and an apology for indignities, by force of arms. Consequently, the year 1840 was destined to present the extraordinary spectacle of a British naval and military force on the coast of China. Chusan, an island on the coast, was captured in the month of July, after a feeble resistance, and various other successes attended the British arms in a few months afterwards. Up till the period we write, however, owing to the temporizing policy of the British commissioner, nothing definite has occurred in the war, and we therefore leave it to the course of events. Meanwhile, the tea-trade has suffered no material interruption, as it has been carried on in a great measure under cover of other flags than the British, though with a loss to British naval interests.

* Six Months with the Chinese Expedition

WORKS ON CHINA.

Among the recent works on China, there are several of value and interest. "*The Chinese—A General Description of the Empire and its Inhabitants*, by John Francis Davis, Esq.," published by the Harper[illegible] one of the best. It is founded on the authority of [illegible] travellers, and well embellished with maps and eng[illegible]. This is the most complete account which has [illegible] lished in this country. M. Pauthier, Member of the Asiatic Society of Paris, has published a volume as part of "*L'Univers Pittoresque*," entitled "*Chine, ou Description Historique, Geographique et Litteraire de ce vaste empire, d'apres des documents Chinois, Premiere Partie, comprenant un Résumé de l'histoire et de la civilization Chenoises depuis les temps les plus anciens jusqu'à nos [illegible]rs.*" In writing this work, M. Pauthier appears to have exerted the same spirit of indefatigable research which actuated M. Champollion in his inquiries respecting Egypt; and his revelations are not less interesting and surprising than those of his illustrious cotemporary. One feels amazed at the fact, that almost every modern improvement in the arts of life was anticipated by the Chinese some centuries ago. Their progress in political science, moral science, legislation, and the ornamental arts, is not less surprising. All these are developed from original Chinese authorities by M. Pauthier, in the course of his history. The work is embellished by seventy-two copperplate engravings, the greater part of which are copies from Chinese originals.

The recent war between Great Britain and China has caused a multitude of books to be written respecting the latter country, most of which are worthless; but the late treaties between China and England, and China and the United States, will occasion more intercourse than hitherto between the Celestial Empire and the nations of Europe and America. The gentlemen who were attached to the American embassy have not yet published the result of their inquiries; but it is to be hoped that there is something worthy of notice yet to proceed from them.

From what is already disclosed in the work of M. Pauthier, it is quite apparent that there yet remains an immense amount of interesting, historical, antiquarian, and ethnographical information to be found in the archives of the Celestial Empire and the numerous works of its literati, to reward the persevering researches of future inquirers.—*Am. Ed.*]

THE OCEAN—SHIPS—NAVIGATION—MARITIME DISCOVERY.

THE OCEAN.

The Ocean may be comprehensively described as a sheet of water, resting in the hollows of the solid structure of our planet, and covering not less, probably, than two-thirds of the entire surface. From calculations, its greatest depth is believed to be about 30,000 feet, or between four and five miles, which, it may be remarked, is also the greatest height of any land above the surface of the ocean. But the greatest depth which has been ascertained by actual measurement is not more than 5000 feet; for such is the pressure and density of the liquid mass at that depth, that no sounding-lead or apparatus possessed by mariners can possibly be made to sink below that point from the surface.

The quantity of water composing the ocean, by the unalterable laws of evaporation and condensation, remains always at a fixed point, there being neither increase nor decrease. It has been remarked by La Place, a French astronomer, that if the existing waters of the ocean were increased only one-fourth, the earth would be drowned, with the exception of some of the highest mountains; and that if, on the other hand, the waters were diminished in the same proportion, the largest rivers would dwindle to the capacity of brooks, and some of the principal arms of the sea would entirely disappear, while at the same time the earth would be deprived of its due proportion of humidity, and the face of nature be dried up and rendered desolate. Broad, therefore, as are the limits of the ocean, they are only in exact agreement with the wants and arrangements of nature in the inhabitable portion of the globe, and as such afford a convincing testimony of the power, wisdom, and goodness of the Divine Creator.

The bottom or bed of the ocean is marked by the same irregularities of surface as the dry ground. It consists of heights and hollows, rocky protuberances and caverns, hills and vales, sand-banks and reefs, of every imaginable form and extent. Like the land, also, it bears a luxuriant vegetation, consisting of plants of various kinds, all of which are exactly suited to their respective situations. The sea has likewise its tribes of animals, from the huge whale down to the minute coral insect, by whose incessant labours the hardest rocky substances are constructed and reared to the surface of the waters. When the more elevated protuberances in the bed of the ocean are raised above the surface level, they assume, as is well known, the character of islands, and when of a large size, of continents. Thus, the tracts of dry land are in one sense the tops of mountains rising from the bosom of the deep. How islands are formed, sometimes by the action of volcanoes bursting upwards in showers of lava in the midst of the sea, and sometimes by the gradual accumulation of matter deposited by coraline insects; and also how tracts of land are added to continents, and also sometimes taken from them, by the influence of currents, rivers, and other natural causes, has been already explained in the article Geology.

TIDES.

The waters of the sea may exhibit to the eye a calm, unruffled surface when not agitated by winds, but they are never altogether still. Their ceaseless motion, which has the important effect of preserving them from stagnation, is caused by two great risings and depressions, or flowings and ebbings, of the waters, in the course of twenty-four hours, known by the name of *tides.* The two tides or flowings of the sea are experienced daily all over the globe, though in some seas, from peculiar local causes, they are less powerful than in other places. It is not a little remarkable, that the condition of high water, or full tide, occurs at directly opposite sides of the earth at the same time. When it is high water at longitude 0, it is also high water at longitude 180, and so on with every other two opposite points of the earth, on the same parallel of latitude.

It has been ascertained, beyond all reasonable doubt, that the tides are caused by the attractive influence of the moon. By the universal law of attraction or gravitation, all masses of matter have a tendency to be attracted or drawn towards each other. The moon, therefore, as a mass of matter, in passing round the earth, has a tendency to draw the earth after it, or out of its natural relative position, and it really does so to a small extent. As it passes round, it draws up the waters in a protuberance, or, in common language, draws a huge wave after it. But it also draws the land beneath the protuberance, and so causes the opposite side of the globe to be drawn away from the ocean, leaving the waters there to form a similar protuberance or high wave. In the one case, the water is drawn directly up or towards the moon; in the other, the water is in some shape left behind by the land being pulled away from it. In both a similar effect is produced; two high tides are caused at opposite extremities of the earth. Where the higher part of either of these great billows strikes our coast, we have the phenomenon of high water; and when the lower touches us, it is low water. Each of the waves is brought over any given place in the circumference of the earth in twenty-four hours, so as to cause high water twice a day. The sun is also known to have a certain attractive influence on the waters of the ocean; but from the great distance of that luminary, the effect is comparatively small. But when this minor influence of the sun coincides with that of the moon, or acts in the same way, we perceive a marked increase in the tides; on such occasions we have what are called *spring* or *large* tides. When the solar and lunar attractions act in opposition, we have *neap* or small tides. The spring tides happen twice a month, when the moon is at full and change; and the neap when the moon is in the middle of its orbit between those two points. A tide requires six hours to rise, which it does by small impulses or ripplings of the water on the shore, and six hours to ebb or fall; but every successive high water is from twenty to twenty-seven minutes later than the preceding, or, on an average, about fifty minutes for two tides, in consequence of the earth requiring that time above the twenty-four hours to bring any given point again beneath the moon. The tides are thus retarded by the same reason that the moon rises fifty minutes later every day. It is evident that the tides will be greatest at that point of the earth's surface which is nearest to the moon, or where the latter is vertical. She is so between the tropics; and accordingly the tides are there greatest, and they diminish as we approach either poles. It is further to be remarked, that the moon does not anywhere draw up the tides immediately. Three hours elapse before the waters are raised, in consequence of the law of inertia, or a disposition which everybody has to continue in the condition of rest or motion in which it happens to be placed. This stubbornness to resist the moon's influence is only overcome by a three hour's action upon the waters; and thus the tidal wave is always three hours behind the moon in its passage. Twice a year, namely, in March and September, the tides are higher than at other times, because then the attraction of the sun and moon is strongest. In some of the firths or arms of the sea on the east coast of Scotland, it has been occasion-

...ndy noticed that there have been four high waters in the twenty-four hours. These, however, are not simple tides. The double risings are caused by the irregular passage of the tidal wave from the Atlantic round the north and south points of the island of Great Britain. When that portion of the wave which proceeds by the south reaches the east coast sooner than that by the north, or *vice versa*, there will be two risings of the water instead of one. A similar phenomenon may perhaps be observed in other parts of the earth. In the Mediterranean Sea the tides are small, and in some places scarcely perceptible; this is caused by the general confinement of that inland branch of the ocean, by the Straits of Gibraltar, which prevent the full action of the tidal wave either in its rising or recession.

CURRENTS.

Besides being affected by the regular motion of the tides, the ocean, in many parts of its extended bounds, is influenced by currents, which act continually in particular directions. Currents are the result of various causes, such as temperature, winds, peculiar construction of coasts and inlets, but chiefly, as is believed, of the rotatory motion of the earth. The globe in its diurnal motion leaves, as it were, the fluid behind; and hence there is a perpetual flow of the sea from the western coasts of Europe and Africa towards the eastern *land-board*, as it is called, of America, and from the west of America to the eastern coast of Asia. This movement is chiefly confined to the tropics, unless where the sea is turned aside by the land, and caused to diverge towards the north or south. If we start in a survey of this motion from the western coast of America, we find it producing a constant current across the vast expanse of the Pacific, till it is turned off by Asia and Australia. A great division of its force is directed through the seas on both sides of the latter continent, and so on through the Indian Ocean, and round the Cape of Good Hope, till it reaches the free expanse of the Atlantic, across which it proceeds in the same manner as across the Pacific. The current of the Atlantic strikes the coast of Brazil, and breaks at Cape St. Augustine into two divisions, one of which proceeds round Cape Horn into the Pacific, while the other advances through the Caribbean Sea, and so on into the Gulf of Mexico. This latter branch conspires, with the vast issue of fresh waters which pours into the Gulf of Mexico, to raise the level of that sea above that of the neighbouring ocean; and causing the surplus to force its way out between Florida and Cuba, produces the celebrated Gulf Stream which is perhaps the most powerful sea-current in the world.

It is obvious, that to the mariner currents must be of great importance. From Portugal, for instance, ships have sailed to the Bights of Benin, on the Guinea coast, being 150 leagues, in two days, though they could not return in less than seven weeks. It is also common for vessels to descend to the latitude of the Canary Islands, in order to get into the tropical current across the Atlantic, which carries them to America in a comparatively short time; it was by this current that Columbus was carried so smoothly on in his first voyage to the new continent. The Pacific, it is said, can be crossed in this way in about ten weeks, being at the rate of 1000 miles per week; and some mariners have expressed an opinion, that China might be reached by this route in less time than by the shorter course round the Cape of Good Hope.

For the same reason that the sea flows from east to west, the air has a tendency, when not counteracted by other causes, to move in the same direction. The earth in its motion leaves the air, like the sea, a little behind it; in other words, does not carry it so fast forward: hence what are called the trade-winds, which, operating in the same direction with the sea-currents, increase the facility of navigation to the westward in a very great degree. It is impossible to avoid remarking, that these natural phenomena, which, it is to be supposed, might have been counteracted or neutralized from the beginning, must have been designed for some end useful and necessary in the economy of the world. Perhaps, like the diffusive powers given to the seeds of certain plants, they were intended to aid in the dispersion of the human race over the globe. It is well known that population exists in many places, which appear cut off from all connection with others, by seas that must have been impassable by navigators in the early ages of their art. Men could only be drifted to such places in early ages by the currents of the sea and air; and thus the cultivation of large and important regions must have commenced much earlier than would have otherwise been the case.

Besides the grand equatorial or tropical current, there is one of a less decided character from the poles to the equator. The sea under the tropics evaporates to a greater extent than elsewhere, by the influence of a vertical sun. The vapours are apt to proceed towards the north and south, where they descend in rain. A surplus of water is thus produced in the high latitudes, which naturally flows back towards the equator. Hence a constant but comparatively slight flow from the north and south towards that warmer region of the earth. Under the influence of this stream, large masses of ice are constantly becoming detached from the polar stores, and drifted to the tropics. In some of the bays on the north side of Iceland, this frigid substance comes in vast quantities, insomuch as to choke them up to the depth of 500 feet. What is still more strange, these masses of ice are sometimes mixed up with trees, some of which are known to be the produce of the torrid zone in America; this is accounted for by the action of the northern division of the great current which parts at Cape St. Augustine. That northern division, after rushing into and out of the Gulf of Mexico, proceeds northward to Newfoundland, and thence at a high latitude returns athwart the Atlantic, finally sweeping along the western coasts of Europe, and rejoining the current which gave it its first impulse. By this current, it is supposed, American timber may easily be carried to the northern shores of Iceland.

The operation of the tides is less observable in the great currents we have alluded to than in those which prevail in the more secluded seas. The abstraction of water from a secluded sea by the recess of the tide, and the rush inwards produced by its flow, are sufficient of themselves to cause very impetuous currents, more particularly in the narrow channels by which the inland seas are connected with the ocean. We find it stated, in a pamphlet respecting the condition of the Orkney islands, that the Pentland Firth, which separates the continent of Great Britain from Orkney, "has no fewer than four-and-twenty contrary currents of the tide at the flood of spring, besides numerous sets and eddies, which, under the local names of *wells*, *swelches*, and *roosts*, boil more madly on the Orcadian shore than ever did witch's caldron on the kindred coast of Norway, if we may believe old tradition and Bishop Pontoppidan. 'The Boar of Papa,' at the opposite extreme of Orkney, is another terrible tide; when he gets a vessel in his tusks, he shakes the masts out—an operation which, in the country phrase, goes by the name of *hackling*." The contrariety of influences which are sometimes brought into play by polar and equatorial currents, and those produced by the tides, occasion many phenomena extremely perplexing, and sometimes very dangerous, to the navigator. In the Cattegat, by which the Baltic is connected with the German Ocean, one current always goes in by the side next Jutland, while another issues forth by that nearest to Sweden. In like manner, a current seems to proceed along the eastern coast of Britain towards the south, while another, flowing in an opposite direction, advances along the coast of Holland. What is still more curious, under-currents are sometimes found going in a contrary direction to those upon the surface. At the Straits of Gibraltar, it is said there is always a surface current going in, as if to supply a want in the Mediterranean, while, at a certain depth, there is another going out. So strong and so steady is this contrariety in the Caribbean Sea, that a boat may be moored by dropping a heavy substance to a certain depth; the upper current impels the boat one way, while the under one draws the sunk object another, and between the two the boat is steadied.

Two currents of equal force, but of different directions, meeting in a narrow passage or gut, will cause a whirlpool, a phenomenon which has ignorantly been said to be produced by subterranean rivers, gulfs, chasms, &c., but essentially is only an eddy, produced by the contact of two currents meeting on a centre. The whirlpool named the Euripides, near the coast of Greece, alternately absorbs and rejects the water seven times in twenty-four hours. Charybdis, in the Straits of Sicily, absorbs and rejects the water thrice in twenty-four hours; and the Maelstroem, on the coast of Normandy, which is considerably the largest, absorbs, every six hours, water, ships, whales, in short, every thing that approaches its malignant influence, and the next six hours is employed in casting them up again. These eddies are sometimes augmented by the force of contending tides, or by the action of the winds. They draw vessels along, dash them upon rocks, or engulf them in their furious vortices, the wreck not appearing until some time after.

WATERSPOUTS.

Marine waterspouts are caused by the action of atmospheric currents, and are as dangerous in their effects as they are wonderful in appearance. Malte-Brun thus describes them:—"Underneath a dense cloud, the sea becomes agitated with violent commotions; the waves dart rapidly towards the centre of the agitated mass of water, on arriving at which they are dispersed into aqueous vapours, and rise whirling round in a spiral direction towards the cloud. This conical ascending column is met by another descending column, which leans towards the water, and joins with it. In many cases the marine column is from fifty to eighty toises (fathoms) in diameter near its base. Both columns, however, diminish towards the middle, where they unite; so that here they are not more than three or four feet in diameter. The entire column presents itself in the shape of a hollow cylinder or tube of glass, empty within. It glides over the sea without any wind being felt; indeed, several have been seen at once following different directions. When the cloud and the marine base of the waterspout move with unequal velocities, the lower cone is often seen to incline sideways, or even to bend, and finally to burst in pieces. A noise is then heard like the noise of a cataract falling in a deep valley. Lightning frequently issues from the very bosom of the waterspout, particularly when it breaks; but no thunder is ever heard."

Sailors, to prevent the imminent danger which their vessels would be exposed to by coming in contact with these tremendous columns, discharge upon them a cannon ball, which, passing through them, causes them invariably to burst, and, consequently, removes all chance of injury connected with them. This phenomenon is accounted for in the following manner:—Two winds meet—a vortex ensues: any cloud which happens to lie between them is condensed into a conical form, and turned round with great velocity: this whirling motion drives from the centre of the cloud all the particles contained in it; a vacuum is thereby produced, and water or any other body lying beneath this vacuum is carried into it upon the usual and well-known principle. The cannon ball, breaking this cylinder, which is always partly hollow, causes it to fall to pieces, in the same manner as a touch upon the surface of a soap-ball reduces the resplendent mass to a drop of common water.

TEMPERATURE OF THE SEA.

The temperature of the sea, like that of the air, is liable to be affected by the latitude and the season of the year, but not to nearly so great an extent as the air Within the tropics, where the season has hardly any influence, it is generally found at about 80 or 81 of Fahrenheit's thermometer, being somewhat more, in general, than the warmth of the neighbouring air, which is deprived to a certain extent of its heat, in order to carry on the process of evaporation. Taking the month of March as one of those during which the heat of the sun must be equally determined in both directions by latitude, we find that in that month the sea has been found, at 11° 32′ south, of 80·6 Fahrenheit; at 31° 34′ south, of 75·7; at 40° 30′ south, of 59·9; though in some instances it has been found several degrees more or less at the same season, and under nearly the same latitude. The chief cause of the variation is the perpetual flow of water from the poles to the equator, which has been already explained. It has been pretty nearly ascertained, that, in the tropical seas, it ranges about 9 degrees of Fahrenheit; in the middle of the temperate zone about 12; and after that, decreases with a more rapid and more equable gradation. The temperature of the sea is also affected by its depth. In deep seas between the tropics, the heat diminishes towards the bottom; while, in more frigid latitudes, it is sometimes observed to become warmer. The sea is a bad conductor of heat; the solar rays can only penetrate about three hundred feet below the surface, nor does the light descend any farther. A small difference is discovered between the observations on temperature in the two hemispheres. For the first 25° towards the south, the decrease of heat is slower, and after that more rapid, than towards the north.

It must be evident to every one who considers the great mass of waters composing the ocean, and the interchange of position which must always be taking place, to a greater or less extent, between the upper and warmer parts and the lower and colder, that this comparative equability of temperature is unavoidable, even if there were no other causes to account for it. The uses of that equability are still more obvious, and must add greatly to the wonder we always experience when the economy of nature is minutely traced. By this equability, the natural result of high latitude is mor[illegible] less corrected, for the advantage of the human be[illegible] who happen to be so placed. A milder air breath[illegible] n the sea softens the climate all over the adjacent land, and produces a freshness which is of the greatest service to vegetation. On the other hand, in those torrid regions where both animated and vegetable nature is apt to sink beneath the vertical rays of the sun, the cooling breath of the ocean comes, generally at fixed times, reviving the parched soil, and communicating to man sensations of relief and pleasure, which are hardly to be imagined by those who have not experienced them.

SALINE PROPERTY OF THE SEA.

The saline property of the sea has never been scientifically accounted for; it baffles all human investigation. Some have alleged that it is caused by fossil or rock salt at the bottom, but for this there is neither proof nor probability. The most reasonable conclusion is, that the sea is a homogeneous salt body; that its waters were created, and have continued, and ever will continue, in this saline condition, in the same manner that the atmosphere has been created and exists as a compound body. The inquiry, therefore, why the sea is salt, is just as needless as why the atmosphere is composed of two or three gases. The two questions are equally shrouded in mystery. "The proportion which the saline matters bear to the water varies considerably. The water of the Atlantic Ocean, within the tropics, contains about one twenty-fourth of its weight of saline matters. There, from the great heat, very great evaporation must go on at the surface; and from the great mass of water, particularly far out at sea, the influence of rivers in counteracting the effect of the evaporation, by adding fresh water, must be less than usual. In the Firth of Forth, the saline matters form only one-thirtieth of the weight of the water. There less fresh-water is removed by evaporation, the climate being much colder; and the fresh water supplied by rivers is greater in proportion, so that the salt matters bear a smaller proportion to the whole. There are chiefly four matters (continues our authority*) contained in sea-water, common salt (muriate of soda), glauber salt (sulphate of soda), muriate of magnesia, and muriate of lime. Potash has been detected in sea-water; and it also contains extremely small quantities of two simple substances lately discovered, namely, iodine and bromine, in union with hydrogen. Disregarding all except the four first, the composition of the water of the Atlantic Ocean, as analysed by Dr. Marcet, may be stated as follows. The quantity examined was 500 grains

"Water,	478·420
Muriate of soda,	13·3
Sulphate of soda,	2·33
Muriate of lime,	0·995
Muriate of magnesia,	4·055
	500 grains."

Thus, it is seen that muriate of soda or common salt is the principal solid ingredient in the waters of the ocean, and that muriate of magnesia is the next in importance. Sea-water is to a certain degree more dense, or of greater specific gravity, than pure water. According to Dr. Arnot, "a ship draws less water, or swims lighter, by one thirty-fifth, in the dense salt water of the sea, than in the fresh water of a river: and for the same reason, a man swimming supports himself more easily in the sea than in a river." Sea-water freezes at 28° of Fahrenheit's thermometer. Fresh water, as is well known, expands equally in its volume, 8° above or below 40°, that is to say, it expands by an increase of temperature up to 48°, or by a diminution of temperature down to 32°, the common freezing point, when it assumes the crystallized or icy form. Thus 40° is the point of mean density, or of smallest volume, in fresh water. By the recent experiments of chemists, it is found that sea-water does not expand by a diminution of temperature down to 32°, because it is reluctant to assume the crystallized form, and when it does freeze at 28°, its ice is very imperfect, being full of pores and interstices, and composed in a great degree of thin spicular flakes, enclosing drops of a strong briny liquid which cannot be crystallized.

Sea-water, on being boiled, or exposed in small quantities to the sun's rays, evaporates, and leaves a residuum of common salt; and the manufacture of this article, by means of pans and furnaces, is carried on upon the shores of almost every civilized country. Innumerable have been the attempts to render sea-water useful as an element of food or drink, in cases of great scarcity of fresh water on shipboard, but in no case has a perfectly pure or sweet water been procured. Filtration has no effect, because the saline matters in the water are chemically united with it, and cannot be removed by means merely mechanical. The process of purifying the water to the best advantage consists in distilling it, the vapour being gathered and condensed into a liquid. But this liquid is not entirely fresh or sweet, in consequence of its containing certain gaseous matters: and therefore, after distillation, the liquid should for a length of time be exposed to the action of the atmosphere, so as to allow the escape as far as possible of the gases with which it is charged. A small quantity of potash or soap put into the water previous to distillation, is said to be useful in purifying it and rendering it more palatable. The following plan for procuring fresh water at sea, in a case of emergency, was pursued by a Captain Chapman, when sailing off the north coast of Finland. By accident he lost nearly all his water; and while thus circumstanced, a gale of wind arose, which blew hard for three weeks, and drove him far out to sea. The Captain was in great anxiety. The water in the ship would last but a short time, and he had no still on board. But necessity, the mother of invention, aided him in contriving one. By means of an old pitch-pot, with a wooden cover, and a pipe made of a pewter plate, and a cask for a receiver, he commenced operations. He put seven quarts of sea-water and an ounce of soap into the pot, and placed it on the fire. As soon as the pot boiled, the condensed vapour began to flow through the pipe into the receiver. In half an hour he obtained a quart of fresh water. This water, though not very palatable, answered for all necessary purposes. He kept the still constantly at work, and got a gallon of water every two hours. And thus the crew was saved from great suffering, if not from actual death.

PHOSPHORESCENCE OF THE SEA.

Every one who has been at sea, and observed the action of the waters at night, must have less or more remarked certain luminous appearances in the waves. Accounts of the phosphorescence of the sea may be found in the narrative of almost every voyager. The following description is given by Mr. Stewart, in his Journal of a Residence in the Sandwich Islands:—"The exhibitions of the day have been followed at night by a phosphoretic scene of unrivalled splendour and sublimity. We had often before observed luminous points, like sparks of fire, floating here and there in the furrow of our vessel, but now the whole ocean was literally bespangled with them. Notwithstanding the smoothness of the surface, there is a considerable swell of the sea; and sparkling as it did on every part as with fire, the mighty heavings of its bosom were indescribably magnificent. It seemed as if the sky had fallen to a level with the ship, and all its stars, in tenfold numbers and brilliancy, were rolling about with the undulations of the billows.

"The horizon in every direction presented a line of uninterrupted light, while the wide space intervening was one extent of apparent fire. The sides of our vessel appeared kindling to a blaze, and as our bows occasionally dashed against a wave, the flash of the concussion gleamed half way up the rigging, and illuminated every object along the whole length of the ship. By throwing any article overboard, a display of light and colours took place, surpassing in brilliancy and beauty the finest exhibition of fire-works. A charming effect was produced by a line coiled to some length, and then cast into the water at a distance, and also by a bucket of water dashed from the side of a vessel. The rudder, too, by its motions, created splendid coruscations at the stern, and a flood of light, by which our track was marked far behind us. The smaller fish were distinctly traceable by running lines showing their rapid course, while now and then broad gleamings, extending many yards in every direction, made known the movements of some monster of the deep. But minuteness will only weary without conveying any adequate impression of the scene: it would have been wise, perhaps, only to have said that it was among the most sublime nature herself ever presents.

"The cause of this phenomenon was long a subject of speculation among men of science, but is now satisfactorily ascertained to be a sea animalcule of the luminous tribe, particularly the species *Medusa*. The *Medusa*

*Chemistry of Nature, by Hugo Reid. Edinburgh, 1837.

pellucens of Sir Joseph Banks, and the *Medusa scintillans* of Mr. Macartney, emit the most splendid light. The degree and brilliancy of the exhibition are supposed to depend on the state of the atmosphere and sea. A more grand display than that which we have witnessed probably seldom if ever takes place."

This phenomenon has been ascribed to various causes, but the explanation presented by Mr. Stewart is the one now most generally admitted. The little animal by which this light is produced is sometimes called *the glow-worm of the sea*. This animal is exceedingly small, thin, and transparent, and, like the fire-fly, with which we are well acquainted, emits a brilliant light. The sea contains many animals of this nature, of different species. The *Medusa* have little antennæ or horns, from which they dart a strong light, while the rest of their body remains in obscurity. All the zoophytes appear to be in a greater or less degree phosphorescent. Some accurate observers have also thought, that in addition to this *glow-worm* light, there is a luminous appearance originating from the decomposition of vegetable and animal substances, similar to the phosphorescence of rotten wood.

THE COLOUR OF THE SEA.

The water of the sea is colourless when examined in small quantities, but when viewed in the mass in the wide ocean, it appears to be of an azure or blue tint. The cause of this generally blue colour of the deep sea has not been as yet clearly explained; but it seems to be in some degree accounted for by reference to certain principles connected with the science of optics. Probably most are aware that light consists of the set of colours which we see so beautifully displayed in the rainbow. Now, it is a law of light, that when it enters any body, and is either reflected or transmitted to the eye, a certain portion of it, consisting of more or less of its colours, is lost in the body. The remainder, being reflected, strikes our visual sense, and whatever colour that may be, the object seems of that colour. Now, it chances that the portion of light most apt to be reflected from masses of transparent fluid is the blue; and hence it is, or supposed to be, that the air and sea both appear of this colour.

While there can be no doubt that the ocean is generally of a blue colour, it is equally certain that there are many portions of sea in which a different hue appears. The causes of these exceptions from the rule seem to be of various kinds. Frequently, the ordinary colour of the sea is affected by the admixture of foreign substances, these being sometimes of a living and organic nature, and sometimes the reverse. The most simple example of the latter class of cases is the common flooding of any stream, when quantities of mud and earthy particles are introduced into the river, and emptied into the sea. What is thus strikingly seen on every coast, on a small scale, will readily be conceived to be of infinitely wider extent in the mighty rivers of the principal continents of the globe. Some seas are coloured *yellow* from a similar cause. Vegetable matter is known to have a colouring effect; but more usually the peculiar tint of the sea results from an infusion of animals of the infusoria tribes. Another class of cases in which the ocean appears to be tinged with a peculiar colour, is referable to the reflection of rays of light from the bed or bottom; and hence, in shallow and clear seas, the colour of the ground is a main cause for any particular tint which the water assumes to the eye.

WINDS—TRADE-WINDS.

A change in the temperature, a diminution of the vapour, or any other cause that may occasion a portion of the surrounding atmosphere to contract or expand, will give rise to the aërial currents denominated winds which, indeed, bear a strong analogy to the currents which occur in the ocean. When the air by which we are surrounded becomes heated, it expands, and becomes specifically lighter, in consequence of which it mounts upwards, and the colder and denser air which surrounds the mass thus rarified rushes in to supply its place. When, also, a condensation of vapour in the atmosphere suddenly takes place, giving rise to clouds which speedily dissolve in rain, the temperature of the surrounding air is sensibly altered, and the colder rushing in upon the warmer, gives rise to a sudden gust of wind. For this reason, a cold heavy shower passing over head, with a hasty fall of snow or hail, is often attended with a violent and sudden gust of wind, which ceases when the cloud disappears, but is renewed when another cloud, sweeping along in the same direction, brings with it a fresh blast. Accordingly, a whistling, or howling, or noise of the wind, is universally considered to be a prognostic of rain, because it indicates that a change is taking place in the temperature of the atmosphere, owing to the vapour in its higher regions being condensed into rain-clouds.—(See article METEOROLOGY.)

The most remarkable winds are those which traverse the ocean steadily in one direction, and are called "trade-winds," from their use in mercantile navigation. An explanation of their cause is given in the article METEOROLOGY. The external limits of the trade-winds are 30 degrees north and 30 degrees south of the equator; but each limit diminishes as the sun advances to the opposite tropic. The larger the expanse of ocean over which they sweep, the more steadily do they blow; accordingly, they are more steady in the Pacific than in the Atlantic, and in the South than in the North Atlantic Ocean.

Sea and Land Breezes.—In most countries near the shores of the sea, but particularly in tropical climates, there are periodical winds called sea and land breezes, of which the navigator takes advantage. The cause of the occurrence of these winds is described in the article METEOROLOGY.

Hurricanes.—The most dangerous winds to the navigator are those which occur in sudden gusts, or squalls, and for the approach of which the sharpest outlook is required. When the squall is in the form of a violent tempest, accompanied by rain, lightning, and thunder, it receives the name of a hurricane. Hurricanes occur most frequently and with the greatest violence in tropical climates; because, in consequence of the very great heat which there prevails, the rarefaction of the air, and also the condensation of the vapour it contains into rain-drops, take place more suddenly and completely than in more temperate regions. By this means the electricity of the atmosphere—that subtle fluid which seems to pervade all bodies, and which universally seeks its own equilibrium—is disturbed, and no longer maintains an equal distribution through the aërial vapour. It accumulates in vast quantities in one mass of vapour or cloud, while in another it is deficient; and consequently, to regain its equilibrium, it flashes in the form of lightning from the surcharged cloud to the cloud that is undercharged, or to the earth itself. Hence hurricanes are always attended with electrical manifestations, which add greatly to the horrors of the spectacle. Hurricanes commence in various ways: sometimes from a single and small cloud, which suddenly expands, overspreading, as with a dense shroud, the whole heavens; and sometimes from a slowly gathering mass of clouds which appear to be irradiated with electric fire. The West Indies, the Isle of France, and the kingdoms of Siam and China, are the countries which are most subjected to the ravages of hurricanes. In the West Indies they most frequently occur in the month of

August, and the Indians, from their experience, originally taught our planters the signs by which their approach may be prognosticated. All ordinary signs, however, may prove delusive; and the best of all prognosticators of storms is the marine barometer, an instrument whose services are of incalculable value.

Calms—Breezes.—"After a storm comes a calm," is an old proverbial expression. The fury of the tempest expends itself, and in all likelihood there shortly after ensues a state of tranquillity, though several days may elapse before the "swell," or heaving agitation of the sea, subsides. When both the atmosphere and the waters are tranquil, the surface of the ocean is beautifully calm, and almost as smooth as the glassy surface of a lake. But a perfect or dead calm, if of any continuance, is almost as disagreeable to the navigator as a driving tempest. The ship makes no progress in its course; the sails are useless; and there are no means of removing from the dull and distressing scene. Fortunately, dead calms are not generally of that continuance which leads to any serious result. A gentle breeze begins to steal upon the extended face of the deep, and the hitherto unruffled surface of the waters begins to show a slight tremulous ruffling, technically called the *crow's foot*. Sailors have a superstitious, and of course foolish belief, that whistling in a calm will bring up a breeze, and this they do with a drawling and beseeching intonation on some prominent part of the vessel.

THE ARCTIC SEAS.

The seas within the arctic circle, at the north or south pole, exhibit some remarkable appearances. In the coldest season, the air deposits its moisture in the form of a fog, which freezes into a fine gossamer netting, or slender icicles, dispersed through the atmosphere, and so extremely minute that they seem to pierce and excoriate the skin. The hoar-frost settles profusely in fantastic clusters on every prominence. The whole surface of the sea steams like a lime-kiln, an appearance called the *frost-smoke*, caused, as in other instances of the production of vapours, by the waters being still relatively warmer than the incumbent air. At length the dispersion of the mist, and the consequent clearness of the atmosphere, announce that the upper stratum of the sea itself has become cooled to the same standard; a sheet of ice quickly spreads, and often gains the thickness of an inch in a single night.

The most appalling phenomenon of these dreary regions is the floating of huge masses of ice, called icebergs, which are formed from the water of the melted snow on the nearest coasts; little by little the incrustations on the shores and cliffs increase to the size of mountains, and these being torn from their fastenings by winds or their own great weight, are swept off into the ocean, where they accumulate by the falling of snow, and finally resemble great islands. These float southwards, and are the terror of navigators. Not unfrequently do the regular packets from Liverpool to the United States fall in with these floating islands, and vessels in the night have been dashed to pieces by driving against them. They are carried towards the Atlantic by the current, which generally flows from the north-east; and after they reach the warmer water of the lower latitudes, they rapidly dissolve, and finally disappear probably in the space of a few months.

WAVES.

The waves of the ocean are various in figure and dimensions, according to the force and direction of the winds, contending currents, and other causes. The best account we have of the theory of waves, is that given by the learned Dr. Arnot, in his work, "The Elements of Physics," from which we may quote a few passages. "The common cause of waves is the friction of the wind upon the surface of the water. Little ridges or elevations first appear, which, by continuance of the force, gradually increase, until they become the rolling mountains seen where the winds sweep over a great extent of water. In rounding the Cape of Good Hope, waves are met with, or rather a swell, so vast, that a few ridges and a few depressions occupy the extent of a mile. But these are not so dangerous to ships as a *shorter* sea, as it is termed, with more perpendicular waves. The slope in the former is so gentle, that the rising and falling are scarcely felt; while the latter, by the sudden tossing of the vessel, is often destructive. When a ship is sailing before the wind, and riding over the *long swell*, she advances as if by leaps; for while each wave passes, she is first descending headlong on its front, acquiring a velocity so wild that she can scarcely be steered; and soon after, when the wave has glided under her, she is climbing on its back, and her motion is slackened almost to rest before the following wave arrives.

"The velocity of waves has relation to their magnitude. The large waves, just spoken of, proceed at the rate of from thirty to forty miles an hour. It is a vulgar belief that the water itself advances with the speed of the wave, but in fact the *form* only advances, while the *substance*, except a little spray above, remains rising and falling in the same place, with the regularity of a pendulum. A wave of water, in this respect, is exactly imitated by the wave running along a stretched rope when one end is shaken; or by the mimic waves of our theatres, which are generally undulations of long pieces of carpet, moved by attendants. But when a wave reaches a shallow bank or beach, the water becomes really progressive, for then, as it cannot sink directly downwards, it falls over and forwards, seeking the level. So awful is the spectacle of a storm at sea, that it is generally viewed through a medium which biasses the judgment; and lofty as waves really are, imagination pictures them loftier still. Now, no wave rises more than ten feet above the ordinary sea-level, which, with the ten feet that its surface afterwards descends below this, give twenty feet for the whole height, from the bottom of any water-valley to an adjoining summit."

SHIPS.

Ships are vessels of a certain size adapted for sailing on the ocean, and the ingenuity of their construction is one of the proudest triumphs of human skill. Of the early history of ship architecture little can be said of any importance. The buoyant property of water, particularly that of the sea, must have been soon observed by mankind; and, therefore, beginning with rude skiffs and canoes, they would in time acquire sufficient experience and skill to form vessels of a larger size, and to guide them in the required direction by means of rudder and sails. The cultivated nations of antiquity, Egyptians, Carthaginians, Phœnicians, and others, possessed ships for commerce and war, some of which were of large dimensions, and moved either by rowers or by the action of the wind on the sails. But of these early ships it is unnecessary here to speak, and we proceed to notice the construction and character of vessels formed according to the principles of modern and improved science.

The nicest and most difficult operation in ship-building consists in first forming a draught or model of the proposed vessel, or, as we may call it, the *plan*, which, the mechanics are to adopt and follow out. In forming this plan, the designer is governed by a consideration of the precise object to be attained. There are two classes of vessels—ships of war and merchantmen—and each must possess certain qualifications. In a ship of war the great object is speed, with ease of movements, and capacity to accommodate her crew, and carry a sufficient weight of guns, stores, and provisions. One point, moreover, is especially to be looked to; this is, that the ship float high enough above water to run no risk of receiving waves or seas in her lower ports during action, when these holes must be necessarily open. In order to be secure of this, the constructor makes an estimate of the whole weight of the ship, including body, spars, armament, men, and munitions, and must so model the bottom that it will have displaced an equal weight of water when arrived at the desired depth. In the case of merchantmen, the primary consideration is to attain the greatest capacity to carry cargo, combined, as far as possible, with safe and easy movements and rapid sailing.

The English excel in ship-building, but in some respects they are outdone by the Americans, whose packet ships carry enormous weights, while they are noted for their extreme speed. Among the admitted and well-established principles of construction is the leading one, that the greatest breadth must always be before the centre, and consequently the bow or front be more blunt than the stern or hinder part. Abstractly, it would seem most important that the bow should be the sharpest, so as to cleave the water with the least possible resistance; but experience has proved that it is far more essential to facilitate the escape of the displaced water along the side of the vessel; for when once a passage is opened for the ship, the fluid tends to reunite behind the point of greatest breadth, where, instead of offering resistance, it presses the ship forward, and fills up the space constantly opening behind her. The principle is evident in the form of the duck and other aquatic animals, which are uniformly broadest in front, and gradually diminish to the tail. As it is, then, less essential that a ship should be sharp forward than aft, there is a further advantage in having the bow full towards the edge, that it may check her in descending into the waves, not abruptly, but gently; pitching, or rising and falling endwise, being the most dangerous to hull and spars of all a vessel's movements. Though sharpness towards the stern-post is vitally essential to fast sailing, yet care must be taken to leave the buttock full towards the surface, in order to check the stern gently in descending, and when scudding before a gale, to lift it in timely season, on the arrival of a sea. To hit the exact mean in these respects, so as not to retard the sailing on the one hand, nor to endanger the ship on the other, requires all the skill of the architect.

There must likewise be a due correspondence between the general bulk of the vessel and its length and breadth; the whole must be properly proportioned. If unduly long, speed may be gained, but there is a difficulty of turning, and also of rising to escape the breakings of the sea; long ships, therefore, are apt to roll and go through waves instead of breasting them, by which their safety is perilled. When a ship is unduly short for its general bulk, it is apt to pitch, which is equally dangerous, and hence the greatest care is required to proportion the various dimensions.

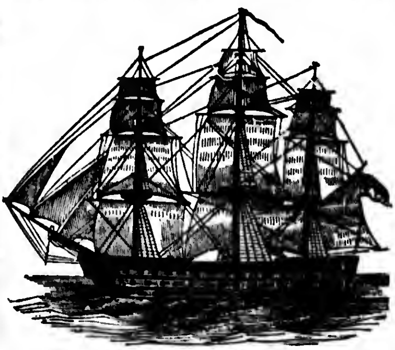
All essential preliminaries being settled, the ship is begun to be constructed; and this is always done in the yard of a ship-builder, close by the water's edge. The wood considered to be best adapted for ship-building is oak, pine, teak, elm, or beech, and whichever is employed, it requires to be strong, well-seasoned, and dry; the greater part, likewise, should be bent or crooked, to suit the curves and angularities in the structure; and for this end growing timber is often constrained to assume particular forms. The keel, which is the lowest part of the vessel, and corresponds to the back-bone of an animal, from which the ribs spring, is formed and laid first on a slip and blocks set for the purpose. As the framework proceeds, all parts are firmly bolted and riveted together, and the whole is finally covered with the planking in even lines from bow to stern. When it is necessary to bend a plank for either the bow or stern, it is heated by steam, and then forced into its place by screws and levers. The planks are fastened to the ribs by wooden pins, and the plan is followed of allowing a seam or space between each plank, which is filled up or calked with oakum, and the whole is smeared with pitch. In some instances, the bottom is further secured by sheathing it in sheets of copper. Meanwhile, the interior beams and partitions have been placed; and when duly prepared, the vessel is *launched*, or shot by an easy movement down the inclined plane on which it rests into the water. After launching, the rudder, or helm, is shipped. The rudder is a wooden apparatus placed at the stern of the ship, a large portion being in the water, and by means of it the vessel is steered and turned about at pleasure; the steering part of the apparatus is on deck, and consists of a wheel placed perpendicularly and connecting chains and pulleys. The principle on which the rudder acts is very simple: the object is to turn the vessel, and to whatever side the inclination is to be made, the rudder is caused to present an obstacle to the water in that direction. The masts of the vessel are now set; and the spars, comprehending the bowsprit and yards, and also the rigging are attached. The spars of a ship are not abandoned to their own unsupported strength, but are sustained by what is called the *standing rigging*. Besides this, there is the *running rigging*, which consists of the tacks and sheets that serve to spread the sails, the halyards, traces, lifts, clewlines, and all other ropes used in making, taking in, or manœuvring the sails.

The sails of a ship are square sheets of canvas bent to the yards, and fore and aft sails traversing on stays or bent to gaffs. Let us proceed to describe an entire suit of sails, beginning forward. On the extremity of the bowsprit is the flying-jib, a three-cornered sail, which goes from the end of its boom upward along its stay, leading to the fore-topgallant-mast-head, and confined to the stay by rings of wood or iron, called the *hanks*. It is hoisted by means of the halyard; hauled down by a downhaul; and when up, is trimmed to hold the wind by a sheet or rope leading to the forecastle. The jib, which leads from its boom to the fore-top-mast-head, is of similar form, and so is the fore-top-mast-stay-sail, running from the bowsprit end towards the mast-head. On the foremast we have the fore-sail, bent to the foreyard, and spread at the foot by means of tacks and sheets; Above it, the fore-top-sail, bent to the top-sail-yard, by means of which it is hoisted aloft, while its lower corners are spread to the extremities of the fore-yard; next, the topgallant-sail, bent to its yard, and sheeting home to the top-sail-yard; and so with the royal and sky sail. All these sails are turned at pleasure, to be presented to the wind, by means of braces attached to their yard-arm, and leading to the main-mast. The main-mast is furnished with a similar suit of sails, somewhat larger; the mizzen-mast, also, though smaller than either, instead of a square-sail on the lower part of the mast, has a gaff sail, hoisting up or down abaft the mast. Some ships have similar gaff-sails on the fore and main-masts, which are found of great use in gales of wind, as a substitute for storm stay-sails. Most carry, also, light stay-sails between the masts; but they are very troublesome. Studding-sails, spread beyond the square sails like wings, are found useful when going before the wind. The perfection of equipping a ship with spars, rigging, and sails consists in so disposing them, that, in a whole-sail breeze the centre of effort of all the sails will be in the same line with the ship's centre of rotation; or that the efforts of the forward and after-sails to turn the ship will be exactly balanced, as not to require any continued assistance from the rudder in either direction.

The retarding apparatus of the vessel consists of heavy iron instruments called anchors, of which each vessel has usually more than one. Large ships carry the following suite of anchors:—1. The *sheet* anchor, which is the largest, and only used in the case of violent storms. 2. Two bower anchors, namely, the *best bower* and *small bower*, so called from their situation at the bows. 3. The *stream* anchor, the *kedge*, and *grappling*, or *grapnel*. The three last are often used for moving the ship from place to place in a harbour or river. Each anchor is let down by a strong cable of iron or rope, and is lifted by means of the windlass placed on deck. To the cable, when in the water, a *buoy* or floating object may be attached, to show where the anchor has been let down; and to save time, or in an emergency, the anchor and cable are sometimes left, while the vessel proceeds, the buoy serving to point out where the anchor may be recovered. The anchor is said to be *a-peak* when the cable is perpendicular between the hawse and the anchor; it is said to *come home* when it does not hold the ship; it is said to be *foul* when the cable gets hitched about the flukes. *Riding at anchor* is the state of the vessel when moored or fixed by the anchor. *Dropping* or *casting anchor* is letting it down into the sea. *Weighing anchor* is raising it from the bottom. We shall proceed now to notice the principal kinds of vessels.

War Vessels.

At the head of the list stands the ship proper, a vessel with three masts, called the fore, the main, and mizzen-masts, and which is square-rigged, or carrying large square sails. The largest ships are vessels of war, named line-of-battle ships, having three complete decks, and carrying 120 guns. A representation is given of such a magnificent floating apparatus in the accompanying figure. The decks are equivalent to different floors. On the first or



First-rate war-vessel.

uppermost, extending on each side of the fore-mast, is the *forecastle*, and next to it, between the fore-mast and the main-mast, are the *waist* and *gangway*; between the main and mizzen masts is the *quarter-deck*; and next to it, towards the stern, is an elevated part called the *poop*. A narrow passage on each side of the vessel, communicating from the quarter-deck to the forecastle, is called the *gangway*, and in nettings above it the seamen's hammocks are stowed as a protection during action.

The forecastle is appropriated to the best or able-bodied seamen, the quarter-deck is the proper situation for the officers, and in the poop are stationed the marines. The quarter-deck is a privileged spot, and as, by a fiction, the sovereign is supposed to be present, every one who enters this deck must salute it by touching his hat, and all present return the compliment by touching their hats likewise. Beneath the poop are the apartments of the captain, and some others. Descending from the upper range of decks, we arrive at the *main-deck*, at the fore part of which is the sick-ward, and next to it the *galley* or cook's room; at the after part, beneath the captain's cabin, is the admiral's cabin. The next, or third range of deck is the *middle-deck*, at the fore part of which is the *ward-room*, or general apartment for the officers. The fourth range is the *lower-deck*, where the sailors sleep and mess, and on which, also, is the *gun-room*, for inferior officers. On all the decks mentioned, cannon or large guns are ranged, each having its appropriate port-hole; and by these holes, on which temporary windows are fastened, light is admitted to the interior. We now descend to a floor beneath the surface of the water, which is called the *orlop-deck*, on which, between the main and mizzen-masts, is the cock-pit, or surgeon's room; the purser's, boatswain's, and carpenter's berths, and midshipman's mess-room. Beneath the orlop-deck is the *hold*, a species of cellar in divisions, containing the boatswain's and carpenter's stores, the powder magazine, shot, the water-casks, and provision stores.

War vessels receive their designations from the number of their decks, or of the guns which they carry. Line-of-battle ships are of various *rates*. The *first*-rates include all carrying 100 guns and upwards, with a company of 850 men and upwards; *second*-rates carry 90 to 100 guns, and from 650 to 700 men; and *third*-rates carry from 60 to 80 guns, and from 600 to 650 men. The rates thus diminish in bulk and complement of men down to sixth-rates. A common rate is a 74 gun-ship, which carries 600 men. The following is a list of the titles and number of the crew of a first-rate ship, classed in the order of their amount of pay:

Captain,	1	Brought forward,	106
Lieutenants,	8	Coxswain of Pinnace,	1
Master,	1	Sailmaker's Mate,	1
Chaplain,	1	Caulker's Mate,	1
Surgeon,	1	Armourer's Mates,	2
Purser,	1	Cooper,	1
Second Master,	1	Volunteers	12
Assistant Surgeons,	3	Gunner's Crew,	25
Gunner,	1	Carpenter's ditto,	12
Boatswain,	1	Sailmaker's ditto,	2
Carpenter,	1	Cooper's ditto,	2
Mate,	1	Yeoman of Store-room,	1
Midshipmen,	23	Able Seamen, Ordinary ditto,	478
Master's Assistants,	6		
Schoolmaster,	1	Cooks' Mate,	1
Clerk,	1	Barber,	1
Master-at-Arms,	1	Purser's Steward,	1
Ship's Corporals	2	Captain's ditto,	1
Captain's Coxswain,	1	Captain's Cook,	1
Launch ditto,	1	Wardroom ditto,	1
Quartermasters,	12	Wardroom Steward,	1
Gunner's Mates,	5	Steward's Mate,	1
Boatswain's Mates,	8	Landsman,	1
Captains of Forecastle,	3	Boys,	31
Captain of Hold,	1		
Ship's Cook,	1	Total Seamen,	690
Sail Maker,	1		
Rope Maker,	1	Captain of Marines,	1
Carpenter's Mates,	2	Lieutenants,	3
Caulker,	1	Serjeants,	4
Armourer,	1	Corporals,	4
Captains of Maintop,	3	Drummers,	2
Captains of Foretop,	3	Privates,	146
Captains of Mast,	3		
Captains of After-Guard,	3	Total war complement of officers, seamen, and marines,	850
Yeoman of Signals,	1		
	106		

A number of the above officers and subalterns are not appointed to third or inferior rates. Latterly, engineers have been added to the list of men in the royal navy, intended for service in the steam marine; they take rank below carpenters.

The burden of a first-rate is from 2700 to 2800 tons; the length of the lower gun-deck is 205 feet 6 inches, and length of keel for tonnage 170 feet 6 inches, the upper decks being longer in proportion; the height from keel to midships from 50 to 60 feet. The guns are generally distributed as follows:—Forecastle, two 18-pounders and two 34 carronades; quarter-deck, two 18-pounders and fourteen 32 carronades; main-deck, thirty-four 32-pounders; middle-deck, thirty-four 32-pounders;

and lower deck, thirty 32-pounders and two 68 carronades. Total, 120 guns.

Ships of less than 44 guns are termed *frigates*. A frigate, of which the following engraving is a sketch, has

Frigate.

only one gun-deck beneath the quarter-deck, and beneath that lighted and ventilated partly by skylights and partly by small holes in the sides, is a deck appropriated to the men, officers, &c.

The following account of the organization and arrangements on board of war-vessels is abridged from a work entitled, "Two Years and a Half in the American Navy," by E. C. Wines, 1833. Though strictly applying to an American frigate, it is generally applicable to a similar vessel in the British navy. "Time on shipboard is divided into watches, and reckoned by bells. Hence you never hear the question, 'What's o'clock? but 'How many bells is it?' The twenty-four hours are divided into six equal portions, called watches. At the end of the first half hour of one of these portions, the bell is struck one; at the end of the second, two; and so on, till the series reaches eight, when it commences again. In the ship's journals, the dates are put down according to the common mode of reckoning time. The division of time into watches differs somewhat at sea and in port.

"Order is the first great rule on board a man-of-war, and that to which all others must bend. From day to day, from week to week, from month to month, and from year to year, the same stroke of the bell is followed by the same whistle, the same call, and the recurrence of the same duties. Every thing has its place, too, and must be kept in it. So true is this, that a person acquainted with the details of a ship, can lay his hand on a given object in any part of her as well in the dark as if a thousand suns were shining on it. To the same grand principle—ORDER—are to be attributed the numerous divisions and subdivisions of the officers and crew.

"At the head of the list of officers stands the captain, whose will is supreme; and from his decisions, for the time being, there is no appeal. He has a general superintendence over the affairs of the ship, and every order of a general nature must originate in him. No important alteration can be made without his knowledge and consent. It is his duty to take a general oversight of the officers' conduct; to see that they are guilty of no improprieties, and to punish such as are. He is responsible for the safety of the ship, both at sea and in port. If any business of a public nature is to be transacted with a foreign power, it falls of course into his hands. These are his duties in time of peace; in war he has still higher responsibilities.

"Next in rank come the wardroom officers, consisting, on board of a frigate, of six lieutenants, a purser, surgeon, chaplain, sailing-master, and lieutenant of marines. The first lieutenant is next in power to the captain; and though his station is less responsible, his duties are more laborious. He has a general supervision over the ship, and is to see that she is kept clean and in proper order. To this end he is obliged to inspect every part of her at least once a day, and report her condition to the captain. When the ship is put in commission, it devolves chiefly upon him to station the men, a business of the most laborious and difficult nature, requiring great patience, a discriminating judgment, and deep insight into the human heart. It is his duty to have the men frequently exercised at the guns; to regulate the expenditures of certain public stores; to take care that the men keep themselves clean and decently clad; to superintend the watering and victualing of the ship; and, in short, to see that all her multifarious and complicated concerns move on regularly and harmoniously. In coming to an anchor and getting under weigh, and when all hands are called to reef topsails, or for other purposes, he takes the trumpet. On him, more than on the captain himself, depends the comfort of the officers. In port, it belongs to him to grant or withhold permission to go ashore; and there are a thousand other ways in which, if he is a man of capricious or malignant disposition, he can gratify his whims or his spleen at the expense of the comfort and feelings of his fellow-officers.

"The other lieutenants are divided into watches, and take turns in performing the duties belonging to their station. The lieutenant on duty is styled in writing the officer of the watch, but is familiarly called the officer of the deck. Some of his duties are common at sea and in port, and others are peculiar to each of these situations. In both he is responsible for the deck while he has charge of it, and has also to take a general oversight of the ship. He must see that the men's rations are properly cooked, and that they have their meals at proper hours. The serving of the grog is also under his control. At sea, his duty is to sail the ship, keeping her on the course given her by the captain, and reporting to him any change in the wind, the discovery of land or strange sails, and any extraordinary occurrences. At night, he has the captain waked at stated periods, and the state of the weather reported to him. On receiving the trumpet, the first thing the officer of the deck does is to glance at the compass, the sails, the dog-vane, the sky, and the water, to discover the state of the ship, the wind, and the weather; and at the end of the watch, he must have a general account of the weather, and other matters which he may deem proper, inserted in the ship's log-book. The duty of the officer of the deck in port is to receive any supplies of water or provisions which may come alongside, to regulate the sending away of boats, to keep a look-out as to what is going on in the harbour, to report the arrival of ships, and any important occurrences to the captain, &c. The lieutenants are also officers of divisions, and frequently have to exercise the men at the guns, besides superintending the monthly issues of slops to their respective divisions.

"Next in rank to the lieutenants comes the sailing-master, whose duties are more comprehensive and arduous than those of any other officer. His supervision and responsibility extends to almost all the public stores in the ship, but particularly to the water, spirits, cables, and anchors. He reports the daily expenditures of water to the captain. It is his business to keep the ship's place, and report it at least twice a day to the commander, together with the bearings and distance of the port to which she is bound, or the nearest land desired to be made. Some commanders leave this entirely to their sailing-masters.

"There is no berth on board a man-of-war more comfortable than that of purser. He holds the keys of the strong-box; and though his regular salary is not much, his emoluments, arising from other sources, are considerable. All the provisions on board are committed to his charge, and the ship's accounts are all kept by him. His respon sibilities are very great, and heavy bonds are therefore justly exacted from him.

"The surgeon and his two assistants form the medical staff of a frigate. The assistant-surgeons form a distinct class of officers, ranking between the wardroom officers and midshipmen. In frigates and ships of the line they mess in the cockpit, but in all other public vessels in the steerage. The business of the staff is of course to take care of the sick, and perform such surgical operations as may be necessary. A daily journal is kept of the names, rank, diseases, and constitutional habits of all the sick on board, and also of the medicines administered to them. From the journal a report is made out and signed by the surgeon every morning, stating the names, rank, and diseases of the sick, and the number added to and taken from the list. This is handed to the captain. Another list, containing only the names, is placed in the binnacle for the use of the officer of the deck. Nothing will excuse either an officer or a man from duty, but the fact of his being registered on the sick list. A general review of the sick takes place every morning after breakfast. One of the assistant-surgeons inspects the ship's coppers every day, to see that no verdigris is allowed to collect upon them. It is the duty of the surgeon not only to attend to the sick, but also to recommend and enforce such precautionary measures as will have a tendency to prevent disease, and thus secure the general health of the officers and crew. On board of every war-vessel there is a chaplain, who conducts the Sunday services, and administers spiritual consolation to the dying. Of late, a schoolmaster has been added to the list of functionaries.

"The midshipmen may be called apprentice officers, and they require to learn certain duties of seamen. They are also useful by carrying messages from the officer of the deck to the captain, and in port one of them takes charge of every boat that leaves the ship. Towards noon, while at sea, they are obliged to go on deck with their quadrants, and take an observation. They have to work out the last day's run, and report the course, distance made good, and ship's place at noon each day, to the captain. They muster the crew when the watch is called at night. They are also required to keep a journal of the cruise, which is, however, only a copy of the ship's log. This is examined every few weeks by the commanding officer; and if it happens not to be written up when called for, the delinquent is generally punished by a curtailment of some of his indulgences. Five of the oldest midshipmen are master's mates; and their duties are more important and responsible than those of the others.

"The boatswain, gunner, carpenter, and sailmaker, form a distinct class of officers, called warrant-officers. The boatswain is charged with the rigging of the ship, and in port attends to squaring the yards. You may know him by his silver whistle, rattan cane, and, above all, by the ruddy hues of his countenance, and the odious vapours that issue from his mouth. The gunner has charge of the military stores, and, when all hands are called, of the main rigging. The carpenter is responsible for the stores belonging to his department, and superintends the caulking of the ship, and other work performed by his subalterns. The sailmaker is charged with the sails, hammocks, and generally all the canvas in the ship. At sea, he is obliged to go aloft on each of the three masts, examine the condition of the sails, and report it to the first lieutenant every morning before breakfast.

"The grand divisions of the crew are into petty officers, seamen, ordinary seamen, landsmen, and boys. This division has reference to rank; but there are others, into which considerations of this kind do not enter. Such are the military divisions, and the divisions into larboard and starboard-watches, into forecastlemen, fore, main and mizzentopmen, afterguard, waisters, &c.

"The petty or warrant officers are appointed by the commander, and may be degraded by him without the formalities of a court-martial. They are selected from among the most experienced and trustworthy of the seamen. They consist, on board of a frigate, of a master-at-arms, eight quarter-masters, four boatswain's mates, eight quarter-gunners, a boatswain's and gunner's yeoman, a carpenter and sailmaker's mate, an armourer, a cooper, cook, and cockswain.

"The highest and most responsible of the petty officers is the master-at-arms, who may be called the principal police-officer of the ship. He has charge of all the prisoners, and every morning makes out and hands to the commander a list of their names, with a specification of the crime for which each is confined, and the time when he was put in confinement. He has charge also of the berth-deck, and it is his duty to see that it is kept in good order. All property that falls in his way for which he cannot find an owner, is thrown into the 'lucky-bag,' the contents of which, if not finally claimed, are sold at auction.

"The office of quartermaster is one of some dignity and considerable importance. It is his duty to keep a look-out with his spy-glass for signals from other ships, and to report them to the officer of the deck and also to report to him all boats that come along-side, and all other movements and occurrences in the harbour, which he may deem of sufficient importance. One quarter-master is stationed at the wheel to steer the ship, and the others keep a look-out, as in port. When the log is thrown, they hold the minute-glass. All the colours and signals are under their charge.

"Boatswain's mates are an indispensable class of men on board of a man-of-war, but their office is the most invidious and least desirable of all. They have to perform all the flogging, and the men accordingly hold them in some degree of detestation. Each of the boatswain's mates has a silver whistle suspended from his neck, with which he echoes the orders of his superiors. The armourer is the ship's blacksmith. The cooper opens the provision barrels when their contents are wanted, and performs other matters in his line of business, when necessary. The duties of the cook are somewhat arduous, and it requires a good deal of patience and care to perform them acceptably to the crew. The meals must always be reported 'ready,' morning, noon, and night. At noon, when dinner is reported ready, the cook takes a specimen to the officer of the deck, who inspects it, to see that it is properly cooked.

"The above are the principal petty officers; and we now come to the rest of the crew, or seamen, who are of different classes. The first class consists of seamen, or able-bodied men, who are expected to be finished sailors; the next class are ordinary seamen; and after these are boys, who perform various useful offices, but chiefly as servants. The boys, and all others on shipboard, who do not keep watch, are called *idlers*.

"On board of a frigate there are six military divisions, one on the quarterdeck, one on the forecastle, three on the gundeck, and one on the berthdeck. The last is commander by the purser, and each of the others by a lieutenant. It is the business of those who compose the purser's division to pass up powder to the combatants. Every officer and man is included in one or the other of these divisions, and is stationed in a particular part of the ship. These are the stations for action, and are called general quarters. The crew is mustered and inspected at quarters always once, and on board many of our ships twice a day. There are ten or twelve men to each of the guns in a broadside, called first and second captains, spungers, loaders, powder-boys, &c. On the intimation being given, the boarders run for their caps, and every man seizes a cutlass. At the first tap of the drum, there is a general rush throughout the ship, and before the music has ceased, you may hear the midshipmen of the divisions calling over the names, George Bell—first captain, sir—James Anderson—second captain, sir—William Stokes—powder-boy, sir—and so on. Having called the names, the midshipmen report to the officers of their divisions, the officers of the divisions to the first lieutenant, and he again to the captain. Should the order be given to retire, another rush takes place, the cutlasses and boarding-caps are returned to their places, and the men, as the case may be, proceed to their daily labours or their evening diversions. All this is but the work of a moment. Sometimes the call to quarters is beaten in the dead of night, and then the men are obliged to get up, lash their hammocks, take them on deck, and stow them in the nettings, and be ready to answer to their names in the space of about eight or ten minutes. The midshipmen have to do the same.

"In addition to their general quarters, the men are also stationed for getting under way, and coming to an anchor, for tacking and veering, and for other general evolutions. I have sometimes been astonished to see how quick, in the darkest night, it is discovered that a man is missing from his post, and how speedily he is searched out and brought to it. But not only does every man know his station; he has a specific duty to perform at every order, and a failure on his part might disconcert the whole operation. Thus, it will be seen that, notwithstanding the complicated nature of naval evolutions, and the apparent confusion which must necessarily prevail when all hands are called, there is in fact the greatest possible order, efficiency, and harmony of action."

The marines act as a body of soldiers, and do duty both as sentries at different parts of the vessel, and as marksmen, both below and aloft, during action. Being in some respects an armed police over the sailors, there is often a feeling of jealousy between the marines and other members of the crew.

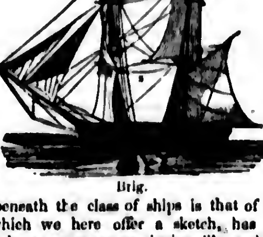
The following is the gradation of officers in connection with the royal navy:—Midshipman; lieutenant; master and commander (usually called captain); post-captain; rear admiral (of which there are several gradations, styled red, white, and blue); and admiral. The senior captain of a squadron, which consists of a few vessels sent upon an expedition, is styled commodore, and he is the general commander for the time being. A fleet is a large number of vessels commanded by an admiral. The affairs of the royal navy are managed by a department of government called the Admiralty, whence the commissions of the officers are issued. Latterly, the condition of both officers and men in the royal navy has been greatly improved, and rendered much more comfortable than formerly.

Merchant Vessels.

Vessels employed in trade, or merchantmen, are of innumerable sizes. The largest is of the ship-proper,

Merchant Ship

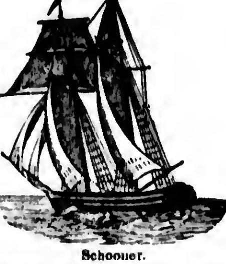
as represented in the preceding figure, with three masts and square sails, but having only an upper deck, the sides of which are usually pierced to carry guns. Vessels of this kind possess holds of very large dimensions for stowing goods, and their burden is from 1000 to 1500 tons.



Brig.

Next beneath the class of ships is that of *brigs*. A brig, of which we here offer a sketch, has only two masts, but it possesses square rigging, like a ship. Brigs are handsome and roomy vessels, carrying from 700 to 800 tons.

With brigs, square rigging terminates, and we now come to classes of vessels in which the rigging is of a



Schooner.

different character. At the head of these stands the *schooner*, a vessel with two masts, and capable of carrying a large press of canvas, but their rigging is various.

Vessels possessing only one mast, are either *sloops* or *cutters*, both distinguished by their tall mast and ex-

Sloop.

tremely large mainsail, which projects towards the stern. Sloops are chiefly engaged as coasting traders, and are of all burdens, from 100 to 600 tons. The class of sloops employed to carry goods and passengers between London and Leith are ordinarily styled *smacks*. There are schooners and sloops of war carrying from ten to twenty guns; they are generally employed in the custom-house service, and adapted for quick sailing.

A *lugger* is a small kind of vessel, but carrying three masts and a running bowsprit, with sails of the form called lug-sails. A *brigantine* is a brig which can be either sailed or rowed. A *xebec* is a light swift-sailing vessel, of three masts, and a long prow, peculiar to the ports of the Mediterranean. A *galley* is another vessel peculiar to the ports of the Mediterranean; it is low built, and carries two masts, but depends chiefly on being rowed with oars; condemned criminals are often sent as a punishment to row these galleys. A *yacht* is a small vessel designed either for state or pleasure. All the preceding classes of vessels possess decks. Small open vessels, not possessing the accommodation of a deck, are of the class of *boats*, of which there are many varieties—as the long-boat, pinnace, wherry, gig, barge, and so forth. Boats are mostly built with the side planks lapping over one another; and this, which is called being *clinker built*, gives them greater buoyancy and strength than if built in the manner of ships.

In every class of merchant vessels, the prime object is to accommodate as large a quantity of goods as possible, and therefore comparatively little space is occupied with accommodation for either the captain or his crew. If the cargo be light, such as cotton, *ballast* is required to be put on board; this consists of sand or any other heavy material, which is placed lowest in the hold, in order to balance the vessel, and give it due hold of the water. In stowing cargo, care is taken to preserve the trim of the vessel—that is, to keep it upright, and also equally balanced fore and aft.

Latterly, vessels propelled by steam power have been introduced and largely employed in the commercial marine, also in the royal navy. Steam vessels carry only a limited quantity of rigging and canvas, the propulsion by the paddles being sufficient in all ordinary circumstances. Much sail, in the case of stiff breezes, would drive the vessel faster than the steam, and thereby cause the paddles to drag through the water: as this would retard the motion, sails are mounted only to give a small addition to the impetus, and to steady the vessel. (See Article CONVEYANCE.)

NAVIGATION.

Navigation is the art of conducting vessels at sea in the direction in which they are designed to proceed: the term is derived from the Latin word *navis*, a ship, and *ago*, to manage or govern. From *navis*, also, is derived the term *navy*, which signifies a collection of ships. The terms *marine*, *maritime*, and *mariner*, are likewise from a Latin root, to wit, *mare*, the sea.

Vessels advance in their course by means of tides, currents, and winds; the winds are in most instances the principal moving agent, and the art of the mariner consists in rendering almost every breath of wind which blows subservient to the purpose of the intended voyage. The winds most favourable for propelling the vessel are those which blow on the *quarter*, or slantingly on the ship's course. The reason for this is very obvious: when the wind blows directly astern, it can affect one or perhaps two sails with commensurate force; but when it comes obliquely, every sail may be trimmed to meet it, and receive a share of the impulsive force. The variety in the rigging of vessels causes much difference in sailing powers: some will sail close to the wind, as it is called, or with a very small angle to the direction of the breeze, while others require winds much more fair. When the wind becomes too powerful, certain sails are taken in, and others are *reefed*, a portion being bound to their respective yards, so as to reduce the surface of canvas. Reefing and bracing the yards are among the nicest points of seamanship.

Ships are navigated, as nearly as possible, by the path which is the shortest distance between the port whence they depart and that for which they are destined; but from contrary winds and intervening land, it is generally necessary to sail in a track of a zig-zag form. When a vessel is obliged to sail to the right or left of the direction of the intended port, it is said to *tack*; when the ship is tacking towards the left, and the wind consequently on the right, it is said to be on the *starboard* tack; and when it is tacking towards the right, it is said to be on the *larboard* tack. A ship does not sail exactly in the direction of her keel, but deviates towards the side that is opposite to the wind; and the angle contained between the apparent and real direction is called *lee-way*.

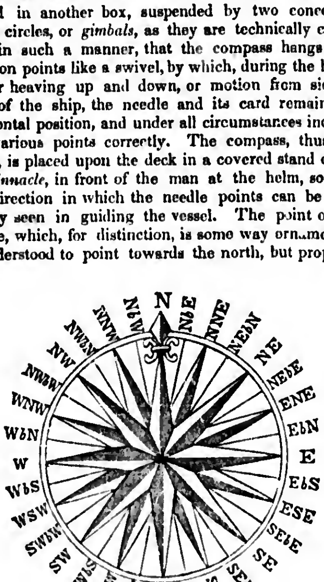
The tacking or changing of directions, in order to present the sails at a proper angle to the wind, is a process requiring considerable seamanship. The ship being already close to the wind, the helm is gradually eased down, so that the rudder may not exert its full force until she begins to turn, nor act suddenly to check the headway, so essential to the success of the evolution; at the same time the head sheets are flown, so as to cause the sails before the centre of rotation to shake, and lose their power of balancing the after ones. As the ship approaches the wind, the spanker is drawn gradually from the lee side towards the centre, that it may keep full, and, by its action so near the stern, continue promoting the rotation. As soon as the sails reach the direction of the wind, and cease to draw, the corners of the courses are drawn up, and the tacks and sheets overhauled, ready to swing the yards. After a while, the sails catch aback, and the fore-sails, soon masking the after ones, act with a powerful lever to turn the bow. At length, having come head to wind, without loss of headway, and the evolution being certain, the after yards are swung round, ready to receive the wind on the opposite side; which operation is then more easily performed, from the sails being becalmed by the fore ones. Lastly, when the after sails are filled by the wind, the head yards are also braced round to receive its impulse, and the ship at once recovers headway, and proceeds on her new tack.

Thus easily is a ship manœuvred in fine weather. Not unfrequently, however, a gale comes to disturb the peaceful course of the mariner, and call forth all his exertions. Let us suppose that, whilst our ship is contending against the head wind, the misfortune is augmented by its gradual increase. Shortening sail becomes necessary, and it is determined by two leading considerations—the stability of the ship, and the strength of her masts; it is to diminish the careening of the one, and avoid endangering the other, that the surface spread to the wind is reduced. In shortening sail, we always begin with the highest and lightest sails, descending gradually, and keeping pace, with an inverse ratio, with the increase of wind. The sails do not, however, come in uniformly in the direction of the length; but the after sails most rapidly; because, as the wind increases, the energy which it exerts in a forward direction upon the masts tends, with a powerful lever, to depress the bow and raise the stern; hence the latter drifts more easily to leeward, thereby bringing the bow towards the wind; this effort is also promoted by the action of the sails passing farther to leeward, and by the ship ceasing to sail on an even keel. From all these reasons, the more the wind increases, the more she tends to come to; so, to avoid a constant recurrence to the action of the rudder, it becomes necessary to shorten sail faster aft than forward, taking in the mizzen-topgallant-sail, and even the spanker, before the fore and main-topgallant-sails; for the same reason, when it becomes necessary to reef, it is not unusual to begin with the mizzen-topsail. Reefing consists in binding a portion of the sails to their respective yards, so as to reduce the surface; and in the case of a heavy gale, it becomes necessary to reef or take in the whole from stem to stern; the helm being at the same time kept constantly hard down, the vessel is said to *lie to.* Should the gale abate, the reefs are shaken out, sail is added, and the vessel bounds actively on its course.

THE COMPASS.

The most important instrument for the guidance of the mariner is the compass. There are different kinds of compasses, to suit peculiar purposes; but that which is commonly in use on shipboard is of the following construction:—The most essential part is a magnetized bar of steel, called the needle, which is supported horizontally on a central pivot, round which it is free to move and to point in any direction. The pivot of the needle rises from a circular *card*, resembling the dial-plate of a time-piece, and round the circumference of which are marked thirty-two points. The adjoining figure represents the card of a compass. North, South, East, and West, are the main or cardinal points, and are indicated by their initial letters respectively, while the subordinate points are also marked by letters, as NbE for north-by-east, NNE north-north-east, and so on. To be able to recite the various points is said to "box the compass." The north is usually indicated by an ornamented figure, or arrow head, as in the sketch of a compass card here presented.

The card and needle are fixed in a round box, enclosed by a sheet of glass, to secure it both from the agitation of the atmosphere, as well as to exclude dust, moisture, and other things which might interfere with the correctness of the indications. The whole is enclosed in another box, suspended by two concentric brass circles, or *gimbals*, as they are technically called, and in such a manner, that the compass hangs as it were on points like a swivel, by which, during the lurching or heaving up and down, or motion from side to side, of the ship, the needle and its card remain in a horizontal position, and under all circumstances indicate the various points correctly. The compass, thus encased, is placed upon the deck in a covered stand called the *binnacle*, in front of the man at the helm, so that the direction in which the needle points can be constantly seen in guiding the vessel. The point of the needle, which, for distinction, is some way ornamented, is understood to point towards the north, but properly,



it points a little to the west of due north; and this, as well as other variations to which it is subject in certain latitudes, must be thoroughly understood by the navigator. In the whole of the northern hemisphere of the globe, the point or northern pole of the needle is the active agent in pointing the direction of the compass. In the southern hemisphere, the southern pole of the needle assumes the active management of the instrument; and, by pointing towards the south pole of the earth, keeps the point of the needle pointing towards the north as before. Practically, it is of no consequence to the mariner which point of the needle is most affected by the polarity of the earth, for in all places and conditions (slight variations excepted) the needle keeps its northern ornamented point towards the north pole of the globe.

The needle being liable to be affected by the proximity of iron, no piece of that metal is used in the construction of the binnacle, or is allowed to be near it. In the case of iron ships, or ships having much iron on board, means are adopted to counteract the tendency which the needle has to point in a wrong direction. From want of attention to this important point, serious disasters at sea have ensued.

THE LOG—SEXTANT.

Provided with a compass, the next object of importance is the *log*, an instrument for measuring the rate at which the vessel proceeds through the water, in a given space of time. The log is a very simple contrivance. It consists of a long cord, having a piece of wood attached to one end, and called the *chip*. This is of a quadrantal form, and being slung at the corners with line, and loaded at the circumference, when thrown overboard it remains erect and stationary, and drags the line off as fast as the ship passes through the water. The line is divided into knots and half knots, representing miles and half miles, or minutes of a degree, to which they bear the same proportion as the log-glass does to an hour. Thus the log-glass being filled with sand to run through in 30″, the length of a knot must be 51 feet, the first being the same proportion of an hour that the last is of a mile. As, however, the log is found to come home a little in the effort to draw the line out, it is customary to mark the knot a foot or two less than the true length. The mode of heaving the log to measure a ship's rate is as follows: The log-reel, upon which the line is wound, being held by one of the sailors, the officer places himself on the rail to leeward, and a third person holding the glass, he proceeds to prepare the chip, so that the peg of one of the lines holding the chip in a perpendicular direction will draw out, by the force of the water, when the wheel is stopped, and allow it to haul in easily. Then, having gathered a sufficient quantity of line into his hand, he throws it far to leeward, that it may not be affected by the eddies which follow in the wake. The stray line, which allows the chip to get astern, now runs of, and the instant that the white rag, which marks its termination, passes through the hand of the officer, he cries "Turn!" and continues to veer out line until the glass runs out, and the person holding it cries "Stop!" Then the line is grasped, and the number of knots that have passed off mark the speed of the ship. When this exceeds five miles, it is usual to use a glass of 15 instead of 30″, counting the knots double. The rate of sailing, per hour, multiplied by the hours, thus gives the mariner the measure of his run.

In addition to these essential instruments for directing the course and ascertaining the distance, the navigator must be provided with octants of double reflection, to measure the altitude of the heavenly bodies, and a circle, or sextant, more nicely graduated, to measure distances between the moon and stars. He should also have with him a book containing the logarithms of numbers, sines, tangents, and secants, to facilitate trigonometrical calculations; tables for correcting altitudes for dip, parallax, and refraction; also lists of latitudes and longitudes for every part of the world; and of tune of high water at every port, at the period of full and change of the moon, from which, at all times, to be able to find the tide; and a variety of tables to facilitate the various problems of navigation. He should also have with him the Nautical Almanac, containing the places and declinations of the fixed stars and planets, and especially the distances of the moon from the sun and other stars, and all that relates to that body, with a view to calculate the longitude by observation. Finally, he must be provided with the general and local charts applicable to his contemplated voyage. Thus furnished, the mariner may set sail with confidence; many do so with no other aids than their compass, log, quadrant, a single chart, and book of navigation, and arrive in safety. But it is less our business to show with how little care a ship may be navigated, than to show how she may be carried from port to port with the greatest possible certainty. Having taken leave of the port, and, when the last land is about to disappear from view, either from the growing distance or the intervention of night, the mariner selects some conspicuous headland, of which the latitude and longitude are noted in his tables, and placing a compass in some elevated position, remote from any iron object to disturb its polarity, proceeds to determine its bearing, and estimate his distance from it, either by the progress made from it, or by the ready estimate of a practised eye. Or, taking the simultaneous bearings of two distinct points of coast, he has still surer data for deducing his position. This is called *taking the departure*, and is carefully noted on the log-slate, with the time of making the observation. Thenceforth the log is thrown every hour, and the course and distance are entered upon the slate, to be copied into the log-book at the end of the day.

WORKING A RECKONING.

At the first noon succeeding the time of taking his departure, the mariner works up his reckoning. Noon is an epoch fixed by nature, being determined by the passage of the sun over the meridian, and is therefore well chosen as the beginning of the day. The log-slate being marked, he copies the courses and distances, if from head-winds or other causes they have been various; the departure from the land is also converted into a course, as is also the current, if there be any known one. He next proceeds to find the difference of latitude and departure from the meridian corresponding to each course, either by geometrical calculation, or, more expeditiously, by reference to tables; then he adds the several differences of latitude and departure, and, if they be of different names, as some north and some south, some east and others west, deducts the less from the greater. With the remaining difference of latitude and departure, he not only finds the course and distance made good, but also the latitude and longitude in; the difference of latitude being applied to the latitude left, by adding or subtracting, in sailing from or towards the equator, at once gives the latitude of the ship. But before the departure can be thus applied to find the longitude, it is necessary to reduce it for the converging of the meridians towards the poles; for, though all degrees of longitude are divided, like those of latitude, into 60 minutes or miles, yet they decrease in length, from being equal to a degree of latitude at the equator, until they become nothing at the poles. There are many ways, more or less accurate, of deducing the difference of longitude from the departure, the latitude being known; they are founded upon this principle: the circumference of the earth at the equator is to its circumference at any given parallel of latitude, as the departure is to the difference of longitude. The most easy and correct way of obtaining the difference of longitude, on an oblique course, is by the aid of a table of meridional parts; for, having taken out the meridional difference of latitude, the mariner has this simple proportion: the proper difference of latitude is to the meridional difference of latitude, as the departure to the difference of longitude. The difference of longitude thus obtained, is applied to the longitude left, adding or subtracting, in sailing to or from the first meridian, and the result will be the ship's longitude; which, with the latitude previously ascertained, determines her position on the chart. The method of navigating thus described is called *dead reckoning*. It is far from infallible, and leaves much to desire. It will, indeed, do pretty well in short runs; but as errors daily creep in from many causes escaping calculation, such as bad steerage, leeway, heave of the sea, unknown currents, and as these accumulate, and become considerable at the end of long voyage, it becomes necessary for the mariner, removed from all reference to terrestrial objects, to resort to the immovable guides in the heavens. All the heavenly bodies are, by the revolution of the earth, daily brought to the meridian, at which time, if their altitude is measured, their declination or distance from the equinox being known, the latitude is readily deduced; it may also be deduced from single or double altitudes of bodies not in the meridian, the times being accurately known. But the meridian altitude of the sun is what furnishes at once the easiest and most correct method of finding the latitude. So great, indeed, are the advantages offered by the meridian altitude of the sun, that no other means of finding the latitude are used, except when these have failed from a clouded atmosphere, or when the momentary expectation of making the land quickens the mariner's anxiety. We shall, therefore, now explain the method of deducing the latitude from the sun's meridian altitude.

TAKING AN OBSERVATION.

Furnished with a sextant, circle, or octant of reflection, the observer goes upon deck, and having examined the adjustment of his instrument, proceeds to bring down the image of the sun reflected by its mirror, until the lower limb just sweeps the horizon. He continues to follow and measure its ascent, until it ceases to rise; the moment that it begins to fall, and the lower limb dips in the horizon, the sun has passed the meridian. The altitude marked by the index being read of, it is next corrected. And first, the observer adds the semi-diameter, in order to make the altitude apply to the centre of the object; next, he subtracts the dip, to meet the error caused by the extension of the horizon, in consequence of the rotundity of the earth, and the elevation of his eye above its surface; also the refraction of the atmosphere, by which the object, when not vertical, is made to appear higher than its true place; lastly, he adds the parallax (a small correction, inconsiderable from the sun's distance), in order to reduce the calculation for the centre of the earth; from which point all calculations are made, and which is ever supposed to be the station of an observer. Having made all these corrections, which many mariners despatch summarily, by an addition of 12 minutes, he has the true meridian altitude of the sun. Taking this from a quadrant, or 90°, gives its zenith distance, or distance from that point in the heavens which is immediately over the observer, and would be met by a straight line passing from the centre of the earth through his position. Now, if the sun were for ever on the equinoctial, the zenith distance would always be the latitude; for, whilst the zenith is the observer's position, referred to the heavens, the equator is there, in like manner, represented by the equinoctial and we have already seen that latitude is the distance from the equator. But as the sun is only twice a year upon the equinoctial, and as his distance from it at times increases to more than 20°, it becomes necessary to take this distance (called his *declination*) into the estimate. The sun's declination is given in the almanac, for the noon of each day; by correcting it for the time anticipated or elapsed, according as the sun comes first to him or to the first meridian, by his position east or west of east of it, the observer obtains the declination for noon at his own position. This declination applied to the zenith distance, by adding when the sun is on the same side of the equator, by subtracting when on the opposite side, gives the true latitude. A daily and accurate knowledge of his latitude is, then, to the mariner of our day, a desideratum of easy attainment. By its aid, nothing is easier than to sail clear of any rock or shoal that crosses his track, either by a watchful look-out at the moment of passing its latitude, or else by avoiding its parallel entirely, until it be surely passed. Moreover, this is his best and surest guide in aiming at his destined port; for he has but to attain the exact latitude it lies in, and then sail directly upon it, east or west, to be sure of success. And here nature is again his friend: by a singular coincidence, discoverable in glancing at the map of the world, most coasts and continents lie in a northern and southern direction. Hence the value attached by seamen to an accurate knowledge of the latitude; and hence the saying of "Latitude, lead, and look-out."

TO FIND THE LONGITUDE.

Various ways have been devised to find the longitude, in all of which the great element is time. The earth performs her diurnal revolution in 24 hours, or, in other words, each part of the circumference of the globe, which is divided into 360 degrees, is brought under the sun once a day. Hence, each part of the circumference (reckoning from east to west) has its own peculiar time of day. When it is noon at one place, it is one o'clock afternoon at another place, two at another, and so on; the time differs all round the globe. Dividing the 360 degrees by 24, we find that 15 is the result; for every 15 degrees, therefore, along the circumference, going westward, there is an hour of difference, in advance; and, going eastwards, an hour behind. If it be noon at Greenwich, it will be one o'clock at a point 15 degrees east from it (that is, the sun has passed over it an hour ago), and eleven o'clock forenoon at a point 15 degrees west from it (that is, the sun will be an hour in getting up to it.) Dividing the 60 minutes of an hour by 15, the result is 4; the earth, therefore, moves under the sun at the rate of a degree, or 60 geographical miles in four minutes, or 15 miles in the minute, or one mile in the four seconds, or a quarter of a mile in the second. Here, then, the element of time is brought at once, and in the most satisfactory manner, to bear upon the distance of any given place, east or west from any other given place. The measuring of such a distance is called finding the longitude. Different places on the globe have been established as starting points in making these measurements. The French reckon from Paris, and the English from Greenwich, a village near London, where an astronomical observatory has been long established and supported at the public expense. In all English works of geography, the longitude is reckoned from Greenwich, although not expressly mentioned. Navigators determine their longitude by watches or chronometers, whose movements are as exact as can possibly be obtained from mechanism. In setting out on a voyage, the chronometer is set to London time, and kept going at that time. At the hour of noon of each day, as determined by an observation with the sextant, the difference is estimated between that hour and the hour indicated by the chronometer, and that difference is the longitude east or west of Greenwich, as the case may be. Some mariners, for security, take several chronometers to sea with them, as one only is by no means a safe guide. In general, however, the masters of coasting traders, or those who pursue short voyages by regular lines of route, depend on books containing lists of longitudes as well as of latitudes.

MARINE BAROMETERS—LOG-BOOK.

The last great requisite in navigation is a good barometer to indicate the approach of foul weather. The most delicate instrument of this kind is the sympesometer of Adie, by which the earliest and most certain indications are presented of coming storms. In treating of the nature and value of instruments of this nature, Dr. Arnott makes the following observations:—"The watchful captain of the present day, trusting to this extraordinary monitor, is frequently enabled to take in sail and to make ready for the storm, when in former times the dreadful visitation would have fallen upon him unprepared. The marine barometer has not been in general use for many years, and the author was one of a numerous crew who probably owed their preservation to its almost miraculous warning. It was in a southern latitude. The sun had just set with placid appearance, closing a beautiful afternoon, and the usual mirth of the evening watch was proceeding, when the captain's order came to prepare with all haste for a storm. The barometer had begun to fall with appalling rapidity. As yet, the oldest sailors had not perceived even a threatening in the sky, and were surprised at the extent and hurry of the preparations: but the required measures were not completed, when a more awful hurricane burst upon them than the most experienced had ever braved. Nothing could withstand it; the sails, already furled and closely bound to the yards, were riven away in tatters; even the bare yards and masts were in great part disabled; and at one time the whole rigging had nearly fallen by the board. Such, for a few hours, was the mingled roar of the hurricane above, of the waves around, and of the incessant peals of thunder, that no human voice could be heard, and amidst the general consternation even the trumpet sounded in vain. In that awful night, but for the little tube of mercury which had given the warning, neither the strength of the noble ship, nor the skill and energies of the commander, could have saved one man to tell the tale. On the following morning the wind was again at rest, but the ship lay upon the yet heaving waves an unsightly wreck."

A journal of events and observations on board ship is usually kept in what is called the log-board, and transferred thence into the log-book. The log-board consists of two boards shutting together like a book, and divided into several columns, containing the hours of the day and night, the direction of the winds, and the course of the ship, with all the material occurrences that happen during the twenty-four hours, or from noon to noon, together with the latitude of observation. From this table, which is written in chalk, and daily effaced, the officers work the ship's way, and compile their journals. From it, also, entries are carried to the log-book, in an expanded form, with any observations and additional particulars supposed to be necessary. The log-book is thus the journal of the ship, and is preserved with great care for exhibition, if required, at the termination of the voyage.*

Thus, then, by the use of various instruments and practical experience in navigation, a ship is conducted from port to port, dangers avoided, and difficulties overcome. Though they who traverse the vast ocean leave no tract for the guidance of those who follow, it is thus converted into a plain and convenient highway, extending to the extremities of the earth.

---

* For much of the matter in the present sheet on ships and navigation, we have been indebted to several articles in the "Encyclopædia Americana" (Conversations Lexicon).

MARITIME DISCOVERY.

No people of antiquity possessed the courage or skill to navigate their vessels out of sight of land, or, at least, to push into the open Atlantic or other great oceans. Maritime intercourse, for the sake of traffic, was carried on only along the shores of the Mediterranean, or down the Red Sea, and along the coast to India, or along the western shore of Europe to Britain. The Romans thought they performed a wonderful feat when they sailed a ship as far as the northern islands of Scotland. In these times there was no other known guide, with respect to the cardinal points, than the stars by night and the sun by day; and, therefore, when clouds covered the visible horizon, or when total darkness ensued at night, the ship was necessarily brought to a pause, or placed in the most imminent danger of being wrecked on some unknown shore. This, however, was not the only difficulty. The nations of antiquity, with all their learning, were utterly ignorant of the form and size of the globe. They believed that the world was a great flat plain, with the habitable earth placed in the midst of the ocean; that this ocean was of interminable breadth; and that, at a certain distance from land, the waters were shrouded in eternal darkness. With such notions prevailing among mankind for thousands of years, it is not surprising that they should have made so slow advances in the art of navigation, or done so little for maritime discovery.

During the middle ages (fourth to the fourteenth century), ship-building was considerably improved by the Italians, who then conducted a large maritime traffic on the Mediterranean; but the art of navigation, in the proper sense of the term, was still in its infancy, and its history cannot be said to commence till the beginning of the fourteenth century, when that wonderful instrument, the mariner's compass, was discovered, or came first into observation in Europe. Of the polarity of the magnet, or its tendency to point to the poles, a sufficient explanation is given in the article Electricity and Magnetism; and it is here only necessary to describe how this polarity is rendered subservient to the purposes of the navigator. The mariner's compass, which consists of a magnetized slip of metal, or needle, as it is called, poised on its centre, and free to point to the poles, was first made known, as far as it can be ascertained, by one Flavio Gioja, an Italian, in the year 1302. As with all great discoveries, its advantages were not at once recognised—it had to contend against a variety of prejudices; but these in time vanished, and about the middle of the fourteenth century its important uses were allowed and established.

Navigation now assumed a much bolder character than formerly. The English, Portuguese, Italians, and Spaniards, pushed their vessels into districts of ocean never previously traversed, and thus the way was fairly opened for maritime discovery. The first great discoverer who made use of the compass, and partly improved its construction, was Prince Henry, a son of the king of Portugal, and who is known in history by the name of *Henry the Navigator.* This intelligent and enterprising prince (born 1394, died 1461), with the concurrence of the Portuguese government, set on foot a series of maritime enterprises, with the view of discovering a route to India by way of the Atlantic. These voyages ultimately proved successful; the islands of Puerto Santo, Madeira, and the Canaries, were successively discovered, and annexed to the crown of Portugal. In 1433, the Portuguese navigators penetrated beyond Cape Bojador, on the coast of Africa, which was considered an extraordinary performance; another expedition afterwards went as far as Cape Blanco, and discovered the island of Arguin and the Cape de Verd Isles; and in 1448, the Azores were reached and made known. Henry the Navigator thus struck a spark which kindled to a flame all over Europe. Not long after his death, the Guinea coast was added to the Portuguese discoveries. In 1484, the Congo was reached by Diego Cam; in 1487, the Cape of Good Hope was doubled by Bartholomew Diaz; and in 1498, Vasco de Gama touched the shores of Hindostan. The Portuguese having received an assignment from the pope of all lands that could be discovered on the African coasts, the Spanish government, burning with anxiety to emulate the late proceedings of its neighbours, was compelled to seek out new countries in a different direction. Ferdinand and Isabella, the sovereigns of Spain, listened, therefore, to the speculations of Columbus regarding a route to India across the Atlantic, and sent him off on a mission. In this his bold attempt to reach Hindostan by pursuing a direction across the Atlantic, he landed on one of the American islands, now called the Bahamas, on the 12th October, 1492. About the year 1499, Amerigo Vespuccii, under an appointment from the Spanish government, discovered the coast of the South American continent, and hence the name of *America* was given to the New World, although, as is well known, Columbus had previously discovered and landed on South America, without being aware that it was the continent which he had reached.

Several subsequent voyages by Spanish navigators disclosed the extent of the east coast of South America; and in 1513, Nunez de Balboa crossed the isthmus of Panama with an exploring party of his sailors, and made the discovery of the Pacific Ocean on the west coast of that continent. It was now seen that America was not, as had been at first believed, a portion of Asia or India, but was a separate territory of vast extent lying between the Atlantic and Pacific. There was yet a doubt with respect to the southern extremity of America, but in 1520, Megellan made the passage from the Atlantic to the Pacific by the straits which separate America from the island of Terra del Fuego, at about the 53d degree of south latitude, and so removed all doubt upon the subject. This navigator extended his voyage across the Pacific to the Philippine islands, where, unfortunately, he was killed; but his companions proceeded in the route homewards by the Cape of Good Hope, and thus, by circumnavigating the globe, settled the long-disputed problem with respect to the sphericity of our planet. This most important voyage was made between the years 1520 and 1523.

In the meanwhile, several maritime discoveries were made by the English nation. In 1495, John Cabot, a Venetian pilot, settled at Bristol, obtained from Henry VIII. letters patent, empowering him and his three sons, Lewis, Sebastian, and Sanctius, to discover unknown lands, and conquer and settle them. In consequence of this permission, the king supplied one ship, and the merchants of London and Bristol a few smaller ones, and in 1496, John and Sebastian sailed to the north-west. In July of the same year, they discovered Newfoundland, and explored it up to latitude 67°. In a subsequent voyage, the father and son sailed as far as Cape Florida, and are believed to have been the first who saw the main land of America. By these and succeeding voyages of discovery in the reigns of Henry VIII., Edward VI., and Elizabeth, the English became possessed of the eastern coast of North America and some of its islands. Between the years 1740 and 1744, Anson was employed in circumnavigating the globe, and visiting different parts of the Pacific, but this extensive and protracted voyage added little to the existing knowledge of geography. At a later period, in the reign of George III., Cook explored the groups of islands in the Pacific, making various interesting discoveries, in which was included a survey of the eastern coasts of Australia and Van Diemen's Land, also a visit to the New Zealand islands. After the voyages of this enterprising navigator, little was left to perform in the way of maritime discovery, except in exploring the northern extremities of the American continent. A series of voyages for this purpose was begun in 1818, conducted by Ross, Parry, and others, and which lately terminated by establishing the fact, that a passage for ships exists between the Atlantic and Pacific, round the northern promontories of America, but that, from the blocking of ice, such a passage can only on rare occasions be open to navigators, and is therefore of no practical value.

The great maritime discoveries made in the course of the fifteenth century, which at once opened up a new view of the globe, led to various improvements in navigation. The *log*, for measuring the ship's progress, also charts on Mercator's projection, were introduced. In 1614, Napier discovered the calculation of numerical quantities by logarithms; and about the year 1620, Gunter invented a scale, by the help of which, and a pair of compasses, every question in trigonometry might easily be calculated by the mariner. In 1731, the art of navigation was greatly advanced by the invention, or rather improvement, by Hadley, of the quadrant, an instrument for ascertaining, by an observation of the sun, the true latitude of a ship at sea. Till nearly this period, an instrument called an *astrolabe*, a species of sun ring, had been employed for this purpose, and was very imperfect in its operation. Between the years 1765 and 1774, Harrison invented a chronometer, or time measurer, by which the longitude could be ascertained at sea with nearly perfect accuracy; and thus the art of navigation may be said to have been completed. In the course of the eighteenth century, the true figure of the earth was fully made known by the voyages of Anson, Cook, and others; and, at the same time, discoveries were made of almost every accessible island and tract of land over the globe. Thus, in the short space of four centuries from the time when the first impulse was given by the Portuguese, the civilized part of mankind had acquired a nearly complete knowledge of the features of our globe, as well as of its true figure and dimensions.

DOMINION OF THE SEAS.

It is a common law of nations that the ocean is a free and universal highway, which no state can appropriate to its own special use. While this exists as a principle generally recognised by all civilized powers, Great Britain has for a considerable period of time claimed *the dominion of the seas*, as a right acquired by its extensive conquests, and the skill and valour of its seamen. By this claim, it is not assumed that Great Britain possesses a legal right of property in the waters of the ocean, or the lands which they may cover. The claim resolves itself into what is termed in law "a military sovereignty," which it would be exceedingly difficult to define, and is practically an empty and vain-glorious boast. Within the last twenty years, during which a large maritime force has grown up in France, Russia, and the United States of America, the claim of the British to the dominion of the seas has been little heard of, and is perhaps now a dead letter in maritime law, as it is in fact. Each nation retains a judicial control over its vessels and their crews, in whatever part of the ocean they may be; all crimes and misdemeanours committed on board of a ship are punishable by law, as soon as the vessel reaches the country to which it belongs.

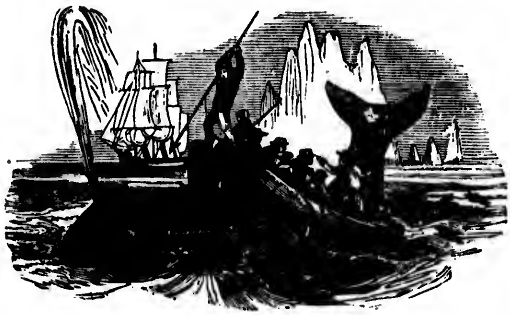
[BOOKS ON THE OCEAN, MARITIME DISCOVERY, AND NAVIGATION.

The *Encyclopædia of Geography* by Murray, already referred to, contains an excellent treatise on the Ocean, in its introduction. Malte-Brun has another in his Geography. The subject of Maritime Discovery has seldom been treated in a general way; but there is a multitude of books in illustration of it. Among these are, Tytler's "*Discoveries on the Northern Coasts of America*," "*Circumnavigation of the Globe*," from Magellan to Cook; Ellis's "*Polynesian Researches*," Leslie's "*Discoveries and Adventures in Polar Seas*," "*Cook's Voyages round the World*," "*Lives and Voyages of Drake, Cavendish, and Dampier*," Humboldt's "*Travels*," "*Lives of the Early Navigators*," St. John's "*Lives of Celebrated Travellers*." These are comprehensive works, not being confined to the explorations of single travellers. Dr. Robertson's "*History of the Discovery and Conquest of America*" is full of information, and has the additional advantage of his delightful and faultless style of writing. His "*History of India*" is not less interesting and valuable. Mr. Wheaton's "*History of the Northmen*," and Crichton and Wheaton's "*History of Norway, Sweden, and Denmark*," abound with information respecting the bold, extensive, and successful enterprises of the early Scandinavian voyagers. One of the books in Lardner's Cabinet Cyclopædia, entitled "*Maritime and Inland Discovery*," is, on the whole, the most general and systematic work on this subject, which has been published in a cheap form.

The best and most comprehensive work on Navigation is Dr. Bowditch's "*Practical Navigator*." Although it was written expressly for the use of mariners, it is rendered perfectly intelligible to the general reader, and it is so full and complete that it fully answers the purpose of making the reader as familiar with "all the ropes in the ship" as it is possible to become by the use of books alone. For the purpose of learning the history of the progress of marine architecture, the French have a highly embellished popular compend, entitled "*La Marine*," by M. Eugene Pacini. The same species of information may be obtained by consulting the several chapters in the Pictorial History of England, in which the useful arts are treated. —*Am. Ed.*]

THE WHALE, AND WHALE FISHERIES.



DESCRIPTION OF THE WHALE.

The cetaceous order of animals, of which the whale is the most remarkable and important member, is distinguished by various peculiarities which render it a link, as it were, between the creature of the land and the sea. While living in part or wholly in the ocean, and so formed as to make their way through its waters with ease and velocity, the cetacea differ from the true fish-tribes in being *mammalian* or suck-giving animals, in being warm-blooded, and in having organs for respiring the atmospheric air, like the ordinary inhabitants of the land. These striking distinctive features would be sufficient in themselves to render this order of animals an object of interesting study, but the cetacea have also strong claims upon attention, as being of very great consequence to the wants and comforts of man. This is especially the case as regards the whale and its varieties, which will form the subject of notice in the present section. In the general account given of the animal kingdom, the dolphin, porpoise, and others of the cetacea, are individually described.

The whale, or *balæna*, as naturalists term it, is the largest of all known animals. The polar seas, if not its exclusive dwelling-place, are at all events the region which it peculiarly frequents, and where it herds in the greatest numbers. There, also, are found the varieties which attain to the greatest bulk. The three principal of these are the *balæna mysticetus*, the common Greenland whale, and what British sailors call the "right" one, from its being the most valued and valuable object of their pursuit; the *balæna physalis*, or the great northern rorqual, a variety which exceeds all others in bulk, and is termed the "razorback" or "finner," by fishers; and, thirdly, the *cachalot*, or spermaceti whale. With the exception of some few points, which will be noticed afterwards, the characters of the Greenland whale are identical with those of the whole tribe, and by calling attention to the peculiarities of structure in this species, in the first instance, much repetition may ultimately be spared.

The size of the common whale was the subject of very exaggerated notions, until within a very recent period. About fifty years ago, a standard writer in natural history asserted that whales were frequently "to be seen above an hundred and sixty feet long;" and that, even at this standard, the animal was much smaller than it had been before man began to disturb and destroy the race. That whales "two hundred and fifty feet in length" were often seen previously, is represented as a thing beyond all question. Mr. Scoresby, however, a very high authority on the subject, declares that the common whale seldom or never exceeds seventy feet in length, and is much more frequently under sixty. Out of three hundred and twenty-two whales which he had personally aided in capturing, *not one* exceeded fifty-eight feet; and the largest ever taken, of which he knew the reported measurement to be authentic, came up only to sixty-seven feet. The body of a large individual of this family measures from thirty to forty feet round the body at the thickest point, or a short way behind the head, which is of great proportionate size, and occupies about one-third of the whole extent from snout to tail. When the mouth is open, it is sufficiently large and long to admit a whaler's jolly-boat with its full compliment of men. The bulk of the head, which is somewhat conical in form, and has a sort of round eminence above and posteriorly, renders the aspect of the mysticetus clumsy and unshapely. A very slight diminution of the circumference indicates the position of the neck, and behind this, the body swells to its greatest calibre, whence it tapers sharply away again towards the tail. The animal has no back or dorsal fin. The two side or pectoral fins are placed about two feet behind the angles of the mouth, and are nearly five feet broad by nine feet in length. The tail is something in the shape of a crescent, with an indentation in the middle of the concavity, the convex side being united to the body. This appendage is placed horizontally, and is about twenty-four feet broad. It is an instrument of immense power, and the whale has sometimes given a stroke with it which has sent large boats high into the air in a thousand splinters. The colour of the body is mainly a velvety black; the under part of the head and abdomen, and the junction of the tail, being partly white and partly of a freckled gray. In old whales, much more of the body assumes the latter tint, and the streaks sometimes resemble a beautiful landscape of trees. On the tail, in one instance, noticed by Ray, nature, in a freakish mood, had set down the number 122, in large and very distinct characters. The eyes of the whale are about a foot behind the angle of the mouth, and are not much larger than those of the ox. The iris is of a white colour, and the organs are guarded by lids and lashes as in quadrupeds. The two blow-holes of the whale, situated on the summit of the head, and descending perpendicularly through it for a length of twelve inches or so into the top of the windpipe, are the only other features worthy of notice in the exterior aspect of the Greenland whale.

The mouth of the common whale is an organ of very wonderful construction. In a large specimen of the race, it may measure, when fully opened, about sixteen feet long, twelve feet high, and ten feet wide—an apartment, in truth, of very goodly dimensions. It conta[illegible] teeth and enormous as the bulk of the creature is, its throat is so narrow that it would choke upon a morsel fitted for the deglutition of an ox. An inch and a half is stated to be the diameter of the gullet in the very largest whales. From this peculiarity of formation, it may be anticipated that the food of the animal is of a very minute nature, notwithstanding the vastness of the cavity which is prepared for its primary reception. The animal is indeed supported upon a multitude of smaller inhabitants of the deep, and, to permit this, its mouth is provided with a remarkable apparatus, composed of what is called the *baleen*, or the well-known *whalebone* of commerce. The baleen is arranged into two rows of laminæ or thin plates, projecting literally from a line in the centre of the arch of the palate, somewhat like the laminæ of a feather. Towards the point of origin, they are comparatively few in number and strong, while towards the lips they divide and taper away into mere bristles, forming a loose hanging fringe or border. There are about three hundred of these plates on each side, and, when dried, they weigh usually above a ton. In the rorqual whale they are more numerous, and we find from the description given by Mr. Frederick J. Knox, of the skeleton prepared and exhibited at Edinburgh, that three hundred and fourteen external plates were counted on each side in the mouth of that animal. The whole number of plates which *could* be counted, not including the more minute bristly terminations, was 3768. The longest plate of baleen, which is always placed about the centre of the series on each side, measured two feet two inches in length by fifteen inches in breadth. "The substance when recent (says Mr. Knox) is highly elastic."

The use of these plates, with their pendulous extremities and fringes, is to retain, as in a net, the multitude of small animals which are floated into the mouth of the whale whenever it is opened. Were it not for such a drainer, formed by these fringes with the aid of the tongue, which is merely a great mass of fat tied down to the lower jaw, the emission of the water would be attended by the escape of all the objects which entered with it. As it is, the most minute matters are retained; and shrimps, sea-snails, small crabs, medusæ, &c., are thus entrapped to support the great monster of the deep.

The remaining features in the structure of the whale need not be individually described at the same length. The skin consists, first of the scarf-skin, or epidermis, which is moistened by an oily fluid, enabling it to resist the action of water; secondly, of the *rete mucosum*, a layer usually held to contain the colouring matter of all animal surfaces; and, thirdly, of the true skin, which, for particular purposes, is open in texture, so as to contain oil, or blubber as it is called, in great quantities. This mass of oil, surrounding the whole animal, and sometimes weighing more than thirty tons in all, serves the important end of keeping the animal warm by its weak conducting powers, amid the coldest recesses of the polar ocean, and is also calculated to resist the enormous pressure to which the body of the creature must be subjected at the depths to which it often descends. Whales have been known to take a line perpendicularly down to the full extent of a mile; and had not this ample layer of fat, between one and two feet thick, been wrapped around them, possessing a resisting power like that of caoutchouc, it is difficult to imagine how, in such a case, they could endure the immense weight of superincumbent water. Moreover, being inferior in specific gravity to the water, it is obvious that all this body of oil must be of incalculable use in augmenting the buoyancy of the animal's frame. Below the skin are situated the muscles or flesh, and the character of this structure is much the same in the whale as in the ox or horse. With the exception of the tail, the arrangement of the various muscles of the whale does not differ very much from that of quadrupeds; and the same remark applies to the osseous structure. The fins are merely rudimental arms, containing nearly the same bones as in man, and the chest strongly resembles that of ordinary quadrupeds. The vertebral column of the rorqual whale contains sixty-three bones, those of the Greenland whale are not quite so numerous. The skull consists of the crown-bone, from which the facial bones and upper jaw project forward, while the lower jaw is composed of two long curved bones, that meet at the point or fore-part of the mouth. These are often put up over gates, and make a handsome archway. The whole of these bones are hard and porous, and some of them, as the lower jaw-bones, contain oil, but they are said to have no proper medulla or marrow. The total weight of Dr. Knox's rorqual skeleton, was twenty-eight tons.

The organs of respiration in the whale are formed upon the same principle as those of land animals, but with modifications to suit the peculiar element in which the creature lives. It is plain that some provision was required to permit the whale to breathe without the risk of having the lungs filled with water. This is accomplished by the extension of the top of the windpipe into the nostrils or blowholes, or rather into the passage which terminates in these in the common whale. By this contrivance, the creature can inhale air while it is feeding or has its mouth full of water. As with terrestrial animals, the air gives a red colour to the blood, or, in other words, oxygenates it, and sustains the animal heat. The whale has frequently to come to the surface, accordingly, to get its air; but this operation is rendered less frequently necessary by the provision of a reservoir of oxygenated blood, which can be drawn upon when required. This is the cause why the animal has such a vast proportionate quantity of blood in its frame. The brain of the whale is held by Cuvier to be large in relation to the animal, but no determinate conclusions have been reached on the subject. The arrangements of the whole nervous system are equally little understood. It is known that whales possess pretty acute vision, but there is a doubt whether or not they have any external ear. Their sense of smell seems to lie in the blowholes, yet the strongest reason for ascribing such a faculty to them at all is founded upon the half-traditionary notion of sailors, that if certain strong-smelling substances are thrown overboard, whales will fly from the spot at once. The mammæ or dugs of the common whale are two in number, and attached to the abdomen; in the case of some other varieties, they are placed on the breast. In both cases they are situated inferiorly. The milk of the animal is said to be rich and creamy.

Such are the general characters of structure in the whale tribe, and, on regarding them attentively, one cannot but feel amazed at the seeming simplicity of the whole supplementary contrivances by which a mammalian animal, so thoroughly terrestrial, one would say, in its general formation, is fitted to live in the deep. The Greenland whale, or mysticetus, to which, more particularly, the preceding description applies, is said by Scoresby *never* to be found beyond the limits of the Arctic seas. There is an excellent reason for this localization. Within the polar latitudes, vast pasture-fields are spread out for the animal which warmer climes have never been known to provide. These feeding grounds, if they may be called so, consist of large tracts of *green water*, covering in all not less than twenty thousand square miles of the Greenland seas. This *green water* is of a deep olive hue, and remarkably opaque. Mr. Scoresby discovered its peculiar appearance to arise from the presence of innumerable animalcules of the medusa family, one common species of which is known by the name of sea-blubber. To give some idea of the numbers of these creatures, Mr. Scoresby calculated that two square miles would contain 23,888,000,000,000,000; and that 80,000 persons must have entered on the task at the creation of man in order to complete the enumeration at the present time. These creatures, many of which are visible only through the microscope, do not all directly serve as aliment to the whale, but they feed myriads of the smaller fishes upon which the whale does live. When feeding, it swims with open mouth under the water, and all the objects that lie in the way of that vast moving cavern are caught by the baleen, and make their egress no more. "This is the simple food (says an old writer) of the great Greenland whale; it pursues no other animal, leads an inoffensive life in its element, and is harmless in proportion to its strength to do mischief." It is gregarious in its habits, being found in shoals, and migrating in this manner (according to most writers) from one ocean to another. When a herd of large ones is seen gambolling together, the sight is as magnificent as the range of nature presents. One whale of sixty feet in length, and seventy tons weight (nearly equal to that of three hundred fat oxen), is a grand enough object of itself, and how much more so must a great herd be when seen sporting in their native element! Let the reader imagine what an effect on the eye must be produced by the sight of one of these enormous living masses leaping right into the air, clear altogether out of the water. This is a feat which they frequently perform, to the high admiration of all who are at a safe distance. They effect it by means of their tail, which is the great instrument of motion, and which derives its prodigious power from the termination and concentration in it of all the muscles and tendons of the spinal column. In some of the larger species, the tail comprises a surface of not less than from eighty to one hundred square feet. Sometimes a whale will turn its head downwards, and, moving its tremendous tail high in the air, will lash the water with violence, raising a cloud of vapour, and sending a loud report to the distance of two or three miles. This is called "lob-tailing" by the mariners. With the aid of the same great instrument, they can travel through the water, horizontally or downwards, at the rate of eight miles an hour; but their usual mode of travelling does not exceed four miles in that space. Considering their bulk, their ease of motion and buoyancy are altogether wonderful, and must be mainly ascribed to the masses of oil they contain.

When the Greenland whale ascends to the surface, which it does usually once in ten minutes, or at the most in twenty, it breathes nine or ten times, and a loud noise accompanies the act, along with an emission of light vapour, in a straight column. This is called the *blowing* or *spouting* of the whale. When alarmed, it snorts much more loudly than usual. It is believed that some whales have other vocal organs, but the mysticetus seems to have no power of making noise but by the blow-holes. The spoutings of the whale consist of the ejection of jets of water to the height of twenty or thirty feet through the same apertures, in such a manner that the act is both seen and heard at the distance of several miles. There is a doubt among naturalists, whether this be an ejection of mucus secreted in the blow-holes, or of water merely from the mouth. The quantity emitted would lead one at once to say that it must be water, were there not a doubt as to the possibility of water entering the blow-holes in this way. The most probable explanation is, that the animal, acting beneath the water, forces up the fluid by means of the air from the lungs. However this may be, the spouting phenomenon is a beautiful one, according to the accounts of all observers.

No point relative to the habits of the Greenland whale affects one so much as the creature's love and care for its offspring. The period of gestation is supposed to be about ten months, and scarcely any dam has ever been observed to have more than one young one in attendance. In suckling, the mother throws herself on her side for the convenience of her offspring, and this usually takes place on the surface of the water, to permit, no doubt, of free breathing. At birth, the young whale measures from ten to fifteen feet, and continues a nurseling for about a year. It attains to its full growth very slowly; not sooner, according to most naturalists, than in twenty years. The whale-fishers turn the strong affection of the whale for its offspring to most fatal account. They try to strike the young one with the harpoon, and if they effect this, are sure of the old one, for she will not leave it. Mr. Scoresby mentions a case where a young whale was struck beside its dam. She seized it and darted off, but the fatal line was fixed in its body. Regardless of all that could be done to her, she remained beside her dying offspring, without moving, until she was struck again and again, and finally perished. Sometimes, however, she becomes furious on these occasions, and extremely dangerous. A naval officer gives the following account of a case which he witnessed in the Atlantic. Being out with fishing boats, "we saw (says he) a whale, with her calf, playing around the coral rocks; the attention which the dam showed to its young, and the care which she took to warn it of danger, were truly affecting. She led it away from the boats, swam round it, and sometimes she would embrace it with her fins, and roll over with it in the waves. We contrived to get the 'vantage ground' by going to seaward of her, and by that means drove her into shoal water among the rocks. Aware of the danger and impending fate of her inexperienced offspring, she swam rapidly round it, in decreasing circles, evincing the utmost uneasiness and anxiety; but her parental admonitions were unheeded, and it met its fate." The young one was struck and killed, and a harpoon fixed in the mother. Roused to reckless fury, she flew upon one of the boats, and made "her tail descend (says the writer) with irresistible force upon the very centre of our boat, cutting it in two, and killing two of the men; the survivors took to swimming for their lives in all directions." Her subsequent motions were alarmingly furious, but, subsequently, "exhausted by the fountain of black blood which she threw up, she drew near to her calf, and died by its side, evidently, in her last moments, more occupied with the preservation of her young than of herself."

The Greenland whale is captured, it is scarcely necessary to say, chiefly for its oil, about thirty tons of which are procured from the body of a large individual, being nearly the half of its whole weight. The flesh and blubber, also, when recently procured, and pickled and boiled, are not unpalatable, and the Esquimaux, in particular, hold them to be superb feeding. But it is for the oil that mariners from all quarters of the civilized world expose themselves to the dangers and privations attending the pursuit of the animal in the Polar seas. If recent statements be correct, however, these sufferings and risks may be greatly diminished, by the adoption of new fishing routes. Scoresby, as has been mentioned, says that the Greenland whale is to be found only within the Arctic circle, but other observers aver, that the mysticetus, as well as other varieties, migrate southwards every year, and in reality make an annual tour round Cape Horn, beginning their travel about March or April. Many persons represent themselves as having been eye-witnesses of their course; and, among others, the naval officer lately quoted, declares that he has repeatedly seen them passing Bermuda in shoals. The main objection to this statement is, that the *green water* exists only near the poles, and that, at the very time when these journeyings are said to be in progress, our fishers are finding and killing whales by hundreds in the north. At the same time, it is undeniable that the whale is migratory in its habits, and the matter is worthy of a thorough investigation, as the establishment of fishing stations in warm latitudes would prevent much suffering at present endured in the North Sea fishing. The female alone, however, is said to take the circuit mentioned, and the reason is understood to be the instinctive desire of the animal to give strength to her young by taking them to a genial clime.

Being by far the most valuable and frequent object of the fisheries, the Greenland whale has received much more attention here than it is necessary to bestow on the great rorqual, though that variety exceeds all others in magnitude, and is indeed the largest of all the living creatures of the earth. Two specimens have been observed which measured the enormous length of one hundred and five feet. One of these, it is stated by Scoresby, was found floating lifeless in Davis's Straits, and the skeleton of the other was observed by Captain Clarke on Columbia River. This last individual, when alive, must have measured nearly one hundred and twelve feet, allowing six or seven for the tail, and it may therefore be regarded as the largest creature of which we have the authentic measurement. Other specimens have measured a hundred, and others from ninety to eighty feet. The rorqual cast ashore at North Berwick, and preserved by Dr. Knox, was eighty-three feet in length. The colour of the rorqual is a pale bluish black, with the abdominal regions of a grayish tint. In shape, the body is not nearly so cylindrical as that of the mysticetus, but is compressed on the sides, and angular on the back. Hence the common name of "razorback;" and from the dorsal fin, which is low down, and of a small size, springs the equally familiar name of "finner." The blubber of the rorqual is less abundant than that of the Greenland whale, and is seldom more than half a foot in depth, and eight or ten tons in weight; while its baleen, also, is much shorter, coarser, and every way less valuable. This latter circumstance arises partly from the upper jaw being less arched than in the common whale. There is another cause for the inferior fineness of the baleen in the rorqual, which is the greater size of the objects which it employs as food. In the stomach of one individual, six hundred great cod, and immense quantities of other large fish, were found. The gullet, accordingly, is much wider than in the mysticetus. Another striking feature in the rorqual, and the one from which the name is derived, is an immense sort of fold or pouch along the under jaw. This was thought to be an air-bag or swimming bladder, till the observations of Dr. Knox satisfied every one that it was merely a great water-reservoir, for augmenting the capacity of the mouth, otherwise so much diminished in this creature by the want of curve in the upper jaw.

The great rorqual has two blow-holes, through which it blows violently and very loudly; and it swims with much speed, its rate of motion varying from five to twelve miles an hour. The species is very numerous in the Arctic seas, and particularly about Spitzbergen and Nova Zembla. It is a much bolder animal than the mysticetus, and having so little oil in its frame, fishers seldom meddle with it, and dislike, indeed, to see it, as it is supposed to be avoided by the more valuable varieties of its race. If struck by the harpoon, it is excited to most dangerous energy; and on one occasion, an individual drew a whole whaling-vessel, with its crew, with such violence on a bank of ice, that every man on board perished. A rorqual struck by Mr. Scoresby dived with so much velocity, that it ran out 2880 feet of line in one minute, and ultimately snapped the cord. Though thus dangerous, however, as well as comparatively valueless, the Laplanders and Greenlanders seize every occasion of attacking it in their small boats. They usually send as many harpoons into it as possible, and get out of the way, leaving it to die alone, as it usually does, and is then cast or hauled ashore.

A lesser species of the rorqual is found in the Greenland seas, having, like the greater one, a dorsal fin, and measuring usually between twenty and thirty feet in length. That this was a distinct species of rorqual was proved by Dr. Knox, who got possession of a specimen that was cast ashore at Queensferry, and found it to have only forty-eight bones in the vertebral column, whereas the other had sixty-three. This was decisive of its individuality as a genus. It has a fine blue tint in the skin, and its oil is considered as highly delicate and medicinal by the Icelanders, but otherwise the species is one of no general importance.

Not so with the cachalot, physeter macrocephalus, or spermaceti whale, of which there are several varieties. All of them are distinguished by teeth in the lower jaw, by one blow-hole, and by the want of baleen. The leading distinctions between the various kinds of the sperm whale lie in the possession of two fins or three fins; of a spout in the neck or in the snout; of flatted teeth or sharp teeth; and finally of a black, a blue, or a whitish back. But, generally speaking, the characters now to be noticed are proper to all. The sperm whale attains to a great size, varying between sixty and eighty feet. The head is enormous in bulk, being fully more than a third of the whole body, and it ends like an abrupt and steep promontory in front. On the upper part of the snout is placed the blow-hole, often verging a little to one side; and it is a remarkable fact, that this is but one of the various deformities, whether congenital or acquired in the terrible battles waged by the creatures with one another, which are commonly found in the body of this whale. Its eyes are unequal, and the left frequently useless. The back has a greenish-gray tint, and below, much of the creature is white. On the back, there are in most of the species one or two small fins, with large protuberances; the side fins are also of small size, but the tail is an instrument of amazing power. The teeth are usually about forty-two in number, and fit into depressions in the upper jaw. In this whale the gullet is wide enough to admit a man, and the animal feeds on large fish. A molluscous animal (sepia octopus), called *squid* by the sailors, is its chief food in deep seas.

The size of head in the sperm whale has a very extraordinary purpose to serve. To assist in floating the animal, a great cavity in the interior of the skull is filled with a fine oil, which becomes concrete on cooling, and forms the spermaceti of commerce. Some of this oil is also found along the vertebral column; and in a bag in the intestines another valuable substance lies, the ambergris of traders. Some authors, it is proper to state, assert that the ambergris is merely the animal's fæces. These are the principal objects of the sperm whale fishery, the blubber procured from this variety of the cetacea not being nearly so abundant as in the case of the mysticetus. At the same time, the blubber of the sperm whale is valuable, and is usually called sperm oil. The sailors know this whale at a great distance by the act of blowing, which it performs with great regularity, at intervals of ten minutes or so. The spout sent up is visible at the distance of two or three miles, and has the appearance of a misty cloud or bush. Having thus blown, or expired, sixty or seventy times, and made inspirations as often, the animal descends, and can remain under water more than an hour, subsisting on the store of blood which it has oxygenated, and keeps in the reservoirs already described. This alternation of appearances and disappearances is gone through by the animal with undeviating regularity, unless it be disturbed. The sperm whale is timid before man, yet it fights fiercely with those of its own race. Fights usually take place when male whales, or "bulls," as they are called, and one or two of which always attend a particular herd of females, meet with rivals desirous of entering their company. They lock jaws with one another, and exert a dreadful degree of power at one another's cost. When alarmed, or harpooned, they sometimes roll over and over on the surface of the water in an amazing manner. Still they are not furious or dangerous towards the mariner, but are commonly killed with ease. The sailors call a herd a "school, and the old bulls the "schoolmasters." The females are said to be smaller than the males by a fourth. They are, like the mysticetus, very fond of their young and also of one another; so much so, that, by cautious management, a whole herd may be destroyed, as they will scarcely quit a wounded companion.

It has been noticed, however, by the sperm-whalers, that the males do not exhibit any such affectionateness of temperament, but, on the contrary, make an immediate and ungallant retreat on the approach of danger, leaving the females to shift for themselves, and to show the gentler constitution of their nature by helping and guarding their wounded companions. Though exposing themselves to risk on these occasions with so much simplicity, the sperm whales are nevertheless very cautious, and careful to avoid peril in the first instance. They have the power of raising their heads perpendicularly out of the water to a very considerable height, and when in this attitude, which seems to be assumed for the purpose of viewing the surrounding expanse, they present the appearance of huge black rocks. They are said to have the ability, also, on noticing any object, to communicate the intelligence to their companions, though the manner in which this is done remains a secret. Mr. Beale, from whose excellent work on the Pacific whale-fishery we shall immediately make some interesting citations, gives it as his opinion that the sperm-whale can communicate signals to a distance of four, five, and even seven miles. This cannot be effected by sounds, for, above water at least, the animal utters no noise whatever, if we except the hissing sound accompanying the act of respiration. Baron Cuvier and others aver, indeed, that the cachalot sends forth loud groans when struggling in the mortal agony, but this statement is contradicted by all practical whalers. With regard to its other habits, the sperm-whale much resembles the Greenland whale. It is often seen, like its northern congener, to leap directly out of the water, or to *breach*, as the sailors call the action. Its purpose is to get rid of various sucking-fish and crabs, which are fond of effecting a lodgment upon its mountainous body, and which often remain there till plucked from off the captured animal by the whalers. The sperm-whale has been erroneously represented by many writers as a voracious creature, pursuing and destroying all the lesser fishes that come in its way. Leaving out of sight the impracticability of such a thing, arising from its unwieldy bulk, the truth of the matter really is, that the great whale of the South Seas is peculiarly harmless and inoffensive with regard to the smaller tribes of the deep. As in the case of the elephant, nature seems to have gifted this mighty creature with a degree of gentleness proportioned to its size and strength, with a benevolent view to the comforts of other oceanic races. Indeed, the sperm-whale is more sinned against in this way than sinning. The sword-fish and other animals have been observed to attack it with the utmost audacity, and to throw it into a state of prodigious alarm.

It has been mentioned that the principal food of the cachalot is the sepia octopus, or sea-squid. This is an animal of so curious an order as to merit a word of special notice. The common sepia is well known by the name of the cuttle-fish. The principal peculiarity of this molluscous tribe is the possession of powerful tentacula, or arms, ranged round the mouth, and provided with suckers which give them the power of adhering to rocks or any other substances with surprising tenacity. Some of the tribe attain to a great size, and, large as the whale is, will furnish it with no contemptible mouthful. In the gullet of one spermaceti whale, an arm or tentaculum of a sea-squid was found, measuring nearly twenty-seven feet long The native divers of the South Seas have a mortal dread of these squids, and no wonder, seeing that the strength of man is totally inefficient to tear away their tentacula when they are once fixed. A naval captain, we are informed by Sir Grenville Temple, once came in contact with a large sepia when bathing. The animal attached itself to one foot; he felt this, and strove to disengage the creature with the other foot, but it fixed upon that too. He seemed then to have made an attempt to free himself with his hands. These also were firmly grasped, and the poor man was soon after found bound hand and foot, and drowned past recovery! Mr. Beale relates an adventure which he himself had with one of these creatures. He saw it near the surf on one of the Bonin islands, and made some half sportive attempts to capture it, not anticipating any possible harm from a creature which had a blubbery body not above the size of a clenched fist, though its tentacles appeared about two feet in length. He took hold of one of them, and was endeavouring to pull the creature from the rock, when suddenly it turned round and sprang upon his arm, which had been bared for the purpose of seeking shells. It fastened its cold slimy body upon him so firmly that he was in great alarm, especially as it endeavoured to fix its mouth next. He ran to the boat to his friends, and the animal was disengaged, but only by cutting it in pieces. These squids are very numerous in the Pacific seas, and the sperm-whale has abundant feeding upon them and other small fishes.

The cachalot is seldom or never seen in the Greenland seas, at least by modern navigators. It is spread, however, over an immense expanse of the ocean, having been captured, at some time or other, almost everywhere between the latitude of 60° south and 60° north. The coasts of New Guinea and the adjacent archipelagoes, the shores of New Holland, Mitchell's Group, New Zealand, Navigator Isles, Ellis's Group, the shores of Peru, Chili, California, Japan, the Persian Gulf, the Chinese seas, the Moluccas, and many other parts of the ocean, abound more or less with this valuable cetaceous tribe.

In the Naturalist's Library, an able periodical, under the conduct of Sir William Jardine, we find the following minor genera of whales enumerated, after a description of the mysticetus, the rorquals, and the cachalot, the three varieties of greatest use to man. 1st, the nar whal, or sea-unicorn, an animal from sixteen to twenty feet long, and provided with a straight tusk or horn (sometimes two), about four or five feet in length, and projecting from the snout. The animal has a spotted, grayish body, handsomely rounded off, and containing usually near a ton of oil, much prized by the Greenlanders, on whose coasts the narwhal is often seen. The horn yields beautiful ivory, and is greatly sought on that account. 2d, The diodons, or two-teethed whales. These are of a size similar to the preceding, and are a variety of little or no value. 3d, The hyperoodons, animals of a dark colour, about twenty feet long, and distinguished by knobs in place of teeth. 4th and 5th, The aodons and the ziphins, two classes of small toothless whales. 6th, The beluga, or white whale, a creature of pure white colour, exceedingly rounded and symmetrical in form, and from twelve to twenty feet long. It abounds on the northern coasts of Asia and America. In 1815, a beautiful specimen of the race haunted the Forth for three months, and was finally killed, and placed in the Edinburgh Museum. 7th, The delphinapterus, a South-sea whale, is about six feet long, and remarkable only for being beaked somewhat like a bird. 8th, The deductor is an Arctic animal, black in colour, and twenty or twenty-four feet long. It has scarcely any snout, and is most noted for its power of uttering loud cries when in distress, which circumstance has obtained for it the name of the *calling* (calling) whale. Whether other species can cry or not

was already noticed as a matter of doubt. These are the most important of those minor varieties of the cetaceous family, which are ranked among the whales. The dolphin, porpoise, and grampus, on the other hand, have been isolated by naturalists, and are usually considered by themselves.

THE WHALE FISHERY.

Whale-fishing is a practice of long standing in the world. It is natural to suppose that those nations dwelling on the shores of the Arctic seas would be the parties earliest engaged in such pursuits; and accordingly we find, that not only did the Norwegians and other Northmen precede all the other nations of Europe in this perilous but profitable line of enterprise, but they also were the first introducers of it among the southern nations. The shores of the Bay of Biscay, where the Normans formed early settlements, became famous through them for the whale-fishing there carried on. In the same region was it first made a regular commercial pursuit, and as whales then visited the Bay in great quantities, the traffic was convenient and easy. The Biscayans maintained it with great vigour and success in the twelfth, thirteenth, and fourteenth centuries. We find from the work of Noel, "Upon the Antiquity of Whale-fishing," that, in 1261, a tithe was laid upon the tongues of whales imported into Bayonne, they being then a highly esteemed species of food. In 1338, Edward III. relinquished to Peter de Puyanne a duty of £6 sterling each whale, laid on those brought into the port of Biarritz, to indemnify him for the extraordinary expenses he had incurred in fitting out a fleet for the service of his majesty. The Biscayans, however, soon gave up the whale-fishing, from the want of fish, which ceased to come southward, no longer leaving the icy seas. The voyages of the Dutch and English to the Northern Ocean, in order to discover a passage through it to India, though they failed in their primary object, laid open the remote haunts of the whale. The British Muscovy Company obtained a royal charter prohibiting all vessels but theirs from fishing in the seas round Spitzbergen, under pretence that it was discovered by Sir Hugh Willoughby. The fact, however, was, that Barentz, a merchant-seaman of Amsterdam, had discovered it in 1596; and neither Dutch, Spaniards, nor Frenchmen, were at all disposed to admit the justice or propriety of the claim made by the English. An extraordinary scene succeeded in the northern seas. The Muscovy company sent out six or seven strongly armed vessels, which took up a position near Spitzbergen, and commenced an attack on all foreign ships that refused either to quit the region at once, or pay the very moderate toll of one-half the proceeds of their fishing. The English succeeded so far as to annoy everybody else, and to prevent themselves from taking almost a single fish, so busy were they in looking after others. All the nations of Europe remonstrated loudly through their envoys against these proceedings, but the Dutch, ever fearless at sea, sent out a strong fleet, which effectually guarded their own fishing. At length, in 1618, a general engagement took place, in which the English were worsted. Hitherto, the two governments had allowed the fishing adventurers to fight out their own battles; but in consequence of the event mentioned, it was considered prudent to divide the Spitzbergen bay and seas into fishing stations, where the companies might not trouble each other. After this period, the Dutch quickly gained a superiority over their rivals. While the English prosecuted the trade sluggishly and with incompetent means, the Dutch turned their fisheries to great account, and in 1680 had about 260 ships and 14,000 sailors employed in them.

Though there have been, in English history, one or two magnificent instances of the success of great companies, possessed of monopolies and exclusive privileges, there can be little doubt that the attempt to prosecute the whale-fishing at this era failed from its not being opened up to private enterprise. After the cessation of the Muscovy Company, a Greenland Company, with an actual capital of £45,000, entered on the trade, and in nine years came to a ruinous close. In 1725, the South Sea Company took up the adventure, and in eight years, after the outlay of a vast amount of money, they also were compelled to submit to a dead loss of their capital, and throw up the attempt.

The legislature now tried a new scheme, being sincerely desirous to encourage and establish the trade, as well as to make it a nursery for seamen. In 1732, a bounty of 30s. a ton was granted to every ship of 200 tons burden that engaged in the fishing. In 1749, it was thought necessary to raise the bounty to 40s., when, as Mr. M'Culloch observes, as many ships seem to have been fitted out for catching the bounty as for catching fish. But a trade supported on any other principle than that of direct benefit received from it by the parties engaged therein, can never be of an enduring nature, and this truth soon appeared in the present case. In 1777, the bounty was reduced to 30s., the consequence of which was, that during the next five years the number of ships employed in the trade was reduced from 105 to thirty-nine! In 1781, the bounty was raised again to its old level, and an inducement was thus held out for the revival of the spirit of trade. But, after all, what a million and a half of money, expended in successive donations under the name of bounty, was totally inefficient to do, the spirit of private enterprise, once fairly awakened, speedily accomplished. The British whale-fisheries throve rapidly between 1781 and 1795, and the legislature found themselves justified in reducing the bounty, at intervals, from 40s. to 20s. The long continental troubles consequent on the French revolution put a complete period almost to the Dutch fishing, while in the same space of time the British fisheries were continually improving, the conduct of them being left entirely to the private spirit of the nation. A small bounty, indeed, was given even down till 1824, but it was uninfluential, and was then withdrawn altogether. Of the change which has of late years come over the whaling traffic of Britain, a few words will be said before bringing the general subject to a close.

No species of fishery, prosecuted anywhere on the face of the ocean, can compare in intensity of interest with the whale-fishery. The magnitude of the object of the chase, and the perilous character of the seas which it peculiarly frequents, are features which prominently distinguish the profession of the whale-fisher from all similar pursuits, and which invest the details of its history with the strong charm inseparable from pictures of stirring exertion, privation, and danger. Such being the case, we shall present, chiefly from the writings of Captain Scoresby, the highest authority on the subject, a full description of the proceedings connected with the British whale-fishery. Long a whaleman himself, Captain Scoresby had ample opportunities of personal observation, and he was gifted, fortunately, with such powers as enabled him to describe the scenes which fell under his notice with clearness, accuracy, and force.

The ships designed for the whale-fishery are usually from 300 to 400 tons in burden, and require to be very substantially built, in order to resist the pressure of the ice. With the view of increasing their strength, most of them have additional planks and timbers, and often, also, iron-plates and stancheons, introduced into their structure, both internally and externally. Such appurtenances and provisions are technically known by the names of *doublings*, *treblings*, *fortifyings*, *pointers*, *ca* ings, &c. Of course, the whale-ship is also furnished with an ample stock of the apparatus and instruments used in the fishing, as well as with the peculiar boats which are employed in capture and pursuit.

The whale-boat is from twenty to twenty-eight feet in length, and provided with from four to six pair of oars. It should float lightly on the water, and be so formed as to move with speed, and to turn easily round. They are "carver-built," as it is called, and the best made ones are composed of straight oak planks, suppled and bent to the required shape, by which means their elasticity is greatly increased. The rapid and dangerous movements of the whale render these various qualities indispensable. The principal weapons with which whale-fishers are supplied, are the *harpoon* and the *lance*. The harpoon is an iron instrument about three feet long, and consists of three conjoined parts, the "socket," "shank," and "withers" or barbs. The socket is about six inches in length; the shank, which is between the withers and socket, is nearly eighteen inches long; and the withers are eight inches long by six in breadth. The united withers are triangular in shape, and the shank is fixed between them. The shank of the harpoon is the most important part of the weapon. It is formed of the most pliable iron, old horse-shoe nails being usually preferred for the purpose; and it is not more than four-sixteenths of an inch in diameter. Much attention is paid to the manufacture of the shank, because on its flexibility the retention of a harpooned whale depends. If the shank should break during the plunges of the whale, the animal is lost to the fishers. Unless the shank will bear to be wound round an inch bar of iron, in the form of a close spiral, and to be again unwound, it is held to be of imperfect materials. The socket is hollow and strong, and swells, from the point of its junction with the shank, to a diameter of two inches. It is only necessary to add to this description of the harpoon, that each of the withers has at its point a smaller and reversed barb, like the beard of a fish-hook. The use of this provision is obvious.

The lance is a more simple instrument. It is nearly ten feet long, and consists of a hollow socket into which a fir stock is inserted, of a shank of iron about half an inch in diameter, and of a sharp, flat point or tongue of steel, seven inches long by two in breadth. This instrument and the harpoon, together with lines and boats, are all the apparatus absolutely necessary for capturing the whale. Some ships have a harpoon-gun, or a gun which projects the harpoon; but this weapon has been found extremely uncertain when put to use.

The ships destined for the Greenland fishery put to sea in March, or during the first days of April. The crew of one of these vessels usually consists of from forty to fifty men, comprising various classes of inferior officers, such as harpooners, boat-steerers, line-managers, carpenters, landsmen, and others. Steering from the direction of Shetland, on a course to the east of north, the whalers commonly reach and pass the west side of Spitzbergen in the end of the month of May. From this point they continue their course till they arrive at the latitude of 78° or 78½° (the best parallel for fish), or till they meet with whales. There is a remarkable indentation in the ice, lying between longitude 5° and 10°, which the whalers for the most part strive to enter; but their course must be regulated greatly by the state of the ice. On reaching a fishing station where whales are seen, preparations are immediately made for commencing the business of capture. Two or three boats at the least are always kept suspended from cranes by the side of the ship, in such a position that they can be lowered into the water, with their complements of men, and the whole necessary apparatus, in the space of one minute. Previously to this time, the harpoons and lines have been got in order. The socket of the harpoon has been furnished with a stock or handle, six or seven feet long, and fastened in its place by means of a splice of strong rope, called a *foreganger*, the eye of which is kept firmly fixed to the iron of the harpoon by the *swelling* of the socket. To the loose end of the foreganger are attached five or six fathoms of line, called the stray line, and this again is connected with the other lines of the boat. In each boat there are about 4320 feet of rope, neatly though loosely coiled up in six separate portions, and laid down in places appointed for the purpose. The line or rope is made of the best hemp, and is about 2½ inches in circumference. An axe, to cut the lines if necessary, a bucket to lave the lines and keep them from being overheated by friction, and a few other articles, are also laid down in the boats for use.

MODE OF FISHING.

Whenever there is a probability of seeing whales, the master, or some experienced officer, keeps a close look-out from the *crow's-nest*, a station at the mast-head so called. With the assistance of a telescope he scans the surface of the waters around, ready, at the first glimpse of a fish, to give notice to the watch on deck. In fine weather, a boat is kept afloat, manned, and engaged also in the look-out. The short time during which whales usually remain above water to breathe (being only two minutes), renders the discovery of them less easy than might be anticipated from their great bulk. Besides, while below water, the animal frequently traverses a space of half a mile in the ten or fifteen minutes intervening between the respirations; and hence the spot at which it may again rise, after being once seen and again disappearing, is left in a great measure a subject of conjecture. The previous direction of the whale's movements, and occasionally a sort of eddy on the surface, are the only guides to the boatmen in this particular. When the whale does come up within reach of a harpoon-cast, and lies unconscious of the approach of its enemies, "then (says Captain Scoresby) the hardy fisher rows directly upon it, and an instant before the boat touches it, buries his harpoon in its back. But if, while the boat is yet at a little distance, the whale should indicate his intention of diving, by lifting his head above the common level, and then plunging it under water, and raising its body until it appear like the large segment of a sphere, the harpoon is thrown from the hand, or fired from a gun, the former of which, when skilfully practised, is efficient at the distance of eight or ten yards, and the latter at the distance of thirty yards or upwards. The wounded whale, in the surprise and agony of the moment, makes a convulsive effort to escape. Then is the moment of danger. The boat is subjected to the most violent blows from its head or its fins, but particularly from its ponderous tail, which sometimes sweeps the air with such tremendous fury, that both boat and men are exposed to one common destruction.

"The head of the whale is avoided, because it cannot be penetrated with the harpoon; but any part of the body between the head and tail will admit of the full length of the instrument, without danger of obstruction. The harpoon, therefore, is always struck into the back, and generally well forward towards the fins, thus affording the chance, when it happens to drag and plough along the back, of retaining its hold during a longer time than when struck in closer to the tail.

"The moment that the wounded whale disappears, or leaves the boat, a jack or flag, elevated on a staff, is displayed, on sight of which, those on watch in the ship give the alarm, by stamping on the deck, accompanied by a simultaneous and continued shout of 'a fall!'*

"* The word 'fall,' as well as many others used in the fishery, is derived from the Dutch language. In the original it is written *val*, implying jump, drop, fall, and is considered expressive of the conduct of the sailors when manning the boats on an occasion requiring extreme despatch.

the sleeping crew, roused by the sound, jump from their beds, rush upon deck, with their clothes tied by a string in their hands, and crowd into the boats, at a temperature of zero. They generally contrive to dress themselves, in part at least, as the boats are lowered down; but sometimes they push off in the state in which they rise from their beds, row away towards the 'fast boat,' that is, the boat attached by its harpoon and line, to the whale, and have no opportunity to clothe themselves for a length of time afterwards. The alarm of 'a fall' has a singular effect on the feelings of a sleeping person, unaccustomed to the whale-fishing business. It has often been mistaken for a cry of distress. A landsman in a Hull ship, seeing the crew, on the occasion of a fall, rush upon deck, with their clothes in their hands, when there was no appearance of danger, thought the men were all mad. But with another individual the effect was totally different. Alarmed with the extraordinary noise, and still more so, when he reached the deck, with the appearance of all the crew seated in the boats in their shirts, he imagined the ship was sinking. He therefore endeavoured to get into a boat himself, but every one of them being fully manned, he was always repulsed. After several fruitless endeavours to gain a place among his comrades, he cried out, with feelings of evident distress, 'What shall I do?—will none of you take me in?'

"The first effort of a 'fast fish,' or whale that has been struck, is to escape from the boat, by sinking under water. After this, it pursues its course directly downwards, or reappears at a little distance, and swims with great celerity, near the surface of the water, towards any neighbouring ice, among which it may attain an imaginary shelter; or it returns instantly to the surface, and gives evidence of its agony by the most convulsive throes, in which its fins and tail are alternately displayed in the air, and dashed into the water with tremendous violence. The former behaviour, however, that is, to dive towards the bottom of the sea, is so frequent in comparison of any other, that it may be considered as the general conduct of a fast fish.

"A whale struck near the edge of any large sheet of ice, and passing underneath it, will sometimes run the whole of the lines out of the boat, in the space of eight or ten minutes of time. This being the case, when the 'fast boat' is at a distance, both from the ship and from any other boat, it frequently happens that the lines are all withdrawn before assistance arrives, and, with the fish, entirely lost. In some cases, however, they are recovered. To retard, therefore, as much as possible, the flight of the whale, it is usual for the harpooner who strikes it, to cast, one, two, or more turns of line round a kind of post, called a ballard, which is fixed within ten or twelve inches of the stern of the boat for the purpose. Such is the friction of the line, when running round the ballard, that it frequently envelopes the harpooner in smoke; and if the wood were not repeatedly wetted, would probably set fire to the boat. During the capture of one whale, a groove is sometimes cut in the ballard, near an inch in depth; and were it not for a plate of brass, iron, or a block of lignum vitæ, which covers the top of the stem where the line passes over, it is apprehended that the action of the line on the material of the boat would cut it down to the water's edge, in the course of one season of successful fishing. The approaching distress of a boat, for want of line, is indicated by the elevation of an oar, in the way of a mast, to which is added a second, a third, or even a fourth, in proportion to the nature of the exigency. The utmost care and attention are requisite, on the part of every person in the boat, when the lines are running out: fatal consequences having been sometimes produced by the most trifling neglect. When the line happens 'to run foul,' and cannot be cleared on the instant, it sometimes draws the boat under water; on which, if no auxiliary boat or convenient piece of ice be at hand, the crew are plunged into the sea, and are obliged to trust to the buoyancy of their oars, or to their skill in swimming, for supporting themselves on the surface. To provide against such an accident, as well as to be ready to furnish an additional supply of lines, it is usual, when boats are sent in pursuit, for two to go out in company, and when a whale has been struck, for the first assisting boat which approaches to join the fast boat, and to stay by it until the fish reappears. The other boats, likewise, make towards the one carrying a flag, and surround it at various distances, awaiting the appearance of the wounded whale.

"On my first voyage to the whale fishery, such an accident, as above alluded to, occurred. A thousand fathoms of line were already out, and the fast boat was forcibly pressed against the side of a piece of ice. The harpooner, in his anxiety to retard the flight of the whale, applied too many turns to the line round the ballard, which, getting entangled, drew the boat beneath the ice. Another boat, providentially, was at hand, into which the crew, including myself, who happened to be present, had just time to escape.

"The whale, with nearly two miles' length of line, was in consequence of the accident lost, but the boat was recovered. On a subsequent occasion I underwent a similar misadventure, but with a happier result; we escaped with a little wetting into an accompanying boat, and the whale was afterwards captured, and the boat with its lines recovered.

"When fish have been struck by myself, I have on different occasions estimated their rate of descent. For the first 300 fathoms, the average velocity was usually after the rate of eight to ten miles per hour. In one instance, the third line of 120 fathoms was run out in sixty-one seconds; that is, at the rate of eight and one-sixth English miles, or seven and one-eighth nautical miles, per hour. By the motions of the fast boat, the simultaneous movements of the whale are estimated. The auxiliary boats, accordingly, take their stations about the situation where the whale, from these motions, may reasonably be expected to appear.

"The average stay under water of a wounded whale, which steadily descends after being struck, according to the most usual conduct of the animal, is about thirty minutes. The longest I ever observed was fifty-six minutes; but in shallow water, I have been informed, it has sometimes been known to remain an hour and a half at the bottom after being struck, and yet has returned to the surface alive. The greater the velocity, the more considerable the distance to which it descends, and the longer the time it remains under water, so much greater in proportion is the extent of its exhaustion and the consequent facility of accomplishing its capture. Immediately on its reappearing, the assisting boats make for the place with their utmost speed, and as they reach it, each harpooner plunges his harpoon into its back, to the amount of three, four, or more, according to the size of the whale and the nature of the situation. Most frequently, however, it descends for a few minutes after receiving the first harpoon, and obliges the other boats to await its return to the surface, before any further attack can be made. It is afterwards actively plied with lances, which are thrust into its body, aiming at its vitals. At length, when exhausted by numerous wounds and the loss of blood which flows from the huge animal in copious streams, it indicates the approach of its dissolution by discharging from its 'blowholes' a mixture of blood along with the air and mucus which it usually expires, and finally jets of blood alone. The sea, to a great extent around, is dyed with its blood, and the ice, boats, and men, are sometimes drenched with the same. Its track is likewise made by a b oad pellicle of oil, which exudes from its wounds, still appears on the surface of the sea.

"Its final capture is sometimes preceded by a convulsive struggle, in which its tail, reared, whirled, and violently jerked in the air, resounds to the distance of miles. In dying, it turns on its back or on its side, which joyful circumstance is announced by the capturers with the striking of their flags, accompanied by three lively huzzas!"

The writer of this animated description points out how remarkably nature seems to assist man in the capture of the whale. By no efforts of its human assailants could the strength of the creature be so far reduced as to permit of its destruction, were it not that its descent, through fright, to a depth of 700 or 800 fathoms, must subject its body to the exhausting pressure of more than 200,000 tons of superincumbent water! It is through this cause rather than from the wounds the whale has received, that it comes to the surface in so helpless a state of exhaustion. The space of time in which different individuals are captured and killed, varies considerably, and, in part, for the same reason. Large whales have been sometimes killed in twenty minutes, while in other instances, the animal costs his assailants a struggle of sixteen hours' duration, and in some cases more, and may escape from them after all. The average time, under favourable circumstances, is one hour, but two or three hours are no uncommon period for the contest to last, even in favourable circumstances. Two harpoons usually despatch a whale of middling size, and its movements may commonly be restrained within the limits of 600 fathoms of line. On the career or flight of a first-size whale, no check can be placed, until its own exertions exhaust its powers.

The ease with which some whales are subdued, and the slightness of the entanglement by which they are taken, have often been the cause of agreeable surprise to fishers. The following case would almost incline one to accuse the whale of a degree of stupidity unknown among the lowest of the brute creation:—"A whale was struck from one of the boats of the ship Nautilus in Davis' Straits. It was killed, and, as is usual after the capture, it was disentangled of the line connected with the first 'fast-boat,' by dividing it within eight or nine yards of the harpoon. The crew of the boat from which the fish was first struck, in the mean time, were employed in heaving in the lines, by means of a crank fixed in the boat for the purpose, which they progressively effected for some time. On a sudden, however, to their great astonishment, the lines were pulled away from them, with the same force and violence as by a whale when first struck. They repeated their signal, indicative of a whale being struck; their shipmates flocked towards them; and while every one expressed a similar degree of astonishment with themselves, they all agreed that a fish was fast to the line. In a few minutes they were agreeably confirmed in their opinion, and relieved from suspense, by the rising of a large whale close by them, exhausted with fatigue, and having every appearance of a fast-fish. It permitted itself to be struck by several harpoons at once, and was speedily killed. On examining it after death, to discover the cause of such an interesting accident, they found the line belonging to the above-mentioned boat in its mouth, where it was still firmly fixed by the compression of its lips. The occasion of this happy and puzzling accident was therefore solved. The end of the line, after being cut from the whale first killed, was in the act of sinking in the water; the fish in question, engaged in feeding, was advancing with its mouth wide open, and accidentally caught the line between its extended jaws—a sensation so utterly unusual as that produced by the line, had induced it to shut its mouth and grasp the line, which was the cause of its alarm, so firmly between its lips, as to produce the effect just stated. This circumstance took place many years ago, but a similar one occurred in the year 1814."

Another case of easy capture, though one not quite so disparaging to the intellect of the whale, has been recorded by Scoresby:—"A harpooner, belonging to the Prince of Brazil, of Hull, had struck a small fish. It descended, and remained for some time quiet, and at length appeared to be drowned. The strain on the line being then considerable, it was taken to the ship, with a view of heaving the fish up. The force requisite for performing this operation was extremely various; sometimes the line came with ease, at others, a quantity was withdrawn with great force and rapidity. As such, it appeared evident that the fish was yet alive. The heaving, however, was persisted in, and after the greater part of the lines had been drawn on board, a dead fish appeared at the surface, secured by several turns of the line round its body. It was disentangled with difficulty, and was confidently believed to be the whale they had struck. But when the line was cleared from the fish, it proved to be merely the 'bight,' for the end still hung perpendicularly downward. What was, then, their surprise to find that it was still pulled away with considerable force! The capstan was again resorted to, and shortly afterwards they hove up, also dead, the fish originally struck, with the harpoon still fast. Hence it appeared, that the fish first drawn up had got accidentally entangled with the line, and in its struggles to escape had still farther involved itself, by winding the line repeatedly round its body. The first fish entangled, as was suspected, had long been dead; and it was this lucky interloper that occasioned the jerks and other singular effects observed on the line."

The whale-fishing is apt to be impeded, as may readily be imagined, by the great masses of ice everywhere abounding in the northern seas. The usual course of proceedings in open water has been described; in different circumstances, different plans must be adopted. *Pack-fishing* is the name given to the chase of the whale on the borders of close packs of drift-ice. The animal loves to shelter his vast bulk under the lee of these frozen masses, and, when struck, usually flies to them for refuge, thus endangering the lines and lives of the whalemen. The common method of providing against such contingencies, is either to strike the fish with two harpoons from different boats at the same moment, or to affix the line of a second boat to that of the one from which the whale has been harpooned, so that the strength of two lines is brought into play against the fish. Sometimes, when the fish gets entangled in the drift-ice, the adventurous seamen climb over it, and lance the animal from that perilous station. Altogether, pack-fishing is troublesome and dangerous, and were it not that the largest whales often resort to such situations, whalers would seldom attempt to fish there.

On the other hand, *field-fishing*, as it is called, or fishing on the edges of those wide connected plains of ice termed fields, is one of the most productive of all the modes of fishing prosecuted in the Greenland seas. When the weather is tolerably mild, it is also a pretty secure mode. The most marked of the advantages held out by field-fishing, is the curtailment of the range of the whale's movements. When harpooned, it commonly descends obliquely beneath the field, and, being unable to rise through the ice, is forced to return to the edge, or nearly to the spot where it made the plunge. Thus, the ship's boats, if stationed along the margin of the field, can at once harpoon it a second time, and despatch it. In open water, the whale, by rising at a spot far apart from where it dived, gains time to breathe freely and recruit its strength, and so either breaks away altogether, or greatly protracts the struggle. For this reason, six boats at a field will do the work of twelve in open sea. Two or more fish are frequently taken at a field at one time, and on r particular occasion six fish were actually captured at once by the seven boats of a single ship. Even in such weather as renders fishing impracticable elsewhere, field-fishing can be prosecuted with success. But there are disadvantages also attendant on this mode. The movements of fields of ice are so rapid, various, and unaccountable, and their powers of doing mischief so unlimited, that the utmost prudence and skill cannot entirely secure vessels lying in their vicinity from the risk of severe damage or total destruction. Small fields or floes are especially dangerous, particularly if they contain small cracks or holes in the centre of them. The chance of a sudden movement in such floes is much greater that in the case of the large fields, and, moreover, after being struck, the whale generally makes for the apertures in the ice, and there breathes freely, rendering it necessary for the men to cross the field on foot, and despatch their prey with the lance. Even when they succeed in doing this, there is no way of getting out the whale but by sinking it, and dragging it from below the ice, at the great risk of pulling out the harpoon altogether; or by cutting the blubber away, and transporting it over the surface of the floe, piece by piece. These operations are attended with vast labour and loss of time. "As connected with this subject (says Captain Scoresby), I cannot pass over a circumstance which occurred within my own observation, and which excited my highest admiration. On the 8th of July, 1813, the ship Esk lay by the edge of a sheet of ice, in which were several thin parts, and some holes. Here a fish being heard blowing, a harpoon, with a line connected to it, was conveyed across the ice from a boat on guard, and the harpooner succeeded in striking the whale at a distance of 350 yards from the verge. It dragged out ten lines (2400 yards), and was supposed to be seen blowing in different holes in the ice. After some time it happened to make its appearance on the exterior, when a harpoon was struck at the moment it was proceeding again beneath. About 100 yards from the edge, it broke the ice where it was a foot in thickness with its crown, and respired through the opening. It then determinately pushed forward, breaking the ice as it advanced, in spite of the lances constantly directed against it. It reached, at length, a kind of basin in the field, where it floated on the surface of the water without any encumbrance from ice. Its back being fairly exposed, the harpoon, struck from the boat on the outside, was observed to be so slightly entangled that it was ready to drop out. Some of the officers lamented this circumstance, and expressed a wish that the harpoon were better fast; observing, at the same time, that if it should slip out, the whale would either be lost or they would be under the necessity of cutting it up where it lay, and of dragging the pieces of blubber over the ice to the ship—a kind and degree of labour which every one was anxious to avoid. No sooner was the wish expressed, and its importance made known, than one of the sailors, a smart and enterprising fellow, stepped forward and volunteered his services to strike it better in. Not at all intimidated by the surprise which was manifested in every countenance by such a bold proposal, he pulled out his pocket-knife, leaped upon the back of the living whale, and immediately cut the harpoon out. Stimulated by this courageous example, one of his companions proceeded to his assistance. While one of them hauled upon the line and held it in his hands, the other set his shoulder against the extremity of the harpoon, and though it was without a stock, he contrived to strike it again into the fish more effectually than it was at first; the fish was in motion before they finished. After they got off its back, it advanced a considerable distance, breaking the ice all the way, and survived this uncommon treatment ten or fifteen minutes. This admirable act was an essential benefit. The fish fortunately sank spontaneously after being killed, on which it was hauled out to the edge of the ice by the line, and secured without further trouble. It proved a stout whale, and an acceptable prize."

If whalers could choose their own ground for fishing, many of them would probably prefer a position among open, navigable drift-ice, where the force of the sea is broken, and heavy swells prevented from affecting the vessel. This kind of fishing is called *open pack-fishing*, and is held to be advantageous for the capture of whales. Where the ice is crowded, however, and affords room for boats to pass through it, the chase becomes difficult and hazardous. Still, as the fishers must take the seas as they find them, fishing is often conducted in this situation of things. Success depends on the boats being spread widely, on the incessant watchfulness of the harpooners, and on their occasionally taking the benefit of a mass of ice, from the elevation of which the fish may sometimes be seen blowing in the interspaces. Celerity in rowing, and the highest degree of activity in all the proceedings, can alone give a chance of success in open pack-fishing.

Whalers must also be prepared to meet and combat all the difficulties attending the prosecution of their employment in *storms* and *fogs*. When a gale occurs during a chase, and after a fish has been harpooned, fishers are often obliged to cut the lines and let the prize go. Sometimes this takes place even when the fish is killed, and it is worthy of remark that a whale so abandoned becomes the lawful prize of the ship that first gets hold of it, though this may occur in the face of the original captors. But it is common enough for whalers during a storm to keep a fish secured by a hawser to the ship, and to retain it thus till the return of moderate weather. Few whalers venture to commence fishing while a storm exists, and it is a matter of equal difficulty and uncertainty to fish during a fog. The mist on such occasions is so thick that it is impossible to see objects, however large, above 100 or 150 yards off; and when a boat is led away by the chase to such a distance that a bell or a horn cannot be heard, its situation becomes very perilous. The only rule in these cases is to make every possible exertion for the rapid despatch of the whale, and if this be impracticable, to leave it.

Captain Scoresby gives an interesting account of the plan pursued by himself in *bay-ice fishing*. Being locked up with his ship in a field of thin bay-ice that was unfit in many places to bear a man's weight, he placed a number of boats in various openings which existed a short way from the vessel. When a whale came to these apertures to breathe, it was struck, and the men endeavoured to drown it, when it darted below the ice, by keeping a steady strain on the line. If this plan failed, Captain Scoresby planted his feet in a pair of ice-shoes, formed simply of thin deal-boards, to the centre of which the feet were tied, and then he boldly crossed the thin ice to the point where, by the direction of the line, he knew the fish would rise. In three instances he was fortunate enough to see the whale through the ice and to plunge his harpoon into its body, after which he used his lance, till in each case the fish was killed. The fish actually rose once or twice beneath the very spot where he stood, and broke through the ice with its head. He was lucky enough to escape all injury, however, though the ice in most places could not have borne the weight of a boy standing in common shoes. This kind of bay-ice fishing, though successful, will be regarded by most persons as somewhat daring and hazardous.

Of course, in all these various ways of fishing, circumstances now and then occur which set at defiance all ordinary rules. The whale, for example, when struck near the margin of a small floe, is usually held in restraint, and killed by the use of the lines from at most *two* boats. On the 25th of June, 1812, however, a harpooner belonging to the Resolution of Whitby, struck a fish close by a small floe, under which it disappeared. Assistance was quickly given, and a second boat's lines were attached to those of the fast-boat (or boat attached to the whale), after which it was left by the other boatmen, who spread out for a second stroke. But in a short time distress signals were made by the fast-boat, and before aid could be afforded, the men were seen to throw themselves into the sea. Immediately afterwards the bow of the boat sank in the water, the stern rose in the air, and the whole majestically disappeared. An accidental circumstance had prevented the cutting of the lines. The men were picked up, and a search commenced for the whale. It was ere long seen, and no less than three harpoons, each having a boat and its lines attached to it, were buried in the animal's body. Every one imagined that all was now secure beyond risk. Not so, however; the whale pushed impetuously forward, and soon the men of one boat found their lines run out, and were obliged to cut them. The harpoon of another boat was drawn out from the body of the fish, and now one boat only remained in connection with the animal. The creature still darted forward with the velocity of light, and not only pulled out the lines of the remaining boat, but made it fly along like an arrow. At length the line snapt, and the whale went off free, with a boat and 6720 yards, or about 3⅘ English miles, of line behind it. The obstruction to its progress, caused by the sunken boat, and by the lines also, which weighed 35 cwt., must have been immense, yet the whale pushed on with unabated vigour. It was pursued, and about *ten miles* from the spot where it was first struck, it was again struck by four harpoons, and yielded at length to its fate. Calculating the additional lines used at the death, this fish ran out nearly six miles of lines. The boat and 31,200 yards of line were lost. After all, the whale proved to be one but of the second or third size. But the largest are by no means the most difficult, in general, to kill.

The harpoon does not always produce a fatal loss of blood, even after the lapse of a considerable period. An Aberdeen whaler struck a fish, which got off in consequence of a storm occurring, and rendering it necessary to cut the lines. Next day the same fish was struck, and again got off; and on the third day the identical whale was a third time harpooned, and captured. A Leith whaler, in 1817, pursued a fish which survived forty hours after being first harpooned, although in the interval four other harpoons were launched into its body. This animal continued, through the greater part of the long period mentioned, to fly at great speed, dragging six boats through the water. Finding that nothing done by the boatmen could arrest its course, the lines were taken on board the ship, which had followed the boats. Strange to say, the strength of the creature was so great, even after its wounds, and its long and most exhausting run, that it dragged the ship in the teeth of a brisk wind for an hour and a half, at the rate of two knots an hour, though the sails were arranged so as to make every possible resistance, and to the best advantage. The whale proved to be of a size proportioned to the immense strength which it displayed.

Whales on being struck are sometimes able to eject the harpoon, by a sudden swelling out or heaving of the body. A curious case is on record, where a whale disengaged the harpoon in this manner, and caused it to spin high up in the air. But the poor fish did not save itself. Having got rid of the weapon, it turned suddenly over upon its back, and the falling harpoon entered the under part of its body, and sank so deeply into it as to cause its speedy capture.

Having killed a fish, the first operation performed by the sailors is to pierce two holes in its tail and to lash it to a boat. The fins are also roped to the body, and then the whole of the boats, joined in a line, unite their efforts in towing it to the ship. Here it is placed with its side parallel to that of the vessel, and is arranged for the operation of *flensing*. In consequence of its enormous weight, it cannot be raised altogether out of the water. Only about one-fifth part of its body is brought above the surface, and here it is firmly secured by ropes, with the abdomen uppermost. Men, armed with spurs on their feet to prevent slipping, then leap on the body, and begin to divide the fat and skin into separate pieces or compartments, by means of blubber knives or spades. A hook called a spec-tackle, which hangs from a capstern or winch on deck, is attached to each piece of fat, and draws it upwards as it is flayed off. Pieces weighing from half a ton to a ton are taken up at a time in this manner, and are cut on deck into smaller pieces, which are then cast down into the main hatches and stowed away. On the blubber being removed from one part, the whale is turned partially round by the ropes and windlass, and this cutting and turning are repeated until the whalebone and blubber have all been removed. The stripped carcass is then allowed to sink. Sharks and filmars often help themselves to the refuse blubber, but they not unfrequently pay for their audacity with their lives. A British whaling-crew will usually flense a common-sized whale in four or five hours. The operation is followed, when the flens-gut, or blubber-box, under hatches is filled with blubber, by another process which is termed *making-off*, from its being the finishing process. The blubber is brought on deck, separated from the skin and fibrous or muscular structure, cut into pieces of a few inches in size, and finally introduced into casks, through the bung-hole.

The instinctive fear of being enclosed in the ice during the cold seasons, and of finding no apertures for respiration, appears to be the reason for the descent of the whales into the open and more southerly seas. In the month of July, when the ice becomes broken, the cetaceous tribes again enter the Arctic waters, and are unassailable by fishers. The whalers, with a lesser or greater amount of cargo, or perhaps, if they have been very unlucky, with what is emphatically called a *clean* ship, are then obliged to return home to their respective ports, where the blubber is separated from its refuse and converted into oil by boiling, and the whalebone scraped, cleansed, and dried for sale. These operations require no special description, the names of the processes sufficiently indicating their character. The greatest cargo ever borne to the shores of Britain by a whaling vessel, was that brought from Spitzbergen by Captain Souter of the Resolution of Peterhead, in the year 1814. It consisted of 44 whales, which produced 299 tons of oil, value, reckoned at £32 per ton, the average price of that year, £9,568; and when to this sum is added the value of the whalebone, and the bounty, the freight would appear to have reached £11,000. When oil rose to £60 per ton, smaller cargoes, in several instances, amounted to an equal value. In 1813, the Scoresbys, father and son, respectively brought home cargoes which produced the sum of £11,000. Captain Scoresby, senior, in the course of 28 voyages, captured the immense number of 498 whales, the oil and whalebone of which amounted in value to above £150,000 But few single cargoes produce such sums, it must be allowed, as £11,000, and few individual men have such a career of activity to look back upon as Captain Scoresby.

PRESENT CONDITION OF THE WHALE-FISHERY.

In the years 1814, 1815, 1816, and 1817, 392 vessels sailed from England, and 194 from Scotland, for the whale-fishery. Of these, the port of Hull, which has long taken the precedence in this trade, sent out not less than 229 vessels, while London, Aberdeen, Leith, and Whitby, the next in proportion, sent out respectively 77, 55, 40, and 39. The total number of whales killed by British ships in the same years, was 5030. They yielded 54,508 tons of oil, and 2697 tons of whalebone. The average to each ship was 8.6 whales, 93 tons of oil and 4.6 tons of whalebone. By comparison with the following more recent years, the progressive condition of the trade will be seen. In 1820, 140 vessels were sent from Great Britain to the fishery. In 1821, when the number was greatest, there were 142 ships, of 44,864 tons, and with 6074 men engaged in the service; in 1824, 120 ships, of 35,194 tons, and 4867 men. In 1829, a great falling off had taken place, the ships numbering only 89, of 28,812 tons. During the years consequent upon that period, a still greater decline took place in the number of employed whale-ships. In 1832, there were only 81 engaged in the trade. In 1837, the number was reduced to 59. In 1838, Aberdeen, which, twenty years before, had sent out 55 ships, sent only five or six from its port. The decline has been similar within the last two years in other quarters of the island. This unfortunate change—for every declension in commerce, generally speaking, must be held a misfortune—merits some attention.

The decline of the British northern whale-fisheries appears to be owing to three principal causes. In the first place, the introduction of gas into universal use of late years in the Island, has materially lessened the demand for whale-oil, and the necessity for its supply. In the second place, the former fishing-fields around Spitzbergen have been greatly exhausted, and whalers have been under the necessity of venturing into more perilous latitudes for the objects of their pursuit. The third cause is in a measure a corollary of the preceding one. In consequence of entering the broken ice of Davis' Straits and other similar seas, a loss of life and property has taken place of late years, so extensive and alarming, that mercantile men have become unwilling to risk their capital, and seamen their existence, in such ill-fated expeditions. The great increase of danger is shown by the fate of the fishing-vessels during the last few years, as compared with the results of former ones. Of 586 ships sent out in 1814, 15, 16, 17, only 8 were lost. In 1819, out of 63 ships sent to *Davis' Straits*, 10 were lost; in 1821, out of 79, 11 were lost; in 1822, out of 60, 7 were lost; and in 1830, not less than 18 out of 87 were lost. The mischief has progressively increased. In 1837, the Davis' Straits whale-fleet lost several of its number, and many vessels were locked up in the ice through the winter, to the loss of the greater part of their crews, and at the cost of almost unparalleled sufferings to the petty remnants of them which escaped with life. And while the perils of the trade have thus largely increased, the profits, owing to the greater difficulty of finding whales, have suffered a corresponding decrease. In 1830, 24 out of the 87 vessels sent out to Davis' Straits, returned *clean*. Not a fish was taken by them. In the most of the years that have followed, the majority of the whalers have returned with comparatively paltry freights, and many without a pound of blubber.

The declension, and apparent approaching extinction of the northern whale-fishing, which has so long been an important pillar of our commercial greatness, could not but excite uneasiness and regret in the minds of many persons who have opportunities of making observations on the subject. Accordingly, we find that various plans have been proposed for the revival of this branch of the trade of Britain. Although we conceive that the substitution of gas for oil is one important cause of the decreased ardour for whaling enterprises, and a cause, besides, neither to be deplored nor capable of remedy, and although it also appears to us that the exhaustion of the old whaling fields is another source of the evils complained of, and one only to be affected by time, yet there might, we believe, be plans adopted which would help at once to restore the lucrative character of the whale-fishery, and to alleviate or entirely prevent the misfortunes which have attended its prosecution of late years. The most rational scheme which we have yet chanced to see proposed, is contained in the following extract from the Aberdeen Herald:—

"The plan is simply to establish a settlement of active and enterprising whale fishers on some favourable spot in the vicinity of Davis' Straits, and to employ only so many large vessels as may be necessary to carry out provisions to the colony, and fetch home the oil, blubber, whalebone, and other articles which may be thought worth importing. From all the information that we at present possess, we should think that the most eligible position for the settlement would be at Pond's Bay, or somewhere between that and Lancaster Sound, on the west coast of Baffin's Bay. There are some situations on the north-east shore (Prince Regent's Bay, for example) that might be found suitable; but of late years, the fishers assert that the whales have been most plentiful towards the other shore."

The practicability of carrying such a plan into effect, and the advantages likely to result from it, are the only two points that fall to be noticed here. The testimony of recent travellers, as well as of seamen who have been compelled to winter in the high latitudes, goes to prove the practicability of establishing and maintaining an efficient colony, even as far north as the place we have pointed out. Captain Ross's remark, that 'the temperature of sensation is more relative than is imagined, the body soon contriving to find a new and much lower scale of comfortable or endurable heat,' has been completely verified by all who have visited the Polar regions. The attention now paid to the quality of ship provisions, and the improved methods of preserving them, have not only put a stop to the inroads of scurvy, but have tended materially to increase the comfort of those who choose to lengthen their stay in cold countries. In East Greenland there are several Danish settlements. Holsteinberg, within the Arctic circle, is a small town, with a church and a clergyman; and still higher up, at Lievely, in Disco Island, the chief Danish governor resides. With an ample store of food and clothing, and materials for constructing houses, there can be no doubt that a colony of hardy whalers would contrive to pass the winter agreeably and in comfort. Nor would they be dependent altogether on the supplies carried with them, or procured from the mother country. The musk ox, the reindeer, the white bear, the hare, and a number of other quadrupeds, would afford them at once sport and a valuable addition to their means of sustenance. Birds, too, and fresh fish of various kinds, would not be wanting to give variety to their repasts; while lobsters, mussels, and other shell-fish, could be had as abundantly as at home. To avoid all risks of famine, it would be proper to have always in the settlement provisions for two years; although it could hardly ever happen that the settlers would be so completely shut up as to be inaccessible during the whole of the summer months.

The advantages of having a numerous body of fishers on the spot, instead of sending them out annually, can easily be made apparent. 1st, There would be a saving of outlaid capital. For some time past, the ships sent from Great Britain to Davis' Straits may have averaged 100 each year; and we believe we speak within limits when we assert, that the oil and whalebone which they have brought home might easily have been carried by one-fifth of the number. Suppose a permanent colony of 4000 fishers were established at Davis' Straits, and 20 of the 100 vessels employed in the carrying trade, the other 80 vessels might at once be withdrawn, making a saving of outlaid capital to the extent of at least £320,000. In this calculation, we take merely the cost of the ships, as the boats, harpoons, casks, and other apparatus, and the provisions included in the outfit, would all be required in the settlement. 2d, The fishery would have a better chance of being successful. At present a sometimes happens that vessels cannot get into the proper fishing station till the season is so far advanced that they are under the necessity of returning home without lowering their boats, and this difficulty arises not from the want of open sea within the Straits, but from accumulations of ice drifted from the north extremity of Baffin's Bay to the Labrador coast. A settlement of fishers wintering inside, would in most cases make a good fishing before the British ships had penetrated far up the straits."

SPERM-WHALE FISHERY.

It is now our purpose to devote some space to the proceedings in the sperm-whale fishery, a branch of maritime enterprise only inferior in importance to the northern fishery. There is no occasion for describing the vessels or apparatus employed, these being similar in every essential point to those already described. Timid as it is, the cachalot often causes such peril by its convulsive efforts to escape, as render its capture not less exciting than that of the mysticetus. Young bulls, in particular, frequently give a world of trouble to their pursuers, and sometimes turn upon them with unbounded fury, intent on mischief, and effecting it both with teeth and tail. The South Sea whalers, like their northern brethren, have their particular cries and watchwords in the prosecution of the chase. When a whale is seen by the man at the look-out, the cry bursts from his lips, "There she spouts!" Instantly the captain starts on deck, with the responsive exclamation, "Where away?" An answer is scarcely needed, for all on board soon perceive the huge animal, blowing regularly at intervals of ten seconds, if within a moderate distance. For a half minute the men stand gazing, and at every spout the spirited cry breaks forth from them simultaneously, "There again!" But idleness is not long the order of the day. The boats are lowered, the men rush into them, and soon are pulling towards the monster, every boat eager to reach him first. As they approach, they see him spouting more slowly. "Ah, he is going down!—he will be lost!"—is the exclamation. But one boat nears him. "One more spout (says Mr. Beale's animated narrative) is seen slowly curling forth—it is his last for this rising—his back is bent, his enormous tail is expected to appear every instant, but the boat shoots rapidly alongside of the gigantic creature. 'Peak your oars!' exclaims the mate, and directly they are flourished in the air; the glistening harpoon is seen above the head of the harpooner; in an instant it is darted with unerring force and aim, and is buried deeply in the side of the huge animal. 'It is socket up;' that is, it is buried in his flesh up to the socket, which admits the handle of the harpoon. A cheer from those in the boats, and from the seamen on board, reverberates along the still deep at the same moment." Now the pained whale plunges violently, and lashes the sea with his tail, so that the noise can be hea l for miles. Suddenly he throws up his tail in the air, and disappears. Out fly the lines, and those of another boat are attached. Eight hundred fathoms are run out, and at last the whale re-appears at the surface, somewhere in the vicinity, spouting hurriedly and agitatedly. By coiling their lines, the boatmen run rapidly up to him, and then the headsman buries his lance in the vitals of the trembling monster. "Stern all!" is at the same moment vociferated, and the boat backs away from the side of the whale. He now becomes infuriated, and rushes at the boats, often upsetting them. The lance is again driven into his sides; his motions become wild and irregular; and after what is called the mortal flurry, he turns over on his side, suffocated most commonly by the internal flux of blood from his wounds.

This is the general routine of the sperm-whale capture, but accidents occur to vary the aspect of the affair. The following whale-chase adventures are from the work of Mr. Beale:—

"On the morning of the 18th of June, 1832, while we were still fishing in the 'off-shore ground' of Japan, we fell in with an immense sperm whale, which happened to be just the sort of one we required to complete our cargo. Three boats were immediately lowered to give him chase; but the whale, from some cause or other, appeared wild in its actions long before it had seen any of our boats, although it might have been chased the day before by some other ship. It was greatly different in its actions to most other large whales, because it never went steadily upon one course. If he 'peaked his flukes,' or went down, going to the southward, we expected he would continue that course under water, but when he again rose, perhaps he was two or three miles away from the boats to the northward; in this sort of manner he dodged us about till near four P. M., at which time the men were dreadfully exhausted from their exertions in the chase, which had been conducted under a broiling sun, with the thermometer standing in the shade at 93°. About half-past four, however, Captain Swain contrived, by the most subtle management and great physical exertions, to get near the monster, when he immediately struck him with the harpoon with his own hands; and before he had time to recover from the blow, he managed, with his usual dexterity, to give him two fatal wounds with the lance, which caused the blood to flow from the blow-hole in abundance. The whale, after the last lance, immediately descended below the surface, and the captain felt certain that he was going to 'sound;' but in this he was much mistaken, for a few minutes after his descent, he again rose to the surface with great velocity, and, striking the boat with the front part of his head, threw it high into the air, with the men and every thing contained therein, fracturing it to atoms, and scattering its crew widely about. While the men were endeavouring to save themselves from drowning by clinging to their oars and pieces of the wreck of the boat, the enormous animal was seen swimming round and round them, appearing as if meditating an attack with his flukes, which, if he had thought proper to do, in return for the grievous wounds that he had himself received, a few strokes of his ponderous tail would soon have destroyed his enemies; but this was not attempted. They had now nothing to hope for but the arrival of the other boats to relieve them from their dangerous situation, rendered more so by the appearance of several large sharks, attracted by the blood which flowed from the whale, which were sometimes only a few feet from them; and also from the inability of one of the boat's crew to swim, by which three or four of his mates were much exhausted in their efforts to save him, which they succeeded in doing after having lashed two or three oars across the stern of the boat, which happened to be not much fractured, on which they placed their helpless fellow-adventurer. After they had remained in the water about three quarters of an hour, assisting them selves by clinging to pieces of the wreck, one of the other boats arrived and took them in, no doubt greatly to their relief and satisfaction. But although these brave whale-fishermen had been so defeated, they were not subdued: the moment they entered the boat which took them from the ocean, their immediate determination was for another attack upon the immense creature, which remained close by, while the other boat, which was pulling towards them with all the strength of its rowers, would still be a quarter of an hour before it could arrive.

"Captain Swain, with twelve men in one boat, therefore made another attack upon the whale with the lance, which caused it to throw up blood from the blow-hole in increased quantities. We, who were on board the ship, and had observed, from a great distance, by means of the telescope, the whole of the occurrence, were employed in beating the ship towards them, but they were far to windward, and the wind being rat er light, we had even our royal-sails set. Soon after the arrival of the third boat, the whale went into its flurry and soon died when, to the dismay of the boats' crews, who had endured so much danger and hardship in its capture, it sank, and never rose again—an occurrence which is not very unfrequent, owing of course to the greater specific gravity of the individual, perhaps from a greater development of bony and muscular structures. Such were the adventures of that day, in the evening of which the crews returned to the ship, worn out and dispirited, having lost a favourite boat with the whole of her instruments, besides the last whale wanted to complete the cargo, and worth at least £500.

"At daybreak, one fine morning in August, as our first mate was going aloft to look out for whales, he discovered no less than three ships within a mile of us; but they were situated in various directions. We soon discovered them to be whalers, who like ourselves were cruising after the spermaceti whale, and therefore their appearance only had the effect of redoubling our vigilance in the 'look-out,' so that we might, if possible, be the first to obtain the best chance if one of those creatures 'hove in sight.' And it was not long before a very large whale made his appearance right in among the ships. The water was smooth at the time, for we had but a light air of wind stirring, so that our boats were instantly lowered without the loss of time of bringing the 'ship to.' But although we managed matters as quietly and secretly as possible, we found, the moment our boats cleared the ship's side, that all the others had been as vigilant as ourselves, and had also lowered their boats after the whale. The whole of them immediately began the chase—nine boats in all, being three from each ship. They all exerted themselves to their utmost, and, as we expected, in vain; for before any of the boats had got even near him, the enormous animal lifted his widely expanded flukes, and descended perpendicularly into the depths of the ocean to feed. Those in the boat, however, having noticed his course, proceeded onwards, thinking the whale would continue to pursue the same direction under water; but as he was going slowly at the time he was up, they did not proceed more than a mile from the place at which he descended, before they separated about a hundred yards from each other, and then 'peaking' their oars, all the men in each boat stood up, looking in different directions, so as to catch the first appearance of the spout when the whale again rose to breathe: when, an hour after his descent had expired, the excitement among us who were on board the ship became wound up to its highest pitch. The captain, who had remained on board, ascended to the fore-topgallant-yard to watch the manœuvres of the boats, and for the purpose of the better ordering the signals to them, or working of the ship. All those who were down after the whale appeared as feverish with anxiety as ourselves, for every now and then they were to be seen shifting their positions a little, thinking to do so with advantage; then they would cease rowing, and stand upon the seats of the boats, and look all around over the smooth surface of the ocean with ardent gaze. But one hour and ten minutes expired before the monster of the deep thought proper to break cover; and when he did, then a rattling chase commenced with the whole of the boats, and they really flew along in fine style, some of them actually appearing to be lifted quite on the surface of the water, from the great power of the rowers; and we had the satisfaction of observing, that our boats were quite equal to the others in the speed with which they were propelled. But it was again a useless task, as the old 'schoolmaster' had outwitted those in the boats, by having gone—while under water—much farther than any of his pursuers had anticipated, and they again had the mortification of witnessing the turning of his flukes as he once more descended into the depths of his vast domain. We now knew to a minute the time that he would remain below, while the people in the boats continued to row slowly onwards the whole time. A fine breeze now sprang up, so that we were enabled to keep company with the boats, keeping a little to windward of them, as the whale was going 'on a wind,' as a seaman would say, meaning that it was blowing across him.

"When the hour and ten minutes had again nearly passed, the nine boats were nearly abreast of each other, and not much separated, so that the success of first striking the whale depended very much upon the swiftest boat, especially if the whale came up ahead. We had now all the boats on our 'lee-beam,' while the ships were all astern of us, the most distant not being more than half a mile, so that we enjoyed an excellent view of this most exciting and animated scene. True to his time, the leviathan at length arose right ahead of the boats, and at not more than a quarter of a mile distant from them. The excitement among the crews of the various boats when they saw his first spout was tremendous; they did not shout, but we could hear an agitated murmur from their united voices reverberating along the surface of the deep. They flew over the limpid waves at a rapid rate; the mates of the various boats cheered their respective crews by various urgent exclamations, 'Swing on your oars, my boys, for the honour of the Henrietta,' cried one; 'Spring away, hearties,' shouted another, and yet scarcely able to breathe from anxiety and exertion. 'It's our fish,' vociferated a third, as he passed the rest of his opponents but a trifling distance. 'Lay on, my boys, cried young Clark, our first mate, as he steered the boat with one hand, and pressed down the after oar with the other. 'She'll be ours yet; let's have a strong pull, a long pull, and a pull altogether,' he exclaimed, as he panted from his exertions at the after oar, which soon brought up his boat quite abreast of the foremost.

"But the giant of the ocean, who was only a short distance before them, now appeared rather 'gallied,' or frightened, having probably seen or heard the boats; and as he puffed up his spout to a great height, and reared his enormous head, he increased his speed, and went along quite as fast as the boats, but for only two or three minutes, when he appeared to get perfectly quiet again, while the boats gained rapidly upon him, and were soon close in his 'wake.' 'Stand up,' cried young Clark to the harpooner, who is also the bow-oarsman, while the same order was instantly given by his opponent, whose boat was abreast of our mate's, with the rest close to their sterns. The orders were instantly obeyed, for in a second of time both boat-steerers stood in the bows of their respective boats, with their harpoons held above their heads, ready for the dart; but they both panted to be a few yards nearer to the whale, to do so with success. The monster ploughed through the main quickly, but the boats gained upon him every moment, when the agitation of all parties became intense, and a general cry of 'dart! dart!' broke from the hindmost boats, who each urged their friends, fearful of delay. The uproar became excessive; and when the tumult of voices, and the working and splashing of the oars, rolled along the surface of the deep, both the harpooners darted their weapons together, which, if they had both struck the whale, would have originated a contention between them regarding their claims. But, as it happened, neither of them had that good fortune; for at the moment of their darting the harpoons, the whale descended like a shot, and avoided their infliction, leaving nothing but a white-and-green-looking vortex in the disturbed blue ocean, to mark the spot where his monstrous form so lately floated. A general huzza burst from the sternmost boats when they saw the issue of this chase, thinking now that another chance awaited them on the next rising of the whale, and they soon began to separate themselves a little, and to row onwards again in the course which they thought he had taken. Our captain, feeling irritated at the ill success of the mate, now ordered his own boat to be lowered, intending to make one in the chase himself; but just as he had parted from the ship, going down a little to leeward, a tremendous shout arose from the people in our own boats, joined with a loud murmuring from the rest of the boats' crews; for the whale, not having had all its 'spoutings out,' had now risen again to finish them, and was coming to windward at a quick rate, right towards our ship. The captain saw his favourable situation in a moment, and, passing quickly to the bows of the boat, he stood to waylay him as he came careering along, throwing his enormous head completely out of the water, for he was now quite 'gallied.' He soon came, and caught a sight of the boat just as he got within dart; the vast animal rolled itself over in an agony of fear, to alter its course; but it was too late; the harpoon was hurled with excellent aim, and was plunged deeply into his side near the fin.

"As the immense creature almost flew out of the water from the blow, throwing tons of spray high into the air, showing that he was 'fast,' a triumphant cheering arose from those in our own boats, as well as from those in the ship, accompanied by exclamations loud and deep, and not of the most favourable kind to us, from all the rest. But onwards they all came, and soon cheerfully rendered assistance to complete its destruction; but which was not done, however, without considerable difficulty, the whale continuing to descend the moment either of the boats got nearly within dart of him. But after an hour's exertion in this way, six out of the ten boats which were now engaged, got fast to him by their harpoons, but not one of them could get near enough to give him a fatal lance; he towed them all in various directions for some time, taking care to descend below the surface the moment a boat drew up over his flukes, or otherwise drew near, which rendered it almost impossible to strike him in the body, even when the lance was darted, although the after part of his 'small' was perforated in a hundred places: from these wounds the blood gushed in considerable quantities, and as the poor animal moved along, towing the boats, he left a long ensanguined stain in the ocean. At last, becoming weak from his numerous and deep wounds, he became less capable of avoiding his foes, which gave an opportunity for one of them to pierce him to the life. Dreadful was that moment the acute pain which the leviathan experienced, and which roused the dormant energies of his gigantic frame. As the life's blood gurgled thick through the nostrils, the immense creature went into his 'flurry' with excessive fury; the boats were speedily sterned-off, while he beat the water in his dying convulsions with a force that appeared to shake the firm foundation of the ocean!"

CONCLUDING ANECDOTES AND OBSERVATIONS.

Mr. Beale continues to remark, in his narrative, that "numberless stories are told of fighting whales, many of which, however, are probably much exaggerated accounts of the real occurrences. A large whale, called 'Timor Jack,' is the hero of many strange stories, such as of his destroying every boat which was sent out against him, until a contrivance was made by lashing a barrel to the end of the harpoon with which he was struck, and whilst his attention was directed and divided among several boats, means were found of giving him his death-wound.

"In the year 1804, the ship 'Adonis,' being in company with several others, struck a large whale off the coast of New Zealand, which 'stove' or destroyed nine boats before breakfast, and the chase consequently was necessarily given up. After destroying boats belonging to many ships, this whale was at last captured, and many harpoons of the various ships that had from time to time been sent out against him were found sticking in his body. This whale was called 'New Zealand Tom,' and the tradition is carefully preserved by whalers.

"Accidents of the most fearful nature have frequently occurred in this hazardous pursuit, which to enumerate would fill the space of volumes; for not only boats, but sometimes even ships, have been destroyed by these powerful creatures. It is a well authenticated fact, that an American whale-ship called the 'Essex' was destroyed in the South Pacific Ocean by an enormous sperm whale. While the greater part of the crew were away in the boats pursuing whales, the few people remaining on board saw an immense sperm whale come up close to the ship, and when very near, he appeared to go down for the purpose of avoiding the vessel, and in doing so he struck his body against some part of the keel, which was broken off by the force of the blow, and floated to the surface; the whale was then observed to rise a short distance from the ship, and come with apparently great fury towards it, striking against one of the bows with his head, and completely 'staving' it in. The ship of course immediately filled, and fell over on her side, in which dreadful position the poor fellows in the boats soon espied their only home, being distant from the nearest land many hundred miles; on returning to the wreck, they found the few who had been left on board hastily congregated in a remaining whale-boat, into which they had scarcely time to take refuge before the vessel capsized. They with much difficulty obtained a scanty supply of provisions from the wreck, their only support on the long and dreary passage before them to the coast of Peru, to which they endeavoured to make the best of their way. One boat was fortunately found by a vessel not far from the coast; in it were the only survivors of the unfortunate crew, three in number, the remainder having perished under unheard-of suffering and privation. These three men were in a state of stupefaction, allowing their boat to drift about where the winds and waves listed; one of these survivors was the master; by kind and careful attention on the part of their deliverers, they were eventually rescued from the jaws of death to relate the melancholy tale."

Not being attended with the dangers to which a northern climate exposes the hunters of the mysticetus, the sperm-whalers of Britain have greatly increased in numbers of late years, and at this day the fishing is prosecuted with great success. As in the case of the Greenland fishery, bounties were given up to 1821, when the trade was fairly left to private enterprise. In 1791, the sperm oil imported into Britain amounted to 1258 tons; in 1827, 5552 tons were imported; and in 1836, the amount was 7001 tons. One good whale will yield forty barrels of oil, and ten barrels of spermaceti are frequently taken from one head. About ten large barrels make a ton. Both sperm-oil and spermaceti bear a high price in the market, and are of great utility in various respects. There is little chance of a decline in the sperm-whale branch of our maritime traffic, not only because the fishing latitudes are comparatively free from dangers, but because the invention of gas does not trench on the use of sperm-oil as it did on that of the Greenland oil, and because spermaceti and sperm-oil are likely to be more and more employed as the country progresses in civilization.

FOREIGN WHALE-FISHERIES.

The whale-fisheries of other civilized nations have undergone as great vicissitudes as those of Britain. About the year 1680, the Dutch sent out not less than 260 ships, manned by 14,000 men, to the northern fishery. In 1828, only one whale-ship sailed from Holland! France has never prosecuted this branch of commerce with much activity or success, yet the little that was once done in this way has become still less. In 1790, 40 French ships were employed in the Greenland seas. The revolution put a stop to the fishing, and though of late years the government has made an attempt to revive it, very little success has resulted.

The people of the United States have been more active and successful in whale-fishing than almost any other nation in recent days. While dependent colonists, they embarked in it with great spirit. From 1771 to 1775, Massachusetts employed annually 183 vessels, of 13,820 tons, in the northern fishery; and 121 vessels, of 14,026 tons, in the fisheries of the south. They were the first to prosecute the trade in the southern Atlantic, on the coasts of Africa and Brazil; and they, too, led the way into the Pacific seas:—"Look at the manner," says Burke (1774), "in which the New England people carry on the whale-fishery. While we follow them among the tumbling mountains of ice, and behold them penetrating into the deepest frozen recesses of Hudson's Bay and Davis' Straits; while we are looking for them beneath the Arctic circle, we hear that they have pierced into the opposite region of polar cold; that they are at the antipodes, and engaged under the frozen serpent of the south. Falkland Island, which seems too remote and too romantic an object for the grasp of national ambition, is but a stage and resting-place for their victorious industry. Nor is the equinoctial heat more discouraging to them than the accumulated winter of both the poles. We learn that, while some of them draw the line or strike the harpoon on the coast of Africa, others run the longitude, and pursue their gigantic game along the coast of Brazil." These are the seas that are still vexed by the American fisheries, which have been pushed, however, into higher southern latitudes than had ever before been visited, and are carried on from the shores of Japan to the icy rocks of New South Shetland. They have been principally carried on from Nantucket and New Bedford, and have proved very lucrative. At present they are also prosecuted with great success from several other places. One class of ships is fitted out for the Pacific in pursuit of the spermaceti whale. These are from 300 to 500 tons burden, carrying from 25 to 30 men, and are absent about 30 to 36 months. Their number is about 170, of about 62,000 tons, and carrying nearly 5000 men. Another class sail to the coasts of Africa and Brazil, in search of the common or right whale. They average about 325 tons each, carry about 25 men, and are absent 8 to 12 months. The whole amount of tonnage of this class is about 40,000; number of seamen engaged, 3000. The quantity of sperm oil brought home in 1815, was 3944 barrels; in 1820, 34,700; in 1825, 62,240; and, in 1830, 106,800. The quantity of whale or black oil brought in in 1830, was about 115,000 barrels; of whalebone, about 120,000 pounds. The sperm oil is chiefly used at home; and 2,500,000 pounds of sperm candles are made, employing about 30 manufactories. The whale oil and whalebone are chiefly exported to Europe. From the report of the secretary of the treasury, May 4, 1832, it appears that for the year ending September 30, 1831, there were exported whale and other fish oil to the value of 554,440 dollars; spermaceti oil to the value of 53,526 dollars; whalebone to the value of 133,842 dollars; and spermaceti candles to the value of 217,830 dollars.

Of the extent of the sufferings sometimes experienced by the whalers, a single example may be given. The Dee, an Aberdeen whaler, sailed for Davis' Straits in April, 1836, and, after many difficulties, was ultimately fast locked up in the ice, in October of the same year, near the mouth of Baffin's Bay. "From this date, the peculiar sufferings of the crew of the Dee, which numbered thirty-three persons, may be said to have commenced. Their allowance remained the same, but, from the scarcity of fuel, their beds became wretchedly damp. At first, to preserve the health of the men, and to keep their shivering bodies in heat, the most praiseworthy precautions were taken. A variety of exercise was allotted to them, such as the unbending of the sails, unshipping the rudder, and other toils, of no utility now unhappily, to the ship. But the crew of the Dee had not long to resort to unprofitable labours to maintain the vital warmth of their frames. Notwithstanding the increasing hardness of the frost, the ice still remained in a loose state, and a fatal crush on the ship became the subject of continual alarm. On the 16th, the latitude was 72° 50′, wind strong, and large icebergs floating past. The ice began to press hard, and on the night of the 16th, the vessel was crushed up until it hung by the quarter, the ice squeezing all along as high as the guard-boards. At daylight, all hands were called up to get out the provisions. At 8 P. M., the wind fell off, but the ship still hung by the quarter. The ice, however, was at rest till 11 P. M., when there was another dreadful crush, which passed off with less harm than could have been anticipated. On the 18th, the ice gave way in several places, and opened up so far that a warp had to be got out to secure the Dee. The other vessels, meanwhile, lay comparatively undisturbed. On the 20th, the ice closed again, with some severe squeezes, around the Dee. To strengthen the ship, its casks were placed in a peculiar way, and ten strong beams put in aft. This was done most seasonably, for shortly after two successive shocks took place, within half an hour of each other, of such tremendous severity, that the crew fled to the ice with their bags, chests, and every thing that could be lifted, under the impression that all was over with the timbers of the Dee. The sufferings of the night that followed were awful. Without fire, or shelter from the biting elements, the crew lay on the ice, gazing on their reeling and groaning vessel, while around them were extended vast fields of ice, studded with icebergs towering to the clouds, and threatening destruction to all that came in the way of their motions. Miserable as their position was, the crew could not go on board for two days, during which time the ship experienced crushes still more severe than formerly. On the 22d, the men went on board to take out the remaining provisions, but had again to fly for their lives.' The ice, however, fell quiet on the same night, and they again took back their provisions to the ship. On the 23d, a good many lanes opened up in the water—a most discouraging prospect, for this was always the time of greatest peril. Once more the crew took to the ice, and, by cutting the nearest parts into small pieces, cleared the vessel a few feet. The men then went for a few hours to rest, but were roused by another crush—the signal that their labours had been in vain. On the 24th, the ice broke up to a considerable extent, and the crew managed to heave the Dee backwards for a hundred yards, to a point where the ice seemed to be thinner. Great difficulties were experienced in conveying the chests and other articles left in the ship, but at length every thing was again on board."

Placed upon the most scanty allowance of food, and kept in such a state of continual alarm from the ice as compelled them to spend days and nights out of the ship, notwithstanding the dreadful severity of the weather, the crew of the Dee began to suffer greatly in their health before the end of the year. "Coughs, swelled limbs, and general debility, with small red discolorations on the skin, sharp pains and stiffness, were the common symptoms, and the cold and wet to which the seamen were exposed, laid the seeds of a worse disease which now began to show its fatal power. This disease was scurvy, and it was marked chiefly by an excruciating pain in the mouth, and swelled gums, rendering eating a torture. On the 18th of December, twenty-one men were affected with scurvy. To add to their distress, the ice again gave way, and threatened to crush the miserable vessel." Before the 1st of February, six deaths had taken place, and among the victims was the lamented commander, Captain Gamblin. The following passage describes the deplorable condition of the crew of the ice in February, 1837, at which time the ship was still frozen in:—

"Though the whalers were at this time three or four degrees farther south than at first, the frost was even more severe than ever. Every liquid was frozen; and while the snow was being melted to cook the victuals, the icicles were hanging on the water-cask, at the distance of six feet from the fire. The beds were covered with solid ice—the pillows frozen in every part but where the head lay, the very hairs of which were in some cases stiff with cold—and vermin of a more rapacious kind began to swarm among the blankets: creatures that ate their way through the skin, and fed on the raw flesh. And the men all the while bowed down with mortal sickness, and incapable of defending or cleaning themselves! So scarce was fuel besides, that it could only be used for the melting of ice and cooking of victuals. Can we wonder that ere the 12th of February, six others of the crew sank under their distresses? Between the 23d and 27th, six additional deaths took place, and, by the 7th of March, other five had followed their departed mates. So many deaths as these enabled the remainder to enjoy full allowance of provisions. Six hands only were able at this time to do duty, and the ship was in great danger of a fatal squeeze from the state of the ice, which was loose, and rapidly breaking up.

"Between the 11th and 15th, three more of the Dee's crew died, and they were the last that were buried below the ice, which was now broken up in all directions. On the 16th, after being locked up for five months and eight days, the Dee entered into open water." The ship had taken on board the crew of the Thomas, a whaler wrecked during the same winter in the ice, and all the survivors of both vessels now turned their eager eyes homewards. But, alas! many of them "were destined never to see their native shores. Fortunately, light and favourable breezes attended, in general, the passage of the ship homewards, otherwise not one man of the Dee's crew could ever have reached his home. The scurvy raged so fearfully on board, that, between the 16th of March and the 22d of April, twenty more of the unfortunate men had fallen victims to it. On the 25th a fishing-boat was hailed, and it was found that the Dee was then off the Butt of Lewis. The fishermen in the boat cruelly refused to give any assistance, suspecting a case of plague, it is supposed. The barque Washington of Dundee, Barnett master, bound for New York, bore down upon the miserable whaler on the evening of the same day, and inquired if any assistance was wanted. On being informed of the state of matters, and that only three hands of the Dee were able to go aloft, Mr. Barnett instantly sent four men on board, and followed in person, carrying with him wine, porter, and other provisions. He then took the Dee in tow, and enabled her to come to anchor, on the 27th of April, in the harbour of Stromness. Every attention was here paid to the survivors of the crew; and on the 5th of May, the owners having sent effective hands, the Dee was again put to sea and carried into the harbour of Aberdeen, after an absence of thirteen months and three days. A heart-rending scene took place on the quay, which was crowded with the relatives of the deceased seamen—with weeping widows, children, and parents. Forty-six men had died on board the Dee, nine of whom belonged to the Thomas of Dundee. Fourteen men only survived of the Dee's own compliment." From this picture of the sufferings of the crew of one vessel, who endured no more than others, in the same as well as preceding seasons, the reader may form an idea of the general hardships of the modern Arctic whale-fishing. It cannot but be felt as a blessing that the progress of lighting with coal-gas is likely soon to put an end to this dangerous traffic.

[WORKS ON THE WHALE-FISHERY.

Scoresby's "*Voyage to the Northern Whale Fishery,*" and his "*Arctic Regions,*" are considered the best authority on this subject. A book published anonymously some years since, entitled "Tales of an Arctic Voyager," contains exceedingly lively and graphic sketches of the scenes which present themselves to the whale fisher. A work entitled "Incidents of a Whaling Voyage," to which are added observations on the scenery, manners and customs, and Missionary Stations of the Sandwich and Society Islands, accompanied by numerous lithographic prints, by Francis Allyn Olmsted (New York, Appleton, 1841), is full of interesting details on this subject. In the Foreign Quarterly Review, No. 14, is an article of value and authority, by J. R. M'Culloch. In the same writer's "Commercial Dictionary," is another, with full statistical details and tables. From the latter we extract the following account:—

STATE OF THE AMERICAN WHALE-FISHERY.

We borrow from a Nantucket journal the following details with respect to this fishery in 1834:—

Spermaceti Whale-Fishery.—The whole number of ships engaged in this valuable branch of the fisheries is 273, of which 257 are now absent, viz.: from

New Bedford	94	Falmouth	6
Nantucket	63	Newport	6
Fairhaven	14	Sagharbour	5
Bristol	13	Salem	3
New London	10	Newburyport	3
Hudson	9	Poughkeepsie	2
Warren	7	Portsmouth	2
Edgarton	6	Dartmouth	2

And one from each of the following ports, viz.:—Boston, Plymouth, Wareham, Rochester, Portland, Wiscasset, Fall River, Providence, Stonington, Newbury, New York, and Wilmington, Delaware. Sixteen ships only are in port, belonging as follows: to New Bedford, 7; Nantucket, 5; Fairhaven, Plymouth, Sagharbour, and Edgartown, each 1.

The aggregate tonnage of the 257 absent ships is nearly 100,000 tons. Of these, only 61 had each, at last dates, obtained 1000 brls. of oil and upwards; and about the same number are not yet reported with any oil. The number of seamen and navigators employed on board these vessels, is not far from 9000. The cost of the entire fleet, as fitted for these voyages of three years' duration, probably exceeds 6,000,000 dollars.

A document before us furnishes a very careful estimate of the spermaceti oil imported into the United States during the year 1834. Since Jan. 1, there have arrived from the Pacific Ocean 55 ships, viz.: into this port, 11; New Bedford, 25; Plymouth, 2; Fairhaven, 6; New London, 2; Edgartown, 2; Sagharbour, 2; Warren, 3; Falmouth, Bristol, and Hudson, 1 each. The cargoes of these ships, including that of the Levant and Spartan (just arrived, and presumed to amount to 5000 brls.), average little more than 2000 brls. each; being in the whole 111,881 brls. Add to this quantity 16,000 brls. estimated to have been brought from the South Atlantic Ocean, making about 128,000 brls., and we have the entire quantity of spermaceti oil imported in the course of the last year. Of this quantity, 70,577 brls. were received at New Bedford, and the residue at Nantucket and other ports.

We deduce from this valuable document one fact, which we repeat with some feeling of pride. It is, that more than half of the ships now engaged in the sperm whale-fishery are commanded by Nantucket men though less than one-fourth of the whole fleet is owned in this place. *Am. Ed.*]

CONVEYANCE—ROADS—CANALS—RAILWAYS.

PRIMITIVE MODES OF CONVEYANCE.

The means adopted in early times for the artificial transport of either person or property, were, as may be supposed, of the rudest kind, as is still the case in those countries which are little advanced in the useful arts. The most degrading species of artificial conveyance that seems to have been practised, was the employment of human labour, in bearing litters or palanquins, specimens of which, on a scale of barbarous splendour, are now seen in India, Burmah, and China.

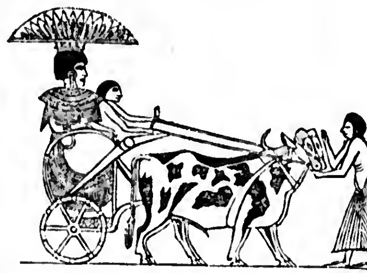
The first and most obvious improvement in modes of transport was the substitution of brute for human labour; and it is reasonable to conclude, that the value of this practice could not have been long in being pressed on the attention of mankind. We find the term "beasts of burden" used in the most ancient records, the animals meant being the ass, the horse, or the camel. No trace, however, exists of the progress from *burden* to *draught*, though it also must have been in very early times. The ass and horse are equally adapted for carrying or drawing, but the camel exerts its power only by carrying; draught is alone suitable for the reindeer and ox, the backs of these animals not being adapted by nature for bearing burdens.

The draught of the reindeer is employed in Lapland as the chief means of artificial locomotion, and is always exerted on a species of sledge, which, by its form, is suitable for gliding easily over the frozen ground or snow. The shape of the sledge somewhat resembles a small boat, with a sharp prow, and flat in the rear, against which the inmate of the vehicle rests. The traveller is swathed in his carriage like an infant in a cradle, with a stick in his hand to steer the vessel, and disengage it from pieces of rock or stumps of trees that it may chance to encounter in the route. He must also balance the sledge with his body, otherwise he will be in danger of being overturned. The traces, by which this carriage is fastened to the reindeer, are fixed to a collar about the animal's neck, and run down over the breast, between the fore and hind legs, to be connected with the prow of the sledge; the reins, managed by the traveller, are tied to the horns; and the trappings are usually furnished with little bells, the sound of which is agreeable to the animal. With this draught, the reindeer, if pressed, will travel from sixty to eighty miles in a day; but more frequently he does not travel more than forty or fifty, which is a good day's journey. Occasionally he halts to moisten his mouth with snow. Before he sets out, the Laplander whispers in his ear the way he has to go, and the place at which he has to halt, firmly persuaded that the beast understands his meaning. In the beginning of winter, the Laplanders mark the most frequented paths, by strewing them with fir boughs; which, being frequently covered with new snow, alternately pressed by the sleighs, hardens them into a kind of causeway, which is the more smooth, if the surface has felt a partial thaw, and been crusted by a subsequent frost. It requires great caution to follow these tracks; for, if the carriage deviates to the right or left, the traveller is plunged into an abyss of snow. In less frequented parts, where there is no such beaten road, the Laplander directs his course by certain marks made on the trees.

In Russia, and also in Canada, sleighs are used in winter for conveyance from place to place, the beast of draught being the horse. As the roads in many parts of Canada are very unsuitable for any species of travelling, it happens that sleighing over the hardened surface of the snow in winter, is by far the best mode of communication in that country. It is almost unnecessary to add, that the sledge or sleigh, which is the rudest kind of carriage for draught, has disappeared in all countries which have advanced considerably in improvement.

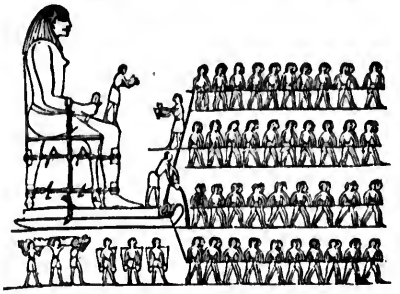
From the rude sledge, drawn with an incalculable degree of labour over the rough ground, the next important step in mechanical construction is to apply wheels, for the purpose of lessening the friction of the moving body. The first application of wheels to carriages is beyond the reach of record. Wagons are spoken of in the book of Genesis, from which it may be inferred that a knowledge of wheels was common in a very early age. It is further known, that the making of wheels formed a distinct trade among the citizens of Thebes in ancient Egypt, three or four thousand years ago.

Ancient Egyptian Carriages.—The most elegant of the Egyptian carriages was a kind of gig, or light open chariot, on two wheels, called the *plaustrum*, which is thus described by Mr. Wilkinson, in his work on the



Manners and Customs of the Ancient Egyptians:—"The plaustrum was very similar to the war-chariot and the curricle, but the sides appear to have been closed, and it was drawn by a pair of oxen instead of horses. The harness was much the same, and the wheels had six spokes. In a journey, it was occasionally furnished with a sort of umbrella, fixed upon a rod rising from the centre or back of the car; the reins were the same as those used for horses, and apparently furnished with a bit; and besides the driver, a groom sometimes attended on foot, at the head of the animals, perhaps feeding them as they went. The annexed wood engraving represents an Ethiopian princess, who is on her journey through Upper Egypt to Thebes, where the court then resided. The plaustra are called in Genesis *wagons*; they were commonly used in Egypt for travelling. Besides the plaustrum, they had a sort of palanquin, and a canopy or framework answering the purpose of a sedan chair, in which they sometimes sat or stood, in their open pleasure-boats, or in situations where they wished to avoid the sun."

From the researches of Mr. Wilkinson, we are enabled to form some estimate of the enormous trouble incurred by the ancient Egyptians in the transport of the heavy stones which they employed in building their temples. Some of these stones weighed 5000 tons, and were usually conveyed from the quarries from which they were cut, in flat-bottomed boats, on canals made for the purpose. Occasionally, however, when this mode of transport was unsuitable, the stone was drawn on sledges, perhaps some hundreds of miles, by oxen or by human labour. The following woodcut represents in an abridged form, the mode of conveying colossal figures in stone from the quarries to the temples in which they were to be set up. "One hundred and seventy-two men, in four rows of forty-three each [we



represent only as far as twenty each row], pull the ropes attached to the front of the sledge; and a liquid, probably grease, is poured from a vase by a person standing on the pedestal of the statue, in order to facilitate its progress as it slides over the ground, which was probably covered with a bed of planks, though they are not indicated in the painting. Some of the persons employed in this laborious duty appear to be Egyptians, the others are foreign slaves, who are clad in the costume of their country. Below are persons carrying vases of the liquid, or perhaps water, for the use of the workmen, and some implements connected with the transport of the statue, followed by taskmasters with their wands of office [but which we have not had space to include]. On the knee of the figure stands a man who claps his hands to the measured cadence of a song, to mark the time, and insure their simultaneous draught. The height of the statue appears to have been about twenty-four feet, including the pedestal. It was bound to the sledge by ropes, which were tightened by means of pegs, inserted between them, and twisted round until completely braced; and to prevent injury from the friction of the ropes upon the stone, a compress of leather or other substance was introduced at the part where they touched the statue." It may be added, that the representation is constructed without any reference to perspective, which was not understood by the ancient Egyptian delineators. Besides the great number of persons employed in drawing these huge blocks, it was customary for a band of some hundreds of soldiers to attend, perhaps for the purpose of overawing the slaves, and compelling obedience in their odious task. A more degrading means of mechanical conveyance it would be impossible to represent.

Conveyance by Camels.—From the earliest times, the camel, in its two varieties of camel and dromedary,* has been employed in the sandy regions of Asia, as a beast of burden; and without its invaluable services in this respect, these countries could scarcely have been habitable. In the sacred writings, we find frequent notices of the camel in connection with commercial transport. The brethren of Joseph having cast him into a pit, "they sat down to eat bread; and they lifted up their eyes and looked, and behold a company of Ishmaelites came from Gilead, with their camels bearing spicery, and balm, and myrrh, going to carry it down into Egypt." Thus the camel formed the engine of carriage among the merchants of Arabia, and conveyed the products of India across the deserts to the populous and wealthy land of Egypt.

The camel is expressly suited by nature for inhabiting and traversing sandy and parched deserts, in which there are places of rest and refreshment only at remote distances. "It is the most temperate of all animals, and can continue to travel several days without drinking. In those vast deserts, where the earth is everywhere dry and sandy—where there are neither birds nor beasts, neither insects nor vegetables—where nothing is to be seen but hills of sand and he[aps] of bones, there the camel travels, posting forward, wi[thout] requiring either drink or pasture, and is often found six or seven days without any sustenance whatsoever. Its feet are formed for travelling upon sand, and utterly unfit for moist or marshy places; the inhabitants, therefore, find a most useful assistant in this animal, where no other could subsist, and by its means, cross those deserts with safety, which would be impassable by any other method of conveyance.

"An animal thus formed for a sandy and desert region, cannot be propagated in one of a different nature. Many vain efforts have been tried to propagate the camel in Spain and America, but they have multiplied in neither of these countries. It is true, indeed, that they may be brought into both countries, and may perhaps be found to produce there; but the care of keeping them is so great, and the accidents to which they are exposed from the changeableness of the climate, are so many, that they do not reward the care of keeping. In a few years, also, they are seen to degenerate; their strength and patience forsake them, and, instead of making the riches, they become the burden of their keepers.

"The camel is easily instructed in the methods of taking up and supporting his burden; their legs, a few days after they are produced, are bent under their belly; they are in this manner loaded, and taught to rise; their burden is every day thus increased, by insensible degrees, till the animal is capable of supporting a weight adequate to its force. The same care is taken in making them patient of hunger and thirst: while other animals receive their food at stated times, the camel is restrained for days together, and these intervals of famine are increased in proportion as the animal seems capable of sustaining them. By this method of education, they live five or six days without food or water; and their stomach is formed most admirably by nature to fit them for long abstinence. Besides the four stomachs which all animals have that chew the cud (and the camel is of the number), it has a fifth stomach, which serves as a reservoir to hold a greater quantity of water than the animal has an immediate occasion for. It is of a sufficient capacity to contain a large quantity of water, where the fluid remains without corrupting, or without being adulterated by the other aliments: when the camel finds itself pressed with thirst, it has here an easy resource for quenching it; it throws up a quantity of this water, by a simple contraction of the muscles, into the other stomachs, and this serves to macerate its dry and simple food. In this manner, as it drinks but seldom, it takes in a large quantity at a time; and travellers, when straitened for water, have been often known to kill their camels for that which they expected to find within them.

"In Turkey, Persia, Arabia, Barbary, and Egypt, the whole commerce is carried on by means of camels; and no carriage is more speedy or less expensive in these countries. Merchants and travellers unite themselves into a body, furnished with camels, to secure themselves from the insults of the robbers that infest the countries in which they live. This assemblage is called a *caravan*, in which the numbers are sometimes known to amount to above ten thousand, and the number of camels is often greater than that of the men. Each of these animals is loaded according to his strength,

* The only essential difference between the two varieties, is hat the camel has two hunches and the dromedary one; but there are mixed breeds between them

and he is so sensible of it himself, that when his burden is too great, he remains still upon his belly, the posture in which he is loaded, refusing to rise till his burden be lessened or taken away. In general, the large camels are capable of carrying a thousand pounds' weight, and sometimes twelve hundred; the dromedary from six to seven. In these trading journeys, they travel but slowly; their stages are generally regulated, and they seldom go above thirty, or at most about thirty-five miles a day. Every evening, when they arrive at a stage, which is usually some spot of verdure where water and shrubs are in plenty, they are permitted to feed at liberty; they are then seen to eat as much in an hour as will supply them for twenty-four; they seem to prefer the coarsest weeds to the softest pasture—the thistle, the nettle, the cassia, and other prickly vegetables, are their favourite food; but their drivers take care to supply them with a kind of paste composition, which serves as a more permanent nourishment. As these animals have often gone the same track, they are said to know their way precisely, and to pursue their passage when their guides are utterly astray. When they come within a few miles of their baiting place in the evening, they sagaciously scent it at a distance, and, increasing their speed, are often seen to trot with vivacity to their stage.

The patience of this animal is most extraordinary; and it is probable that its sufferings are great, for when it is loaded, it sends forth most lamentable cries, but never offers to resist the tyrant that oppresses it. At the slightest sign, it bends its knees and lies upon its belly, suffering itself to be loaded in this position; by this practice the burden is more easily laid upon it than if lifted up while standing. At another sign it rises with its load, and the driver getting upon its back, between the two panniers, which, like hampers, are placed upon each side, he encourages the camel to proceed, with his voice and with a song. In this manner, the creature proceeds contentedly forward, with a slow uneasy walk of about four miles an hour, and when it comes to its stage, lies down to be unloaded, as before."*

From Major Skinner's account of his "Journey to India," in the course of which he travelled twenty days with a numerous caravan from Damascus to Bagdad, we have the following lively picture of the mode of conveyance by camels:—

"I must give a description of our equipage, now that we are fairly launched on the great waste. I ride a white camel, with my saddle-bags under me, and a pair of water-skins, quite full, beneath them: over the saddle is my bed. A thick cherry-stick, with a cross at the end of it, serves to guide the animal; a gentle tap on the side of his neck sends him to the left, and one on the opposite makes him turn back again to the right; a knock on the back of his head stops him, and a few blows between the ears bring him to his knees, if accompanied by a guttural sound, resembling, as the Arabs say, the pronunciation of their letter *sche*. To make him move quickly, it is necessary to prick him, with the point of the stick, on the shoulders.

"To the north there is a range of bare hills, and at their bases are patches of green; the rude tents of a tribe of Bedouins are pitched, and their cattle enliven the scene. We passed over a perfect level this morning, strewed with flowers, and thick with pasture for the camels, where we are now resting. It is not usual here, as in many parts of the east, for the camels to wind in long strings, one after the other. Our numbers, amounting to fifteen hundred, are scattered over the surface in all directions, as far as the eye can trace.

"In travelling, the sheiks or chiefs of the caravan, attended by the military part of their equipage, mounted on dromedaries, move in advance, while the loaded camels follow at some distance, in parallel masses, opening out, or changing the form, as the grass renders it necessary. They fall so naturally into military figures, that it is difficult to conceive their doing it without direction.

"We have several tents in the caravan. They are pitched so as to permit the camels belonging to each to lie in the intervals, where they are placed in *squads* for the night. They are by no means agreeable neighbours; for, although they are not able to move from their place, they make a most unpleasant gurgling noise, the bales of the merchants always form the windward defence, for the tents have no sides to them, and but flutter over the goods to keep the sun from their owners.

At the usual hours of prayer, a loud call is heard throughout the camp, and parties flock to where the muezzin takes his stand. At sunset, as the camels draw in from the pasture, all the Arabs are on their knees, in a line of two or three hundred, in two ranks. The priest, like a fugleman, in front, gives the time for bowing their heads, and performing the rest of the enjoined ceremonies. As they rise on the signal, they sink again to their knees, and press their foreheads to the earth with the utmost devotion: the scene is singularly impressive.

"The rate at which a loaded camel travels is estimated at two miles and a half an hour by almost every traveller. Our caravan has not, I think, exceeded this; but the variety of its movements has been very tiresome. The Arab drivers, who walk in front of the animals, never miss an opportunity of a piece of pasture; but, however distant it may be from the proper course, lead them towards it, and, with the short sticks they carry, beat them into the thickest part of it. The camels are anxious enough for the matter themselves, and huddle so together that their riders' legs are in tolerable danger of being crushed in the contact.

"There is so strong a resemblance to a voyage at sea in a passage across the desert, that I cannot divest myself of the belief that the moving mass is but a collection of small vessels, carried into a heap by the tide. Every man is ready with his stick to fend off the animal that approaches him; one push separates the camels as it would separate a couple of boats; and the camels move away, quite unconscious of the circumstance, till another movement swings them together again."

TRAVELLING IN PAST TIMES IN BRITAIN.

The modes of travelling, and conveyance generally, were of a comparatively rude and primitive kind in Britain till the latter part of the seventeenth century; and any thing like comfortable and quick travelling cannot be said to have been known till a century later, when mail-coaching was introduced. In old times, people of an humble rank travelled only on foot, and those of a higher station on horseback. Noblemen and gentlemen, as much for ostentation as use, kept running footmen—a class of servants active in limb, who ran before them on a journey, or went upon errands of special import. The pedestrian powers of these footmen were often surprising. For instance, in the Duke of Lauderdale's house at Thirlstane, near Lauder, on the table-cloth being one morning laid for a large dinner-party, it was discovered that there was a deficiency of silver spoons. Instantly the footman was sent off to the duke's other seat of Lethington, near Haddington, fully seventeen miles off, and across hills and moors, for a supply of the necessary article; he returned with a bundle of spoons, in time for dinner. Again, at Hume Castle, in Berwickshire, the Earl of Home had one night given his footman a commission to proceed to Edinburgh (thirty-five miles off), in order to deliver a message of high political consequence. Next morning

* Goldsmith's Animated Nature, vol. iv

early, when his lordship entered the hall, he saw the man sleeping on a bench, and conceiving that he had neglected his duty, was about to commit some rash act, when the poor fellow awoke, and informed Lord Home that his commission had been executed, and that, having returned before his lordship was stirring, he had only taken leave to rest himself a little. The earl, equally astonished and gratified by the activity of his faithful vassal, rewarded him with a little piece of ground, which to this day bears the name of the *Post Rig*—a term equivalent to the postman's field, and an unquestionable proof, as all the villagers at Hume devoutly believe, of the truth of the anecdote. The custom of keeping a running footman did not cease amongst noble families in Scotland till the middle of the last century. The Earl of March, father to the late Duke of Queensberry, and who lived at Neidpath Castle, near Peebles, had one named John Mann, who used to run in front of the carriage, with a long staff. In the head of the staff there was a recess for a hard-boiled egg, such being the only food taken by Mann during a long journey.

When the matter of communication was of particular importance, or required to be despatched to a considerable distance, horsemen were employed; and these, by means of relays of fresh animals and great toil of body, would proceed journeys of some hundreds of miles to accomplish what would now be much better done by a post-letter. Some journeys performed on horseback in former days would be considered wonderful even in modern times with good roads. Queen Elizabeth died at one o'clock of the morning of Thursday, the 24th of March, 1603. Between nine and ten, Sir Robert Carey left London (after having been up all night), for the purpose of conveying the intelligence to her successor James, at Edinburgh. That night he rode to Doncaster, a hundred and fifty-five miles. Next night he reached Witherington, near Morpeth. Early on Saturday morning he proceeded by Norham across the Border; and that evening, at no late hour, kneeled beside the king's bed at Holyrood, and saluted him as King of England, France, and Ireland. He had thus travelled four hundred miles in three days, resting during the two intermediate nights. But it must not be supposed that speed like this was attained on all occasions. At the commencement of the religious troubles in the reign of Charles I., when matters of the utmost importance were debated between the king and his northern subjects, it uniformly appears that a communication from Edinburgh to London, however pressing might be the occasion, was not answered in less than a fortnight. The crowds of nobles, clergymen, gentlemen, and burghers, who at that time assembled in Edinburgh to concert measures for opposing the designs of the court, always dispersed back to their homes after despatching a message to King Charles, and assembled again a fortnight thereafter, in order to receive the reply, and take such measures as it might call for. And even till the last century was pretty far advanced, the ordinary riding post between London and Edinburgh regularly took a week to the journey.

In consequence of the inattention of our ancestors to roads, and the wretched state in which these were usually kept, it was long before coaching of any kind came much into fashion. Though wheeled vehicles of various kinds were in use among the ancients, the close carriage or coach is of modern invention. The word *coach* is Hungarian, and the vehicle itself is supposed to have originated in Hungary. Germany certainly appears to have taken the precedence of the nations of Western Europe in using coaches. They were introduced thence into England some time in the sixteenth century, but were, after all, so little in vogue throughout the whole reign of Elizabeth, that there is no trace of her having ever used one. Lord Grey de Wilton, who died in 1593, introduced a coach into Ireland, the first ever used in that country. One was introduced into Scotland—we rather think from France—about the year 1571. It belonged to the famous Secretary Maitland of Lethington, who, during the horrid civil war between the adherents of Mary and those of her son James, made a journey in that vehicle from Edinburgh Castle, which he was holding out for the queen, to Niddry in West Lothian, for the purpose of holding a consultation with some others of her friends—the first time, it is believed, that a close carriage was ever used in Scotland. Fynes Morison, who wrote in the year 1617, speaks of coaches as recently introduced, and still rare in Scotland. For a long time, these conveniences were only used by old people, who could not well bear riding. The young and active despised them, as tending to effeminacy, and as not being so quick of movement as the horse. The Duke of Buckingham, in 1619, first used a coach with six horses—a piece of pomp which the Duke of Northumberland thought proper to ridicule by setting up one with eight. Charles I. was the first British sovereign who had a state carriage. Although Henry IV. was killed in a coach—the only one, by the way, he possessed—his ordinary way of appearing in the streets of Paris was on horseback, with a large cloak strapped on behind, to be used in case of rain. In Scotland, previous to the time of the civil war, coaches were only used by persons high in the state. It is very curious to find that the same sort of complaints now made by persons interested in coaching respecting the introduction of steam locomotives, were made when coaches were introduced. Taylor, the water-poet, complains, in the reign of Charles I., that large retinues of men were now given up by the great, since they had begun to use coaches. Ten, twenty, thirty, fifty, yea, a hundred proper serving men, were transformed, he says, into two or three animals. The old-wifical thinkers of that day were as much concerned about the fate of the discharged men-servants, as the twaddlers of the present are distressed about the needless horses. It is further very amusing to find Taylor, in his antipathy to coaches, complaining that their drivers were all of them hard drinkers.

In a pamphlet called the "Grand Concern of England Explained," published in 1673, the writer very gravely attempts to make out that the introduction of coaches was ruining the trade of England. The following is an example of his mode of reasoning:—"Before the coaches were set up, travellers rode on horseback, and men had boots, spurs, saddles, bridles, saddle-cloths, and good riding-suits, coats and cloaks, stockings and hats, whereby the wool and leather of the kingdom were consumed. Besides, most gentlemen when they travelled on horseback used to ride with swords, belts, pistols, holsters, portmanteaus, and hat-cases, which in these coaches they have little or no occasion for. For when they rode on horseback they rode in one suit, and carried another to wear when they came to their journey's end, or lay by the way; but in coaches they ride in a silk suit, with an Indian gown, with a sash, silk stockings, and the beaver hats men ride in, and carry no other with them. This is because they escape the wet and dirt which on horseback they cannot avoid; whereas in two or three journeys on horseback, these clothes and hats were wont to be spoiled; which done, they were forced to have new very often, and that increased the consumption of manufacture. If they were women that travelled, they used to have safeguards and hoods, side-saddles and pillions, with strappings, saddle or pillion cloths, which, for the most part, were laced and embroidered; to the making of which there went many several trades, now ruined." But the writer has other reasons to urge against coach travelling. "Those who travel in this manner," he observes, "become weary and listless when they ride a few miles, unwilling to get on horseback, and unable to endure frost, snow, or rain, or to lodge in the fields." Besides, he asks "what advantage it can be to a man's health to be called out of bed into these coaches an hour or two before day in the morning--to be hurried in them from place to place till one, two, or three hours within night; insomuch that, after sitting all day, in the summer time, stifled with heat and choked with dust—or in the winter-time, starving or freezing with cold, or choked with filthy fogs, they are often brought into their inns by torchlight, when it is too late to sit up to get supper, and next morning they are forced into the coach so early that they can get no breakfast? What addition is it to men's health or business to ride all day with strangers, oftentimes sick, ancient, diseased persons, or young children crying; all whose humours he is obliged to put up with, and is often poisoned with their nasty scents, and crippled with boxes and bundles? Is it for a man's health *to be laid fast in the foul ways, and forced to wade up to the knees in mire; afterwards* sit in the cold till teams of horses can be sent to pull the coach out? Is it for their health to travel in rotten coaches, and to have their tackle, or perch, or axle-tree broken; and then to wait three or four hours (sometimes half the day), and afterwards to travel all night to make good their stage?"

These, however, do not exhaust the patriotic clamours of the writer against the odious innovation of stage-coaching. He says that the practice "discourages the breed of horses," an argument which, it is amusing to observe, has also been used in opposition to the introduction of railways in recent times. In certain very peculiar circumstances, he allows, stage-coaching might be tolerated, but in no other. "If some few stage-coaches were continued, to wit, one to every shire-town in England, to go once a week backward and forward, and to go through with the same horses they set forth with, and not travel above thirty miles a day in the summer, and twenty-five in the winter, and to shift inns every journey, that so trade might be diffused—these would be sufficient to carry the sick and the lame, that they pretend cannot travel on horseback; and, being thus regulated, they would do little or no harm; especially if all be suppressed within fifty miles of London, where they are no way necessary, and yet so highly destructive."

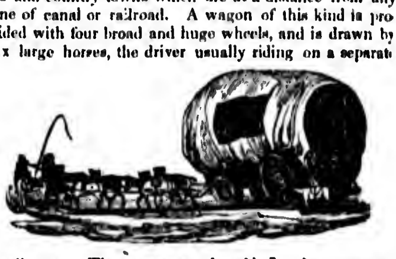
We have thought fit to introduce these extracts here, not so much for the purpose of amusing our readers with their absurdity, as to afford a caution to the general opponents of improvement. Arguments of a similar illogical nature are now used in reference to almost every proposed melioration in our social condition, and will doubtless, in a century hence, be quoted for their short-sighted folly, though at present meeting with countenance from a large class in the community.

Notwithstanding the introduction of stage-coaches in the seventeenth century, they were placed only on the principal roads, and used almost exclusively by persons of refined taste and wealth. The popular mode of conveyance continued for at least a century afterwards to be by stage-wagons; these were very large and cumbersome machines, drawn by six or eight horses, and devoted chiefly to the carriage of goods to and from the metropolis. The only part of the vehicle which afforded accommodation to passengers, was the tail of the wagon, as it was called, a reserved space with a hooped-up cover at the hinder part of the machine; and here, sitting upon straw as they best could, some half dozen passengers were slowly conveyed on their journey. The chance attacks of highwaymen, and other incidents which occurred to the occupants of the wagon, also their adventures at the inns where they slept for the night, are graphically described by Smollett in his story of Roderick Random, and will be in the recollection of most of our readers.

The wagons thus employed in the double office of carrying both goods and passengers, were, as we have said, confined chiefly to the great lines of road in England. On all the less important routes, and particularly in Scotland, the only means of conveyance for goods was by pack horses. These animals were loaded with sacks thrown

across the back; and, if not too heavy, piled to a considerable height. A number together were generally conducted in a line along the narrow and badly constructed paths, that which went before carrying a bell, by the tinkling sound of which the cavalcade was kept from straggling after nightfall. This exceedingly rude mode of conveyance continued in operation in some parts of the country till the year 1780, or thereabouts, when one-horse carts came into use.

The old-fashioned wagons still remain in use in England, notwithstanding the numerous improvements in modes of conveyance and locomotion. They are chiefly employed for the carriage of goods between the metropolis and country towns which are at a distance from any line of canal or railroad. A wagon of this kind is provided with four broad and huge wheels, and is drawn by six large horses, the driver usually riding on a separate



small pony. The wagons employed in London to convey coal from the wharfs to the houses of consumers, or beer from brewers, are of the same unwieldly form, and are drawn with a needless expenditure of power.

The length of time consumed in journeys by even the best kind of carriages of past times, is now matter for surprise. The stage-coach which went between London and Oxford in the reign of Charles II. required two days, though the space is only fifty-eight miles. That to Exeter (168½ miles) required four days. In 1703, when Prince George of Denmark went from Windsor to Petworth to meet Charles III. of Spain, the distance being about forty miles, he required fourteen hours for the journey, the last nine miles taking six. The person who records this fact, says, that the long time was the more surprising, as, *except when overturned*, or when stuck fast in the mire, his royal highness made no stop during the journey.

In 1742, stage-coaches must have been more numerous in England than in Charles II.'s time; but it does not appear that they moved any faster. The journey from London to Birmingham (116 miles) then occupied nearly three days, as appears from the following advertisement:—"The Litchfield and Birmingham stage-coach set out this morning (Monday, April 12, 1742), from the Rose Inn, Holborn Bridge, London, and will be at the Angel, and the Hen and Chickens, in the High Town, Birmingham, on Wednesday next, to dinner; and goes the same afternoon to Litchfield. It returns to Birmingham on Thursday morning to breakfast, and gets to London on Saturday night; and so will continue every week regularly, with a good coach and able horses." Thus the whole week was occupied in a journey to and from Litchfield by Birmingham, an entire space of probably not more than two hundred and forty miles—that is, at an average of forty miles a day.

Of the stage-coach journey to Bath, about 1748, we learn some particulars from Smollett's celebrated novel. Mr. Random enters the coach before daylight. It proceeds. A highwayman attacks it before breakfast, and is repulsed by the gallantry of the hero. Strap meanwhile accompanies the coach on horseback. A night is spent on the road, and the journey is finished next day, apparently towards evening—108 miles! At that time there was no regular stage-coach from London to Edinburgh; and the newspapers of the latter city occasionally present advertisements, stating that an individual about to proceed to the metropolis by a post-chaise, would be glad to hear of a fellow adventurer, or more, to lessen the expenses for mutual convenience. However, before 1754 there was a stage-coach between the two British capitals. In the Edinburgh Courant for that year, it is advertised that—"The Edinburgh stage-coach, for the better accommodation of passengers, will be altered to a new genteel two-end glass coach machine, hung on steel-springs, exceeding light and easy, to go in ten days in summer, and twelve in winter; to set out the first Tuesday in March, and continue it, from Hosea Eastgate's, the Coach and Horses in Dean Street, Soho, London, and from John Somerville's in the Canongate, Edinburgh, every other Tuesday, and meet at Burrowbridge on Saturday night, and set out from thence on Monday morning, and get to London and Edinburgh on Friday. In winter, to set out from London and Edinburgh every other [alternate] Monday morning, and to go to Burrowbridge on Saturday night; and to set out from thence on Monday morning, and get to London and Edinburgh on Saturday night. Passengers to pay as usual. Performed, if God permits, by your dutiful servant, Hosea Eastgate." Here the distance of two hundred miles requires six days in winter, being at the rate of little more than thirty-three miles a day. So lately as the end of the last century, the journey by the stage between Edinburgh and Glasgow (forty-two miles) occupied a whole day, the passengers stopping to dine on the road. It was considered a great improvement when, in 1799, a coach was started with four horses, which performed the journey in six hours. The usual time now taken is four and a half hours. It is not unworthy of being noticed, that, when the mail-coaches were started by Mr. Parker, in 1788, six and a half miles an hour was the utmost speed attained.

The length of time spent by carriers on the roads, whether with pack-horses or carts, was of course proportionally greater. An aged gentleman writing his recollections of past times (1770 to 1780) in Scotland, drolly observes, "that the common carrier from Selkirk to Edinburgh, thirty-eight miles distant, required two weeks to make out his journey between the two towns, going and returning, with a suitable resting-time at each to his poor fatigued horse, which had perhaps not less than five or six hundredweight of goods to drag along. The road originally was among the most perilous in the whole country; a considerable extent of it lay in the bottom of that district called Gala Water, from the name of the principal stream. The channel of the water itself, when not flooded, was the track chosen, as being the most level, and easiest to be travelled on. The rest of the way, very much up-and-down-hill, was far worse. The townsmen of this adventurous individual, on the morning of his way-going, turned out to take leave of him, and to wish him a safe return from his perilous undertaking."*

* Robertson's Rural Recollections

ROADS.

It will appear from the preceding notices respecting travelling and modes of carriage for goods, that little or no improvement could be expected in either case, till a great change for the better was made on the state of the roads. In no branch of art do our ancestors seem to have been more deficient or heedless than in that of making roads and keeping them in constant repair. In this respect, indeed, they were in a condition of greater ignorance than the ancient Romans, whose roads were on the most extensive and efficient scale, suitable to the necessities of the period, and may here be shortly described.

ANCIENT ROMAN ROADS.

It is, we believe, generally allowed that the Romans gained a certain degree of knowledge on the subject of road-making from Greece and Carthage, and also perhaps from Egypt; but whatever they learned they greatly improved upon, and therefore they are entitled to be called the first and best roadmakers of whom history has preserved any account. One great leading principle actuated the Roman authorities in establishing roads: it was that of maintaining their military conquests. On vanquishing a barbarous country, their first efforts consisted in penetrating it with good roads, which were maintained with jealous care, and were connected as far as possible in unbroken lines with the seat of government at Rome. this, indeed, formed one of their grandest engines of subjugation, and affords us a striking proof of their sagacious and active character.

Speaking of the subordinate Roman capitals in Asia Minor, Syria, and Egypt, Gibbon describes as follows the manner in which they were connected by roads:—"All these cities were connected with each other and with the capital by the public highways, which, issuing from the Forum at Rome, traversed Italy, pervaded the provinces, and were terminated only by the frontiers of the empire. If we carefully trace the distance from the wall of Antoninus [in Scotland] to Rome, and from thence to Jerusalem, it will be found that the great chain of communication, from the north-west to the south-east point of the empire, was drawn out to the length of 4080 Roman [or 3740 English] miles. The public roads were accurately divided by mile-stones, and ran in a direct line from one city to another, with very little respect for the obstacles either of nature or private property. Mountains were perforated, and bold arches thrown over the broadest and most rapid streams. The middle part of the road was raised into a terrace which commanded the adjacent country, consisting of several strata of sand, gravel, and cement, and was paved with large stones, or in some places near the capital, with granite. Such was the solid construction of the Roman highways, whose firmness has not entirely yielded to the effect of fifteen centuries. They united the subjects of the most distant provinces by an easy and familiar intercourse; but their primary object had been to facilitate the marches of the legions; nor was any country considered as completely subdued, till it had been rendered in all its parts pervious to the arms and authority of the conqueror. The advantage of receiving the earliest intelligence, and of conveying their orders with celerity, induced the emperors to establish, throughout their extensive dominions, the regular institutions of posts. Houses were everywhere erected, at the distance of only five or six miles; each of them was constantly provided with forty horses; and, by the help of these relays, it was easy to travel a hundred miles in a day along the Roman roads. The use of the posts was allowed to those who claimed it by an imperial mandate; but though originally intended for the public service, it was sometimes indulged to the business or conveniency of private citizens."

From other accounts, we learn that the Roman roads varied in importance and uses. The great lines were called *prætoriæ viæ*, as being under the direction of the prætors; and these formed the roads for military intercourse. Other lines were exclusively adapted for commerce, or civil intercourse, and were under the direction of consuls. Both kinds were formed in a similar manner. The plan on which they were made was more calculated for durability than ease to the traveller; and for our modern wheel carriages they would be found particularly objectionable. Whatever was their entire breadth, the centre constituted the beaten track, and was made of large ill-dressed stones, laid side by side to form a compact mass, of from twelve to twenty feet broad; and, therefore, in their external aspect, they resembled the coarse stone causeways which are still in use in towns and in the highways of France. Some of the roads had double lines of this solid pavement, of this nature, with a smooth brick path for foot passengers; and at intervals along the sides, there were elevated stones on which travellers could rest, or from which cavalry could easily mount their horses. One important feature in the construction of all the Roman roads, was the bottoming of them with solid materials. Their first operation seems to have been the removal of all loose earth or soft matter which might work upwards to the surface, and then they laid courses of small stones, or broken tiles and earthenware, with a course of cement above, and upon that were placed the heavy stones for the causeway. Thus, a most substantial and durable pavement was formed, the expense being defrayed from the public treasury. Various remains of Roman roads of this kind still exist in France, and also in different parts of Britain. One of the chief Roman thoroughfares, in an oblique direction across the country from London to the western part of Scotland, was long known by the name of Watling Street, which has been perpetuated in the appellation of one of the streets in the metropolis.

MODERN MACADAMIZED ROADS.

We now proceed to offer some account of the introduction of a proper kind of roads in modern times. Attempts to improve the roads forming the leading thoroughfares in England, were made at the beginning of the eighteenth century; and for that purpose turnpike acts for various districts were passed by parliament. It is a very remarkable fact, that some of the counties in the neighbourhood of London petitioned Parliament against the extension of turnpike roads into the remoter parts of the country. Those remoter counties, it was pretended, from the cheapness of labour, would be able to sell their corn at a lower rate in the London market than themselves, and would thereby reduce their rents and ruin their cultivation. In spite of these remonstrances, turnpike roads were extended into the remoter counties, and, as ought to have been expected, so far from injuring the neighbourhood of the metropolis, they greatly increased its value—for a free and easy interchange of commodities is always universally beneficial.

It is of little moment to ascertain the exact period when these improvements were effected on the roads of England; for, upon the whole, they were only partial, and as yet the proper mode of road-making was not understood. The plan consisted in making the paths somewhat more level than formerly, and of filling up the ruts and holes with stones gathered from the adjacent fields. By this means the holes, ruts, and sloughs were considerably limited in both breadth and depth; but as perfect levelness was not attained, carriages were dreadfully jolted over the rougher parts, and the wheels sunk jarringly into the softer ground beyond. As also no pains were taken to lay down stones of equal bulk, but small and large mixed, it happened that the larger ones in time wrought to the surface, and so created additional jolting to vehicles and damage to the roads. The defects in this species of improved roads were so conspicuous, that various engineers of eminence, and other individuals, turned their attention to the subject; and among these is to be numbered Mr. M'Adam, whose plans surpassed all others, and, as is well known, are now generally adopted. The name of this gentleman has become so completely associated with the idea of good roads, that a slight sketch of his history may here be acceptable.

John Loudoun M'Adam was the representative of an old and respectable landed family—the M'Adams of Waterhead, in the Stewartry of Kirkcudbright, and was born, September 21, 1756, in the town of Ayr. By the death of his elder brother, he became, in infancy, the only son of his father, and entitled to inherit the distinction—considered in Scotland, in such cases, a matter of some consequence—of being the representative of the family, and chief man of his name. In consequence of the destruction, by fire, of a house which he had built for his residence at Lagwyne, in the moorland parish of Carsphairn, his father removed, about this time, to Blairquhan, in Ayrshire, which he rented from Sir John Whitefoord. The family estate was now sold to the Earl of Stair, from whom it was afterwards purchased by a junior branch of the M'Adam family, who still possesses it. Mr. M'Adam received his education at the school of Maybole, under a teacher named Doick, who possessed considerable local reputation. On the death of his father in 1770, when he was only fourteen years of age, he was sent to New York, where his uncle William, a younger brother of his father, had been settled for some years as a merchant. Here he remained fourteen years, during which the war of Independence took place. Under the protection of the British forces, who possessed the city, he realized a considerable fortune, as an agent for the sale of prizes. At the conclusion of the war, he returned, with the loss of nearly the whole of his property, to his native country, and resided for some time at Dumcrieff, a beautiful place in the neighbourhood of Moffat, subsequently the seat of Dr. Currie, the biographer of Burns. He afterwards lived for thirteen years at Sauchrie in Ayrshire, where he was in the commission of the peace and a deputy lieutenant. During this period, he enjoyed the society of his first wife—a lady named Nichol, whom he had married at New York, and who brought him three sons and three daughters, most of whom survive him. He married, secondly, in 1827, Miss de Lancey, who survives him, but has no family.

In the year 1798, Mr. M'Adam received the government appointment of agent for victualling the navy in the western parts of Great Britain, and accordingly removed to Falmouth. He subsequently resided for many years at Bristol, and latterly at Hoddesdon in Hertfordshire. It was while acting as one of the trustees upon certain roads in Ayrshire, that he first turned his attention seriously to the mechanical principles involved in that branch of national economy. While engaged in England in duties of an entirely different kind, he continued silently to study the process of road-making in all its details, keeping particularly in view the great desiderata of a compact and durable substance and a smooth surface. By the exertions of various able engineers, who had turned their attention to road-making, the highways of Great Britain were already in the course of a rapid improvement; but Mr. M'Adam was the first to point out and prove, in practical operation, that a bed, of a few inches in depth, formed of fragments of primitive rock—granite, greenstone, or basalt—small enough to pass through a ring not larger than two inches and a half in diameter, was the best material for ordinary roads. His system, in its leading features, is so conspicuously displayed in the public eye, that any minute account of it would be superfluous. It was not till 1815, when on the borders of sixty, that he began to devote his whole mind to the business of road-making. Being then appointed surveyor-general of the Bristol roads, he had at length full opportunities of exemplifying his system, which he forthwith proceeded to do in a manner that attracted general attention, and caused it to be quickly followed throughout the whole kingdom. In 1823, Mr. M'Adam was examined before a committee of the House of Commons respecting the propriety of converting the ruble granite causeway of the principal thoroughfares into a smooth pavement, resembling those which he had already formed on the principal roads. He expressed himself as decidedly of opinion that such a change should be made: "I consider," said he, "that the expenses would be materially reduced; the convenience of passing over the surface would be generally facilitated, particularly in the leading streets; and the same weight of stone, now put upon those streets as pavement, would be obtained at infinitely less expense, in a different form, for the purpose of road-making." The consequence was, that, in London, Edinburgh, and Dublin, some of the principal lines of street, which had previously been remarkable for solidity of pavement, as well as the large sums that pavement had cost, were—to use a phrase already familiar to every ear—*Macadamized*.

In introducing this improvement into British roads, Mr. M'Adam had spent several thousand pounds from his own resources. In 1825, he proved this expenditure before a committee of the House of Commons, when an equivalent sum was voted to him, besides an honorary tribute of two thousand pounds, in consideration of the public benefits resulting from his labours. The inadequacy of this remuneration is very striking; and it is impossible to avoid contrasting it, in some bitterness of spirit, with the ratio in which services of other and less beneficial kinds are usually acknowledged. Many a lieutenant, in being promoted to a captaincy for some little display of personal bravery, has reaped nearly as valuable a reward as that bestowed upon Mr. M'Adam for bringing into operation a mechanical improvement, the consequences of which, in saving animal labour, facilitating commercial intercourse, and rendering travelling easy, quiet, and pleasant, are beyond all calculation. Though the remuneration was thus small, and never, as we have been informed, fully paid, Mr. M'Adam would have been the last to complain of it. He never made money an object, but, on the contrary, rejected on principle many opportunities of gathering wealth, which his office as a superintendent opened up to him, and which many men of by no means blunt feelings as to professional propriety would have taken advantage of. He therefore died a poor, but, as he frequently expressed himself, "at least an honest man." Mr. M'Adam's decease took place, November 26, 1836, at Moffat. He was in the 81st year of his age.

According to the principles of road-making, as laid down and consistently acted upon by Mr. M'Adam, a road ought to be an artificial and hard flooring, placed on a level and dry surface. To make a good road, therefore, we must in the first place level and prepare the ground. If the ground be soft, as, for instance, have a covering of turf and earthy matter beneath, the top must be pared off, and as much earth removed as will produce a hardish base. In some instances, it may be necessary to excavate, and fill up the gap with compact and substantial materials; but should this be the case, the materials used must on no account include any large stones, or be otherwise unequal in their nature: The principles on which the road should be made are thus alluded to by Mr. M'Adam:—"Roads can never be rendered perfectly secure, until the following principles be fully understood, admitted, and acted upon: namely, that it is the natural soil which really supports the weight of travel; that while it is preserved in a dry state, it will carry any weight without sinking, and it does, in fact, carry the road and carriages also; that this native soil must previously be made quite dry, and a covering, as much impenetrable to rain as possible, must then be placed over it, to preserve it in that dry state; that the thickness of a road should only be regulated by the quantity of material necessary to form such impervious covering, and never by any reference to its own power of carrying weight."

To put these principles in practice—after the base of the road has been prepared, it should be laid with a layer of small stones, made by breaking larger stones into pieces weighing about three ounces. No round pebbles or channel stones must be employed; all must be angular or irregularly shaped pieces. The covering of this kind of material, technically called *road metal*, should be spread to a depth of from six to ten inches, as may be found necessary, and raked level on the surface. The sides of the road must possess wet ditches or gutters, into which all water may be readily conveyed and run off. For this purpose, culverts, drains, and gratings may be necessary.

In certain cases it may be expedient to carry a line of road across a bog or peat morass; and this may be done with perfect security by laying a bottom of shrubs, furze, or small branches of trees, on the soft understratum, and covering it over with gravel, and the ordinary stone material above. The road so formed may perhaps yield or bend a little when travelled by a heavily loaded vehicle, but will sustain as much tear and wear as any other portion of the highway.

The width of the road is a matter of taste and convenience, but it should not be less than thirty-three feet, to allow a free passage of vehicles in different directions. On all the good roads in Britain, near towns, a side footpath, protected by a curb-stone, is added to the ordinary breadth. "With respect to the shape of the surface of the road, when completed, there is also some difference of opinion; but all agree that it should be convex, the only difference being in the quantity. The degree of convexity should be governed in a great degree by the locality. A road formed of soft materials should have a greater convexity than one formed of hard materials; for the obvious reason that water will injure a soft road quicker than a hard one. A road upon uneven ground should have a greater convexity than one upon level ground, to prevent the descent of rain-water along the face of the road, which is there caught by the slightest impressions of wheels; and thus wear channels, as may too often be seen, from the top to the bottom of the hill A wide road also requires to be more crowning than a narrower one; which more readily frees itself from rain-water, inasmuch as the distance the water has to run is less. But it must be borne in mind, that the freeing of a road from rain-water is not the only object to be kept in view in making a road crowning. The ease and safety of carriages, and particularly those with heavy burdens or with high loads, must be consulted. A carriage moves most freely, or with the least resistance, when the load lies evenly upon the wheels. Just in proportion as the weight or load is thrown on one side or the other, the resistance is increased. Hence the inconveniency of a very crowning road on a steep; and hence the utility of bars or breaks in long ascents. It is plain that a road should be equally and duly convex in every part of it; otherwise it becomes more partially worn; the more level parts being most used.

When a road is carried round a hill instead of going directly over it, or when a road is made on a side-hill, it should not be made convex from the middle, but it should be formed like half of a common road, with the highest part on the upper side, thus giving the water a tendency to run off on the lower side. Mr. Walker recommends the least possible convexity consistent with a proper drainage of the road. In most localities this will rarely exceed four inches; that is, the middle should be four inches higher than the sides. An idea of a perfect road may be formed from a frozen canal, where flatness, smoothness, and hardness are combined; in imitation of such a surface, railways were invented, and fully illustrate the principles assumed. Roads cannot be made with all of these perfections, but they should always be kept in view; for the nearer we approach to this standard, the greater will be the draught. M'Adam says, roads should be made as flat as possible. 'Where a road is made flat,' he says, 'people will not follow the middle of it, as they do when it is made quite convex, which is the only place where carriages can run upright, by which means three furrows are made by the horses and the wheels, and the water continually stands there; and I think that more water actually stands upon a very convex road, than on one which is reasonably flat.'

"In laying out a new road, it is of some importance that the rises and falls be not too great. The most approved angles of ascents and descents in England are about one inch in a foot—from this to one inch in a yard. In order to obtain ascents not exceeding these, it is necessary in our uneven country to wind up a hill instead of going directly over it. In such cases the road is to be built upon the side of a hill, and this is considered the most advantageous ground upon which a road can be built, provided the hill has not too great an ascent; because what is taken from the upper side serves to form the embankment on the lower side. While we are speaking of embankments, we may mention the English method of forming them, which is so manifestly superior to our own, that it deserves to be imitated. 'The natural sod, which would be covered by the base of the embankment, having been cut off and set aside, the earth is then wheeled or carted on to form the two outsides, which are raised to the required height, leaving the middle open. The sods are then placed on one another, the grassy surface at right angles to the face of the outer slopes, forming as it were a battering wall of sods against the embankment.' This method is found effectual in preventing the banks from washing away and gullying. While the outsides are forming, the lumps of earth, stone, &c., run downward to the middle; and in this way the whole is finished. When the work settles, it is found to tend towards the centre, thus preventing the outside slopes from giving way."*

The following judicious observations are made by the same authority on the subject of fences, and junctions of different roads:—"Fences are necessary along the sides of a road in all enclosed countries; but they should never be allowed to rise higher than four feet on common roads. It is absolutely necessary that the air and sun have free admission to a road; besides, where the fences are high, it gives a sweeping power to the wind, which is not beneficial. Mr. Telford thinks that fences should never be more than four feet high, and that all trees within twenty feet of the sides of the road should be removed. He also thinks that twenty per cent. of the expense of repairing or improving roads is incurred by the improper state of the fences and trees along the sides, particularly on the sunny side; this will be manifest to any person who will take the trouble to examine the condition of that part of a road which is much shaded, compared to the other parts which are exposed to the sun and air.

*"The junction of one road with another requires a little attention: it should always be made at right angles, and on the same level, if possible. All engineers agree that plantations of trees should not be made close to roads; but what the distance should be depends on the elevation of the country, the soil, the breadth of the road, as well as its direction, &c., &c. An elevated situation is always more exposed to winds than a level or hollow. A broad winding road has chances of the direct influence of the sun and wind, according to the obliquity of its angles; a road running north and south, though planted closely on both sides, will enjoy the sun during a part of every day in the year; one running east and west, planted on the south side with trees forty feet high, or more, will enjoy no sun during the winter months. The least injurious trees are single rows trained to high stems, properly pruned."

For some time after a road has been laid with fresh materials, it presents a rough surface, unpleasant to the feelings of those who are conveyed over it: but this roughness is gradually abated, the small stones are crushed into a compact mass, and finally, the road is smooth, hard, and level. The length of time that may elapse before any new repair is required, depends on the amount and kind of traffic, as well as the weather. Rain is a great enemy to macadamized roads, and particularly so when accompanied with much traffic. The water lies on the surface, and softening the material, the action of the horses' feet and of the wheels causes a certain depth of thin liquid mud. This mud should, by all means, be scraped off to a side, for the longer it lies, the stratum beneath is the more liable to be cut up and damaged. The scraping of the roads, therefore, becomes an essential duty of all who are interested in preserving the highways economically in repair. When the mud which is scraped aside thickens by exposure, it should be carted off, and may be employed on many soils as a useful manure. Besides containing a proportion of refuse from horses, it is loaded with particles of iron from wheels and horse shoes; and being substantially silica or ground stone, it may be administered with special advantage to heavy clay grounds.

Roads exposed to much traffic require to be renewed in surface at least once a year. The first indications of decay are observable in the form of slight hollows, and ruts next make their appearance. In some cases, where the decay is only partial, a small quantity of metal may be scattered in the hollows, bringing them up to a level with all around. However, this is not usually done on well-kept roads near large towns. There the road undergoes a thorough repair once a year, which is preferable to partial mendings. The best time for repairing roads is about November, or before the winter frost and snow set in. In commencing the repair the road should be picked across, at intervals of twelve or fifteen inches. This is done by men, each having a pick by which he indents the hard bottom, or forms scores an inch deep in the road. The use of such a preliminary process, is to cause a ready union between the new and old materials. If the fresh metal were scattered over the old road, without any preparation, it would with difficulty unite to the substratum, and at best form an upper crust, which would be too easily damaged.

With respect to the keeping of roads in efficient repair, the most advantageous plan consists in assigning the entire duty to a contractor. This person, by undertaking to keep all the roads in a county or district in constant or uniform repair, is able to execute his functions much more economically than the private gentlemen who act as trustees of the highways and turnpikes. The trustees appointed by local acts of parliament to superintend highways, now generally employ contractors to keep the roads in repair at a specified price per mile, the payment being made from funds collected from the lessees of the toll-bars.

The aggregate length of the turnpike roads of Great Britain is now calculated to be 25,000 miles, at a general breadth of from fifty to sixty feet.* The cost of

* Scientific Tracts. Boston: 1833.

* Turnpikes were so called from poles or bars, swung on a pivot, having been placed on them, and turned either way when dues were paid. Gates are now substituted for these poles in Great Britain. In Germany, the pole is still used, one end being depressed to raise the other and so permit a free passage.

keeping these roads in repair differs considerably in different counties. In the neighbourhood of London, the annual cost is about £550 per mile, in Yorkshire it is £60, and in Wales £20. The average is about £50. Nearly all the road trusts are in debt for borrowed money. It is supposed that the debt is on an average of £320 per mile, or probably £6,000,000 for the whole.

Law of the Road.—For general convenience and safety, drivers of vehicles and riders, in travelling along a road, are expected to take a particular side; and this practice is now so well understood, and is in itself so proper, as to have become a part of the common law. The law of the road is, that when drivers meet from different directions, each shall keep his left hand to the wall or footpath. Secondly, when one driver overtakes another, and wishes to pass him, he must keep his left hand to the vehicle which he passes. In the case of either meeting or passing, each party is entitled to the half of the road. The same rules apply to riders. If these regulations be neglected, and an accident occur, the law is always in favour of the party who kept his own proper side, and no excuse can shelter the aggressor. The trustees of the road are liable in an action of damages for any injury that may be sustained through the carelessness of themselves or servants, in leaving the road grossly out of repair.

According to a well-known rule, foot-passengers on pavements or side-paths are expected to walk with their right hand to the wall—that is, they keep their left hand to those whom they are meeting and passing. This custom prevents confusion in the streets of large towns, but is not a matter of law.

CANALS.

A canal is an artificial channel of water, and is usually constructed for inland navigation. Where natural rivers can be resorted to for purposes of this kind, they are preferable to canals, because little expense may be required to suit them for navigation, and they may be easily kept in repair. But few rivers, generally speaking, are sufficiently level, straight, or deep, to admit of being profitably navigated by barges, and therefore artificial channels require to be cut. Canals are extremely suitable in level countries, possessing rivers or brooks which can afford a due supply of water. In China, from a very early age, certain large rivers have formed natural canals longitudinally through the country from west to east, while artificial canals have been made to proceed in a cross direction from north to south, thus effecting a universal water communication throughout the empire. Canals existed in ancient Egypt in connection with the Nile, on a similar plan to what now prevails in China. Notwithstanding that canals were known to have existed from a remote antiquity in the east, it was long before they were introduced into western Europe. In modern times, they were first used by the inhabitants of the Netherlands, in consequence of the extreme flatness of their country, and the numerous channels of water which intersect it in all directions, in connection with the lower branches of the Rhine, and other rivers. In Holland and Belgium, therefore, canals in a great measure exist as an essential requisite in the general arrangements of the country, and are, in point of fact, so many wet ditches or drains to receive the superfluous waters.

In countries differently constituted, canals are constructed only with reference to the profit, in the form of commercial speculation. The great question, accordingly, in forming the project of a canal, is, whether the anticipated amount of traffic will raise tolls sufficient to compensate the outlay of the undertaking and subsequent charges for repair and superintendence. It simplifies such an inquiry to know the following truths in reference to cost of conveyance. The cheapest mode of conveyance is by sloops, smacks, brigs, packets, steamboats, &c., and these will at all times be employed for heavy and bulky goods, such as coal, barrels of liquids, iron, and other cumbrous materials proceeding coastwise. The next cheapest mode of conveyance is by barges on rivers; and the next is by means of canals. After this are ranked, in point of economy, conveyance by land, on railways and roads, the last being the dearest, though often the only means of transport which can be obtained. According to this view, canals can never answer as profitable speculations, when they have to compete with coasting vessels of any description, or with any species of conveyance by rivers. They cannot even in certain circumstances compete successfully with railways, on account of the slowness of speed at which barges or boats are drawn along them; and as speed is becoming daily a matter of greater moment in traffic, canals are gradually losing the conveyance of every kind of goods for which quickness of transit is desirable. For the sake of economy in national resources, it is very desirable that these truths in statistics should be generally understood and remembered.

When the undertaking appears warrantable, from a careful consideration of circumstances, the next thing to be taken into account is the obtaining of an adequate supply of water, and the fixing on the best—that is, the most level and unexpensive—line of route. In some parts of England, where an enormous traffic could be reckoned upon, canals have been projected and executed on a stupendous scale; mountains have been perforated to admit channels of water through them, valleys raised by embankments, and bridges built in the form of aqueducts across rivers; in short, no expense has been spared to render the inland navigation complete.

The supply of water necessary for a canal which is level throughout its course, is small in comparison with that of one pursuing an uneven line. When there is a common level of surface, the only expenditure of water is by evaporation; but when the level is various, a large loss is incurred at the locks in raising or lowering vessels. A lock is a portion of the canal enclosed by folding doors, and must at least measure the length of a vessel. If a vessel is to be raised from one level to another, it is drawn up to the doors of the lock, and these are opened to admit it. Having sailed into the lock, the doors are closed behind it, and it is now in a kind of prison from which there is no apparent escape. While in this situation, the doors at the opposite end of the lock, which retain the water at a higher level, are slowly opened, and admit a rush of the liquid mass, which speedily buoys up the vessel, and allows it to sail off along the higher level. The lock is not immediately emptied, but remains full of water, and is therefore ready to be employed in letting a vessel down. When the vessel approaches, and is fairly within the lock, the upper doors are shut, and then the lower doors are opened; by this means the vessel is carried into the lower level along with the rush of liquid, and is drawn on its course. A lockful of water has now evidently been shot from a higher to a lower level on the canal, and is lost, unless required for lower locks. To prevent inundation of the banks from the issuing of water from the locks, waste outlets require to be provided at certain distances, particularly at the lower termination of the line of canal. The provision of water to supply the locks is ordinarily from an artificial lake, which is established near the highest ground in the line.

The breadth of most canals varies from twenty to thirty feet, and the depth from four to six feet. If the depth of water be sufficient to keep the vessels from touching the bottom, no greater volume is necessary, for less power is required to pull a boat upon a shallow than a deep water, there being less liquid agitated or displaced. At one side of the canal a narrow road, called the towing-path, is constructed, and upon this the horses, which drag the vessel, proceed. There is a difference in the manner in which the dragging rope is attached to the vessel. In Holland it is the practice to attach the rope to near the bow of the boat, and to cause it to proceed over the outer extremity of a pole or species of mast, so as to keep it considerably above the water, and prevent its friction on the banks. This is not attended to in England, where the rope proceeds direct from the bow to the horse, and, except when in a state of great tension, it trails along the bank and surface of the water. In either case, the draught of the horse is exerted with a loss of power, for instead of being a fair draught behind, it is oblique, or in the direction of the rope slanting to the vessel. The tendency of the draught is to bring the boat to the shore, which is counteracted by the helm, and this again assists in diminishing the general amount of available power.

Throughout the canals of England and Scotland, only one horse is employed to drag a boat, loaded to the extent of from fifty to seventy tons; and with this weight dragging after it in a manner most disadvantageous, it will travel at the rate of two miles and a half or three miles an hour. That one horse should be capable of drawing fifty tons of goods in this unexpensive manner gives an apparently favourable view of canal conveyance; but laying all charges out of the question, the slowness of the motion, and consequently the detention of goods by the way, is a drawback of the most serious nature, and in reality renders canals almost useless for the transport of any but heavy and raw materials. Latterly, on a few canals, attempts have been successfully made to run "swift boats" for passengers, drawn by two horses, at a rate of seven or eight miles per hour; but as these vessels are run at a great expense for horse power, and at the utmost speed are not quicker in their transit than stage-coaches, it may be expected that they will utterly fail in competing with railways.

It may not be generally known that the principal obstacle to the use of steam-engines on board canal-boats, is the injury done to the banks by the action of the water from the paddles. How far this obstacle might be overcome by the use of the Archimedian screw propeller, it would be premature to say. Meanwhile, an attempt has lately been made in Scotland to introduce the use of steam-power for inland navigation, by means of a railway and locomotive tug, along the line of the Forth and Clyde Canal. The following account of an experiment is from the Edinburgh newspapers of November, 1839:—

"The experiment, which was of a novel nature, was conducted by Mr. John Macneil, civil engineer, and consulting engineer to the Canal Company. It is well known that the haulage of boats on this canal has hitherto been performed by horses; the rates of speed being, for the heavy sloops, brigs, &c., in the London, Dundee, and other trades, about 1½ to 2 miles per hour, when drawn by two or five horses, according to the state of the weather; and for the swift or passenger boats between 8 and 9 miles per hour, on an average, when drawn by two horses. The object of the experiment was to ascertain the possibility of using locomotive steam power to draw the boats, instead of horses. Accordingly, a single line of rails, upon blocks, like an ordinary railway, was laid down for a considerable space along the canal banks, near Lock 16; and a locomotive engine and tender, built by Mr. William Dodds, having been brought down the canal and set on the rails on the morning of the 21st, Mr. Macneil, Mr. Johnston, the canal director, and several engineers and gentlemen, being present, the experiment commenced by attaching to the engine the towing-line of the first passenger-boat that made its appearance, and which contained upwards of ninety passengers, with their luggage. There was a trifling delay in disengaging the horses and tying the line to the engine; but this was amply compensated when the 'Victoria' briskly set off, and almost immediately gained a speed of 17½ miles per hour, which she kept up round two curves, and until the termination of the rails made it necessary to stop, amid the cheers of the delighted passengers. This experiment was repeated, during the course of the day, with each passenger-boat as it came on the railed space, and with equal success each time. On one occasion a towing-rope, which was much decayed, got foul of a curb-stone and broke, but without causing the slightest inconvenience, except about one minute's delay. The engine employed being intended only for a slow trade, was not calculated to go at greater speed than 18 miles per hour; but it was the opinion of all present, that, with proper passenger locomotives, a speed might be obtained equal to that upon the best railways, few of the latter possessing the advantage secured by the canal bank of a perfect level throughout. The nature of the motion was highly gratifying to all the passengers, being more uniform, steady, and smooth, than when the boats were drawn by horses. Several of the heavy (masted) vessels were also taken in tow during the two days of trial, at the rates of 3, 3½, 4, and 5 miles per hour; and on one occasion, two loaded sloops, and a large wagon-boat, were together attached to the engine, and hauled with ease at the rate of 2¾ miles per hour, whilst only one-fourth of the steam was allowed to pass the throttle valve. The foregoing statements render palpably apparent the immense advantages which might be gained by this new adaptation of steam power—a great economy of haulage expenses, as one engine might draw at least six sloops, which now would require from eighteen to twenty-four horses, and, if necessary, at double the present speed; and a proportional increase of the present traffic on the canal, which might be reasonably expected. Passengers would increase in a great proportion, when attracted by economy and speed of transport. The Union Canal from Edinburgh to Falkirk might be traversed in 2 hours, and the Forth and Clyde Canal from Falkirk to Glasgow in 1½ instead of 4 hours and 3½, as at present, and this by only assuming 16 miles per hour, though more might easily be performed, as the experiments have shown."

Fully more satisfactory results ensued from subsequent experiments, but as the mode of draught has not come practically in operation, it is unnecessary to narrate them here.

One of the largest canals in Europe is that which extends from the German Ocean to the river Ai, at Amsterdam, by which vessels are enabled to reach that city by a direct channel, instead of sailing round by the Zuyder Zee. This ship canal was begun in 1819, and finished in 1825, at an expense of £850,000. Its length is nearly 52 English miles; its breadth 125 feet at the surface, and 38 feet at the bottom; and its depth 20 feet 9 inches. Traversing a perfectly flat country, it has no locks except at its extremities, and is of such magnitude, that two frigates or the largest merchant vessels can pass each other. There is a towing-path for horses on each side and about eighteen hours are required to perform the voyage from Amsterdam to the ocean. As a commercial speculation the canal yields no profit, but its service to the shipping of Amsterdam is incalculable, and without it the town must have sunk into comparative insignificance.

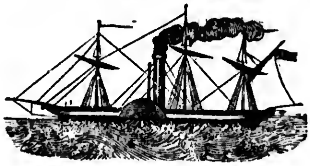
France possesses about fifty different canals, some of which are of great importance for general traffic. The chief canal is allowed to be that of Briare, called also that of the Loire and Seine. It was completed in 1642 measures 34½ miles in length and has 40 or 42 locks. The width is 25 feet at bottom. By this canal Paris receives large supplies of inland produce. The Canal du Midi, or Languedoc Canal, makes a communication between the Mediterranean at the city of Cette and the Atlantic Ocean at the mouth of the Garonne, passing through the province of Languedoc. Altogether, there are 900 miles of canals in France.

The United States of North America possess upwards of 2500 miles of canals, the whole of which have been constructed within the last thirty years. The principal undertaking of this kind is the Erie Canal, which unites the river Hudson at Albany with Lake Erie at Buffalo, a distance of 363 miles. The Miami Canal, from Cincinnati to Lake Erie, which extends 265 miles, is another great undertaking; and there are a number of other canals scarcely less important for the general traffic of the country. The Rideau Canal in Canada, extending a distance of 160 miles, from the Ottawa (a tributary of the St. Lawrence) to Lake Superior, is a stupendous undertaking, and will ultimately be of great service to the trade of British America.

The canals of Great Britain are believed to extend to an aggregate length of 2400 miles. The greater part are in the midland districts of England, including Lancashire, and have for their object the connection of the large seats of manufacture with the sea on both sides of the island and with the Thames at London. The Grand Trunk Canal, connecting the Mersey with the Trent and Humber, extends 93½ miles. The Birmingham and Worcester connects the Grand Trunk Canal with the Severn. The Grand Junction connects the Grand Trunk with the Thames. Thus, the four great ports of the kingdom, London, Bristol, Liverpool, and Hull, are connected by canals. So generally are these and other canals spread over England, that it is supposed there is not a place south of Durham more than fifteen miles from water communication. The trade on some of the lines of canal, since the introduction of railways, has sunk in an extraordinary degree, greatly to the loss of the proprietors. Ireland has about 300 miles of canals, mostly government undertakings, and in general they possess little trade.

Scotland has a number of canals, but they are chiefly confined to the western and middle district of the country. That which possesses the largest traffic is the Forth and Clyde Canal, reaching from the Clyde, a short way above Dumbarton, to the Forth, at Grangemouth. This canal, which was opened in 1790, and affords a ready communication for small vessels between the east and west coast, extends 39 miles in length; its highest level is 160 feet, with 20 locks on the eastern acclivity and 19 on the western. The canal is connected with Glasgow by a side cut; and it is now joined by the Union Canal, which extends from near its eastern extremity to Edinburgh. This latter canal has proved a poor commercial speculation, but has been of great service to Edinburgh, by introducing coal at a cheap rate to the city, and affording an exceedingly convenient means of conveyance for goods to and from Glasgow. The Caledonian Canal is formed in a great measure by a chain of lakes, stretching across the country from Inverness on the east to Loch Eil on the west coast, a distance of 59½ miles. The canal part is 20 feet deep, 50 feet wide at bottom, and 110 feet at top, which affords a passage to frigates of 32 guns, or merchant vessels of a similar size. This great canal was undertaken as a public work by government; and after a labour of eighteen years was opened in 1822, having then cost £800,000. It possesses 13 locks on the east and 12 locks on the west coast, the highest level being 94 feet. By this canal the dangers of rounding the northern extremity of the island, by the Pentland Firth, may be avoided; but from the prejudices of seamen it has never been much used, and is now abandoned by government to a private company. As a means of allowing steam-boats to run between the Clyde and Inverness, the canal has been of great public service.

CONVEYANCE BY STEAM POWER.



STEAM-BOATS.

Until the year 1807, the only means of communication by sea was by sailing vessels affected by the winds, and on the land by the power of draught in animals, both of which were exceedingly defective. In 1807, Fulton introduced the use of steam-propelled vessels on the Hudson, between New York and Albany. In 1812, Bell introduced a similar mode of steam navigation on the Clyde at Glasgow; and in two or three years afterwards, steam-boats were common on British rivers and on the sea around the coasts. We do not consider it of the least moment to mention how or by whom steam propulsion was first discovered; the merit of this and every other great invention is alone due to the person who brought it into practical use, and in the present instance it is clear that that person was Fulton.

Leaving all account of the *mechanique* of steam power, as applicable to propulsion, to be given in our article on the Steam-Engine, we need here only allude to the extraordinary changes which have been effected upon conveyance by sea and land by this newly applied motive force.

Steam navigation has hitherto been chiefly applied to coasting and voyaging on rivers and estuaries, and in these respects it has greatly altered the system of transit. In 1840 there were in the United Kingdom and colonies 630 steam-vessels, possessing an aggregate burden of 71,000 tons. The rivers on which they principally plied were the Thames, the Mersey, the Clyde, the Forth, the Tyne, and the Severn. The Clyde alone owned 76 steamers, having nearly 8000 tons. Besides those which were devoted to making trips up and down these rivers, a large proportion plied regularly between different coasts in Britain and Ireland, and between different ports and the Thames. From the Thames, also, steamers proceeded to many different ports on the continent. In short, steamers are now found traversing the whole line of coast, steering up and down rivers, and holding communication with ports in distant parts of the globe.

One of the finest lines of large steamers now in operation in Britain is that between Edinburgh and London. it has for several years consisted of from six to eight vessels of about 800 tons each, and these sail regularly twice a week. Formerly, the passage by sailing smacks occupied, on an average, six or seven days, but sometimes it was three weeks; now the voyage by steam is performed with remarkable precision in from 48 to 54 hours, the distance being 400 miles. The lines of steam-packets between Glasgow and Liverpool, Glasgow and Belfast, Liverpool and Dublin, Bristol and Cork, Aberdeen and London, Dundee and London, London and Rotterdam, London and Hull, London and Newcastle, Southampton and Havre, Dover and Calais, are all upon a great scale, and effect an amount of communication for passengers and transit for goods, of which no description of ours could convey any just idea.

The above may, however, be considered only to include those vessels which proceed on voyages of not more than two days' duration. Latterly there have been added steamers which proceed between England and Lisbon, and thence to Madeira; also steamers to India by the Cape of Good Hope; and more lately still, steamers which make the voyage across the Atlantic, and form a means of regular communication between Britain and North America. The Great Western, a steamer of 1340 tons burden, was the first large vessel which plied regularly on this station. This vessel departed from Bristol on the 7th of April, 1838, and reached New York on the 23d of the same month; but the clear days occupied on the passage were only 14. This voyage established the practicability of steam-vessels crossing the Atlantic, and now there are several which sail at regular intervals. Besides crossing from London, Bristol, and Liverpool, to New York, and returning, there is also a line of large steamers which sail between Liverpool and Halifax in Nova Scotia. The largest of the Atlantic steamboats is the British Queen, which measures in entire length 275 feet. Her two engines are of 250 horse power each, and she is calculated to carry 1862 tons. The outward voyage of 18 days of this magnificent steam-vessel requires a consumption of 540 tons of coal, and her homeward voyage of 12 days 360 tons. Larger and more powerful vessels are now in preparation.

On the coasts and rivers of North America, steam navigation has been carried on to a much greater extent than in Great Britain or any other country. In 1834, there were 234 steam-vessels on the Ohio, Mississippi, and other western waters; but now the number is above 500. Some of the American steam-vessels are larger than any in Britain, and also more splendid in decoration; but they are much more liable to accidents, from the employment of steam at a very high pressure, and a general carelessness in the mode of management.

The Rhine, the Seine, the Danube, and other large rivers on the continent of Europe, are now navigated by steam-vessels, chiefly for conveying passengers. The engines used are mostly made in England.

RAILWAYS.

Before the practice of steam navigation had attained that degree of improvement which it now possesses, a not less wonderful mode of travelling by steam power on land had come into use; wherefore, during the first thirty years of the nineteenth century, infinitely greater improvements in the means of locomotion have been discovered and brought into practical operation for the benefit of mankind, than had ever previously been known. To understand and value the application of steam-power to land-travelling, we must advert to the subject of draught on common roads.

There exist three obstacles to the rapid motion of carriages—terrestrial attraction, the atmosphere, and friction. By no human power can the two former be removed: but the latter can be so far modified as to form little or no opposition. On all common roads, no matter how well they may be constructed, there is a certain degree of roughness which it is impossible to remove, and this causes so great a friction, that to overcome it much of the drawing power is consumed without advancing the carriage. On some roads, the plan of laying down continuous lines or *tramways* of smooth pavement for the wheels to roll over, has been resorted to, but has never been found generally answerable, not only in consequence of the great expense of construction, but because drivers will not take the trouble to keep their vehicles upon it.

The draught of a horse upon a macadamized road may be estimated at fifteen hundredweight, walking at an ordinary pace and for several hours continuously. Particularly strong horses may habitually draw twenty or twenty-two hundredweight, but to cause them to pull to that amount is not economical. Allowing, however, that all horses can draw a ton weight, that is a small amount of draught in relation to great purposes of commerce; and the speed at which the fleetest horse can travel, when drawing a weight after it, though perhaps ten miles an hour, is unsuitable for the rapid transit of passengers on long journeys. To drag a mail-coach from London to Edinburgh, a distance of about 400 miles, in 43 hours, which was reckoned a good speed, it was necessary to employ four horses, and to change these every eight miles on an average; thus 200 horses were required for the performance of the whole journey. Having attained this rate of locomotion by improvements on roads, carriages, and in the breed of horses, nothing more could be done. Something new required to be devised.

The idea of employing steam-power to drag carriages over common roads, and thus save a large outlay for horses, besides accomplishing a greater speed, was suggested by various enterprising minds, but to its practical application there were and are many serious objections. Independently of the ordinary and unavoidable roughness of common roads, all highways are less or more uneven, because to construct them upon a perfect level throughout would be attended with an expense which the tolls from no traffic could sustain. The general unevenness of roads, therefore, causes a great loss of drawing power. In these circumstances, it is evident that, for the avoidance of friction and economizing of forces, an entirely new species of road required to be contrived. This important desideratum is found in the invention of *railways*. The design of a railway is to furnish a hard, smooth, and unchanging surface for wheels to roll upon. No provision, as respects smoothness, is required for any part of the path, except the narrow lines which are immediately to come under the rim of the wheels. Accordingly, it is sufficient to provide two rows or lines of strong and straight iron rails, that is, long slips of iron about an inch in thickness, and four or six inches deep. These rails, laid in two parallel lines, to suit the width of a carriage, are raised a little above the general level of the ground, being placed neatly end to end, and secured by fastenings to blocks of wood or stone at short intervals. Such is the very simple contrivance of a railway, or *chemin de fer* (road of iron), as it is called by our French neighbours. By the establishment of railways, a way was opened for the adaptation of steam power to locomotion, and now, as is well known, this has come generally into use.

The earliest railway of which there is any account was one constructed near Newcastle-upon-Tyne. In Roger North's Life of Lord Keeper North, he says that at this place, in 1676, the coals were conveyed from the mines to the banks of the river, "by laying rails of timber exactly straight and parallel; and bulky carts were made with four rollers fitting those rails, whereby the carriage was made so easy, that one horse could draw four or five chaldrons of coal." One hundred years afterwards, about 1776, Mr. Curr constructed an iron railroad at the Sheffield colliery. The rails were supported by wooden sleepers, to which they were nailed. In 1797, Mr. Barnes adopted stone supports in a railroad leading from the Lawson main colliery to the Tyne, near Newcastle; and in 1800, Mr. Outram made use of them in a railroad at Little Eaton in Derbyshire. Twenty-five years afterwards, this species of road was successfully adopted on a public thoroughfare for the transportation of merchandise and passengers, namely, the Stockton and Darlington railway, which was completed in 1825, and was the first on which this experiment was made with success. From that time, accordingly, a new era commenced in the history of inland conveyance.

It is a remarkable circumstance, that the early practisers of railway conveyance could not imagine that a carriage, moved by steam-power, could proceed along rails without the aid of toothed wheels and a rack; and to overcome this imaginary difficulty, no small degree of expense and labour was fruitlessly incurred. About the year 1815, Mr. Blackett, of Wylam, near Newcastle, effectually proved, by repeated experiments, that the adhesive power of the wheels on the rails was at all times sufficient to cause a progressive motion in an engine, with a train of loaded carriages, upon a railway either level or with a small acclivity. Important as was this discovery, fifteen years elapsed before steam locomotives were established. This great triumph of art occurred in connection with the opening of the Liverpool and Manchester railway, on the 15th of September, 1830, since which period railways have spread to all populous parts of the country.

Simple as is the idea of a railway, a prodigious expense is necessarily incurred in bringing it into practical operation. All inequalities of surface in the ground must be removed, low parts must be filled up by embankments, high parts must be reduced, eminences, which it would be impolitic to level, must be perforated by tunnels—the whole route being brought as nearly as possible to a level. Besides, the land over which it is to proceed must be purchased, frequently at an exorbitant cost; and the preliminary expense of overcoming petty opposition and securing an act of parliament to establish the line, sometimes amounts to as much as £2000 per mile. An entire charge of £30,000 per mile is considered a moderate outlay in the construction of railways in Britain.

No long line of railway that has yet been formed is perfectly level throughout, but the acclivity is seldom more than one foot per mile, and this does not produce any retardation, which it would be absolutely necessary to obviate by an excess of expenditure. Every line, also, is curved, or bent from a truly straight direction, at various places in its course; and this is another evil which it is necessary to tolerate to a certain extent, rather than avoid by uneconomical outlay. For the reasons now stated, nearly all railways are neither perfectly straight nor perfectly level; and so far as such is the case, there is loss of power in drawing vehicles along them. Yet, in the most disadvantageous known circumstances, the railways are so comparatively smooth and suitable for transit, that they allow the nearest approach to a total absence of friction. It is deserving of notice, that the absence of friction in railroads is advantageous not only in the saving of power, but the saving of painful sensations to the traveller. The suffering usually endured in ordinary modes of land-conveyance is that which chiefly arises from *friction*. Friction is the grand evil to be overcome. Were friction altogether removed, we should feel no sensation in moving; as, for example, we experience no sensation of motion in being carried along with the earth in its ceaseless rotations, although proceeding at an inconceivable velocity. It may be argued from these premises, that no one need fear to be carried at any rate of speed—even a hundred miles an hour—provided the motion be perfectly smooth or free from friction, and that there is a protection from the atmosphere. Practically, in locomotion upon railways, a degree of friction is required between the wheels and the rails, to cause adhesion, and this is accomplished by the ordinary roughness of the iron.

Rails.—The experience of ten years has introduced a few improvements in the construction and management of railroad. At first, malleable iron rails were considered to be preferable to those of cast-metal; but now it is understood that cast rails, if properly made, will endure all the tear and wear to which they can be fairly subjected. To be of the strongest and best form, each individual rail should be at least twelve feet in length, four inches in depth at the two ends, and thence gradually swelling beneath in the fish-belly form to the centre. The thickness should be fully one inch, and the upper surface, on which the wheel is to run, should be an inch and three-quarters or two inches, so as to project laterally like the cross top of the letter T. The rails are to be supported at their joint extremities, where they are pinned together, and also at intervals of every three feet. The supporters should consist of transverse bars of wood, sunk in the ground; by being thus crossing from the one track to the other, both lines of rail are kept from separating or shifting, and if there is any tendency to subside, both are equally lowered. On many lines of railroad stone sleepers are preferred to wood, but, as it seems with no adequate advantage. Stone sleepers present too unyielding a base to the rolling of the wheels, and cause a jolting most injurious to the mechanism of the carriages. In several instances, lines with stone sleepers have been taken up, and wood substituted. The railways in Belgium are laid on wood. To attain the highest perfection in the mode of laying rails, a plan has been followed on the Newcastle and Shields line, and also on that of the Great Western between London and Bristol, of placing rails having an even under side upon longitudinal beams of timber, which are united at certain intervals by transverse bars: thus the whole substructure is a handsome framework laid on the ground, and presents the best species of support. In general, this will be found too expensive a kind of railway; and it may be anticipated that the method of fixing rails upon cross-bars of wood, at intervals of three feet, will ultimately come into universal use.

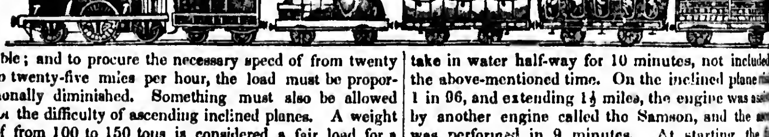
Turn-outs.—If all the wagons upon a railroad, whether for the transportation of passengers or merchandise, were to travel at the same time, and at the same speed, two sets of tracks would be sufficient to accommodate the whole, as there would be no necessity of their turning out to pass each other. But in the transportation of passengers, greater speed is desirable than in the transportation of merchandise; for the transportation of merchandise, whether by horse-power or steam-power, can be done more economically, and with less injury to the road, at a low than a very high rate of speed. It is, therefore, a very considerable object, in railroads upon lines of public travel, to allow wagons to pass others travelling in the same direction. Provision must be made, accordingly, for turning out. This provision is particularly necessary in case of a road with a single set of tracks, on which the carriages must meet. These turn-outs are made by means of a movable or switch-rail at the angle where the turn-out track branches from the main one. This rail is two or three feet, more or less, in length, and one end may be moved over that angle, and laid so as to form a part of the main track, or the turn-out track. The switch-rail is usually moved by the hand, so as to form a part of that track on which the wagon is to move.

Carriages—Wheels.—The principal consideration, in regard to the construction of carriages, relates to their bearings on the axle and the rim of the wheel. The rule given by Mr. Wood, as to the bearing on the axle, is, that in order to produce the least friction, the breadth of the bearing should be equal to the diameter of the axle at the place of bearing. This diameter must be determined by the weight to be carried; and the breadth of the bearing will accordingly vary with it. In order to keep the wheels fairly on the rails, they are furnished with thin edges which dip on the outside; these *flanges* are about an inch and a half in depth. The mid-wheels of locomotives are now made without flanges, but the fore and hind pair require flanges of rather more than usual depth. Wheels of large diameter move with greater ease over the rails than those which are small, because the large ones, in this as in all similar cases, have more power in overcoming obstacles. Yet there is a proper medium in the dimensions of wheels. Large wheels are inconvenient in point of height, and are apt to produce a rocking motion. It would appear that the most suitable diameter for the wagon or carriage wheels is from two and a half to three feet, which is the usual size. The wheels of the locomotive have a diameter of about four feet; to make them broader is considered injudicious.

Curvatures in the Road.—The curvatures of the railroad present some obstructions, since the axles of the car and wagons being usually fixed firmly to the frames, every bend of the tracks must evidently cause some lateral rubbing, or pressure of the wheels upon the rails, which will occasion an increased friction. If the wheels are fixed to the axles, so that both must revolve together, according to the mode of construction hitherto most usually adopted in passing a curve, the wheel that moves on the outside or longest rail must be slided over whatever distance it exceeds the length of the other rail, in case both wheels roll on rims of the same diameter. This is an obstruction presented by almost every railroad, since it is rarely practicable to make such a road straight. The smallest curvature that is allowable should not be less than a radius of 300 feet. In going round a height, the radius should on no account be so small as this, in order that the engine drivers may have a clear look-out ahead, and so prevent collisions and overtakings on the road.

Inclined Planes.—Where the inclination of the road is greater than that for which the ordinary power is calculated, the ascent must be effected by means of an additional power, the amount of which can be readily computed, since in those parts no additional friction of the cars or wheels is to be provided for, and only the additional resistance arising from gravity is to be overcome. If, for instance, the additional inclination is one in ninety-six, or fifty-five feet in a mile, the additional power must be to the weight as one to ninety-six, or as fifty-five to the number of feet in a mile, namely, 5280. In descending planes, so much inclined that the gravity would move the carriages too rapidly for safety, the velocity is checked by means of a break, which consists of a piece of wood of the same curvature as the rim of a set of the wheels, upon which the break is pressed by means of a lever, so adjusted as to be within reach of the conductor, in his position on the carriage.

Locomotive Engines.—Within the last few years, very considerable improvements have been made in the construction of the locomotives by which the draught of the trains of carriages is effected. Originally the locomotive was placed upon four wheels, the two front ones being smaller than those behind. Now, six wheels are employed, the front and hind pair being smaller than those in the middle, these middle ones being the wheels upon which, by the action of cranks from the engine, the whole mass is propelled. As may be seen by the small annexed engraving, which represents a railway train, the locomotive consists of a long iron barrel or cylinder supported by six wheels, with a chimney rising in front, and affording standing space behind for the engineer who conducts and regulates the machine. It is unnecessary to confuse the mind of the unscientific reader with a minute account of this wonderful apparatus; it will suffice to say, that the end of the barrel-like object next the engineer, consists of a furnace or fire-box, and the heat generated in it by the consumption of coke, is conducted thence through a great number of tubes in the cylinder, and finally escapes at the chimney. The cylinder in which the water is boiled and steam generated, is sheltered from the external air by a case; and by receiving the action of heat from so many tubes passing through it, the steam is rapidly generated for the use of the engine. The engine lies horizontally beneath the chimney, and in such a position as to permit the working of the piston upon the crank of the axle of the middle set of wheels. By means of lever handles affecting the mechanism, the engineer can at pleasure produce or stop the motion, as effectually and much more readily than a coach-driver could set off or arrest the progress of his horses. Immediately behind the locomotive is a carriage called the tender, which is loaded with a supply of fuel and a tank round its sides containing water. The weight of a locomotive, supplied with its proper quantity of water and fuel, is about twelve tons. The tender, when filled with water and fuel, weighs seven tons: it can carry 700 gallons of water, and eight hundredweight of coke forms a sufficient supply for a trip of from thirty to forty miles with an ordinary load. The cost of a locomotive is about £1700, and it seldom wears longer than two years without undergoing a very extensive repair. On the Great Western Railway, which is of unusual breadth of track, the locomotives are much larger and more powerful. Ordinary locomotives evaporate seventy-seven cubic feet of water per hour, but those on the Great Western evaporate about 200 cubic feet. It is calculated that the evaporation of one cubic foot per hour, produces a great mechanical force of nearly two horse power; consequently, to ascertain the power of a locomotive, we must multiply by two the number of cubic feet which it evaporates per hour. In common circumstances, an ordinary sized locomotive exerts a power of 150 horses, and larger one exerts a power of 400 horses. To estimate this degree of force, it is necessary to recollect that a horse upon a common road cannot draw for any length of time more than fifteen hundredweight, while on a railway it will pull with equal ease ten tons, being thirteen times the amount. We may now, therefore, compute that the power of a locomotive, such as is usually employed, is equal to a draught of 1500 tons. With the weight to drag, however, only a slow motion is obtainable; and to procure the necessary speed of from twenty to twenty-five miles per hour, the load must be proportionally diminished. Something must also be allowed for the difficulty of ascending inclined planes. A weight of from 100 to 150 tons is considered a fair load for a locomotive to draw; but it is seldom more than sixty to seventy tons. The following experiments on the power of draught were made by Dr. Lardner on the Liverpool and Manchester Railway in 1832:—



"On Saturday, the 5th of May, the engine called the Victory took 20 wagons of merchandise, weighing gross 92 tons, 19 cwt., 1 qr., together with the tender containing fuel and water, of the weight of which I have no account, from Liverpool to Manchester (30 miles), in 1 hour, 34 minutes, 45 seconds. The train stopped to take in water half-way for 10 minutes, not included in the above-mentioned time. On the inclined plane rising 1 in 96, and extending 1½ miles, the engine was assisted by another engine called the Samson, and the ascent was performed in 9 minutes. At starting, the fire-place was welled with coke, and the coke supplied to the tender accurately weighed. On arriving at Manchester, the fire-place was again filled, and the coke remaining in the tender weighed. The consumption was found to amount to 929 pounds net weight, being at the rate of one-third of a pound per ton per mile. Speed on the level was eighteen miles an hour; on a fall of 4 feet in a mile, 21½ miles an hour; fall of 6 feet in a mile, 25½ miles an hour; on the rise over Chat Moss, 8 feet in a mile, 17⅞ miles an hour; on ground sheltered from the wind, 20 miles an hour. The wind was moderate; but direct ahead. The working wheels slipped three times on Chatmoss, and the train was retarded from two to three minutes. The engine, on this occasion, was not examined before or after the journey, but was presumed to be in good working order.

"On the 29th of May, the engine called the Samson (weighing 10 tons 2 cwt., with 14 inch cylinders, and 16 inch stroke; wheels 4 feet 6 inches diameter, both pairs being worked by the engine; steam 50 lbs. pressure, 130 tubes) was attached to 50 wagons laden with merchandise; net weight about 150 tons; gross weight, including wagons, 223 tons 6 cwt. The tender weighed 7 tons, making a gross load (including the engine) of 240 tons 3 cwt. The engine with this load travelled from Liverpool to Manchester (30 miles) in 2 hours and 40 minutes, exclusive of delays upon the road for watering, &c.: being at the rate of nearly 12 miles an hour. The speed varied according to the inclinations of the road. Upon a level, it was 12 miles an hour; upon a descent of 6 feet in a mile, it was 16 miles an hour; upon a rise of 8 feet in a mile, it was about 9 miles an hour. The weather was calm, the rails very wet; but the wheels did not slip, even in the slowest speed, except at starting, the rails being at that place soiled and greasy with the slime and dirt to which they are always exposed at the stations. The coke consumed in this journey, exclusive of what was raised in getting up the steam, was 1762 lbs., being at the rate of a quarter of a pound per ton per mile."

General Appearance and Management.—In America and Belgium, most lines consist of but one track; in Great Britain all possess two tracks, suitable for trains going in opposite directions, besides which there are turn-offs at which quick-going trains may pass those of slower motion. At certain convenient points along the line there are station-houses, at which the trains stop to take up and set down passengers, and there is no stoppage at any other place. On most of the lines there are slow trains, taking goods and second-class, or an inferior kind of carriages, and fast trains, taking only first and second-class carriages; some lines also have mail trains, which proceed at more than usual speed, and taking only first-class carriages, stop at fewer places by the way. The first-class carriages are covered, and resemble three coach bodies united, but of more commodious dimensions; second-class carriages are open at the sides, and not lined with any stuffing; third-class carriages are entirely open; goods carriages are open trucks, on which the articles are piled and fastened; trucks for cattle are open with a railing round the sides. All the carriages in a train are linked one to the other by strong iron hooks; and to prevent them from shocks against each other, the various carriages are provided with projecting rods on springs, cushioned at the outer extremities. Generally, the fares charged for transmission are higher than they need be; a common charge is at the rate of 3d. per mile for each passenger in a first-class carriage; and it is understood that lower rates would create more than a compensatory amount of traffic.

There are certain excellences in the arrangements of the railways which deserve to be mentioned. Each line, being the property of a private association, is secluded from one end to the other from the intrusion of the public; and therefore no jostling or confusion takes place, either upon entering or leaving the carriages. The rails of one line, likewise, join those of another, by which means carriages generally proceed onwards without changing passengers or luggage. A carriage in which passengers take their seats at London goes straight to Preston—that is, along the lines of three companies. The extraordinary magnitude of the railway undertakings has enabled the directors to organize rules which could never be enforced in the irregular scramb of stage-coaching. It is customary to dress the subordinate functionaries on all the lines in a uniform resembling that of the London police—each man having his number inscribed in figures on some part of his dress; so that, if any one be guilty of incivility or inattention, he can be easily reported to his superior. There is one pleasing peculiarity in the arrangements, which is entitled to the highest commendation: it is the rule that no officer shall on any account take a fee from passengers, on pain of instant dismissal. Those who imagine that fees to guards, coachmen, or waiters, are requisite to ensure civility, will be surprised to find that railway attendants are infinitely more polite and attentive than their brethren of the coach conveyances. This, in itself, gives travelling by railway a great superiority over all other modes of public conveyance.

The London and Birmingham line, which was the first completed after that of Manchester and Liverpool, has always appeared to us to be among the best managed of the various railways, as well as the most complete in all its arrangements. There are accommodations on this line which are to be seen on no other. On all the lines there are waiting-rooms both for ladies and gentlemen at the different stations; but exclusively of those on this line, there is a large and commodious house of entertainment at the Birmingham terminus, where meals stand ready prepared for the passengers. At Wolverton, a place half way from the metropolis, and where the train stops ten minutes, there is likewise a large establishment in the form of an open booth or shop where tea, coffee, or viands of a more substantial kind, with different liquors, are sold on the instant to those who require refreshment.

Passengers who make the journey for the first time by the mail-train, will be amused by observing a travelling post-office in the string of carriages. This "Grand Northern Railway Post-Office," as the inscription on its side denotes, is a carriage consisting of two small apartments, one of which is appropriated to the guard, whose duty is to exchange the bags, and the other is fitted up with a table for sorting letters, and holes round the walls for their reception. The manner in which the duties of the clerk and guard are performed in this flying-office, is strikingly significant of the new order of things introduced by the railway system. Outside the vehicle a species of net is extended by a hoop, and into this the letter-bags are dropped as the train sweeps onward in its course, the bags which are to be left being at the same time tossed from the window by the guard. The fresh bag of letters being received, it is speedily opened, its contents re-arranged, and a new bag for next town being made up, it is projected as before at the place of its destination. By this means a letter may be written, sent through the post-office, and delivered at the distance of twenty miles, in the space of a single hour.

The number of railway companies incorporated by act of parliament up till January 1839, in Great Britain and Ireland, was 107, and the capital which they were allowed to raise by shares was £41,610,814; they were besides allowed to raise by loan £16,177,630. A considerable number of these railways being jobbing, or at least crude speculations, have never commenced, and the number of railways actually begun to be prepared or finished at the beginning of 1840, in the united kingdom, was only about fifty. The principal lines are—the Liverpool and Manchester Railway, about thirty two miles long, and uniting these populous towns; the London and Birmingham Railway, about one hundred and twelve miles long, connecting the metropolis with the centre of England; the Grand Junction Railway, continuing the London and Birmingham line to that of Liverpool and Manchester, and also to a

Entrance to the Railway Tunnel, Liverpool.

railway proceeding northward to Lancaster, and thus forming a most important thoroughfare obliquely across the country; the Midland Counties, North Midland, and Great North of England railways, connecting the great seats of trade in Northumberland, Durham, Yorkshire, and Derbyshire, with the London and Birmingham line; the New Castle and Carlisle Railway, connecting these towns; the Great Western Railway, about one hundred and seventeen miles long, connecting London with Bristol, and with smaller tributary lines opening up the west of England; the South-Western Railway, about seventy-seven miles long, connecting London with Southampton; the Manchester and Leeds Railway, connecting these populous towns. In Scotland, the Edinburgh and Glasgow Railway, and the Glasgow and Ayr Railway, are the principal lines. The greatest of the whole of these undertakings is the Grand Western. This line has two tracks, each of seven feet wide, while on all other railways in this country the width is between four and five feet; the carriages, therefore, which run on the Grand Western, must be necessarily confined to itself. The most prosperous of all the lines is that of the London and Birmingham, the weekly revenue of which is upwards of £16,000: the weekly revenue of the Grand Junction, which joins it, is £9000.

The speed at which railway trains usually proceed is from twenty to twenty-five miles per hour, though sometimes it is much more. At the ordinary rate of speed, a journey from London to Liverpool by the mail train is performed in about nine hours; and when railways are extended north to Edinburgh, the journey from London to that city will be performed in eighteen hours, or perhaps less. Travelling by railway at any of the common rates of speed is attended with less personal danger than stage-coaching, because the locomotives are perfectly under control. Any deaths or personal injuries which have occurred on railways, are, with scarcely an exception, attributable to the carelessness of the engine-drivers, and by the employment of a superior class of men to direct the motions of the trains this fruitful cause of mischief is in the course of being obviated. With this improvement, conveyance by railways will be ranked among the most useful and stupendous inventions of art.

[RECENT OPERATIONS IN RAILWAYS.

Since the first publication of the preceding article, the subject of transportation and travelling by railways has received increased attention in Great Britain and on the continent of Europe, especially in France. Like all other subjects which are discussed in countries possessing an active and widely diffused system of newspapers, it attracted the universal attention of the trading and business community; and speedily led to an extensive system of speculations. An immense number of companies were formed and routes were surveyed and laid out for railways in every part of the United Kingdom. Parliament was beset with innumerable applications for charters; and the whole trading community became infected with the rage for speculation in railway shares. The same scene was exhibited in France and Belgium on a smaller scale. At length certain statistical calculations were made and published, by which it became apparent that more capital would be required to complete all these railways within the time proposed than could possibly be raised for the purpose; and that the amount of travelling required to enable the companies to pay their current expenses and the interest on the capital invested, was much greater than could ever become necessary;—in short, that the greater number of the projected railways would ultimately turn out a dead loss. The consequence was, as usual in such cases, a general explosion of these schemes, and the ruin of the large holders of stock. Nevertheless, a considerable number of railways, which had been judiciously planned and were sustained by heavy capitalists, are either completed or in a course of completion.

In the United States, many extended and useful railways have been completed within a few years. The most important and profitable of these is the Great Western Railroad from Boston to Albany, which by opening a direct communication between New England and the Western States, has wonderfully benefited the manufactures and trade of New England, and especially of its capital, Boston. A similar undertaking with reference to Philadelphia is now proposed, the Central Railroad from Philadelphia to Pittsburg; and its completion is expected to prove of immense importance to the industry and trade of Philadelphia.

In every part of the United States the railway system is making steady and rapid progress, thereby increasing the facilities for internal commerce and national defence.—*Am. Ed.*]

NATURAL PHILOSOPHY.

Natural Philosophy is a term of wide import, and has a reference to all those branches of physical science which treat of existing substances, their motions, their mutual connection, and their influence on each other. In this enlarged sense it may be considered as embracing astronomy, mathematics, dynamics, hydrostatics, geology, chemistry, optics, botany, in short, a vast range of human knowledge, which for the sake of convenience is usually divided into distinct branches of science. In its more limited and ordinary meaning, the term applies only to inorganic substances, and the laws which regulate their connection with each other, but without alteration of character; and it is this most important branch of knowledge, which in reality is the basis of all others, of which we now propose treating. We shall commence with an explicit definition of the meaning of the term *substances* or *matter*, it being necessary that this be clearly understood.

MATTER AND ITS PROPERTIES.

Matter—or that of which all bodies are composed whose existence is made known to us by means of the senses or by the test of philosophic experiment—is possessed of various properties, some of which are essential to its existence, while others are only accidental or contingent. The essential properties of matter are Impenetrability, Extension, Figure, Divisibility, Inertia, and Attraction.

Impenetrability is that quality of bodies, in virtue of which each occupies a certain portion of space, and excludes other bodies from existing in the same place at the same instant. In the usual sense, we call any hard body, such as a stone, impenetrable, because it firmly resists our efforts to pierce it. But as it is understood philosophically (although we can condense, pierce, and remove the greater number of them), all bodies are alike impenetrable, because they equally possess the property of excluding other substances from the spaces which they occupy. This, in fact, is saying no more than that two things cannot be in the same place at once, which is a self-evident truth, whether we apply it to a single particle of matter or a large mass.

Every body, or portion or particle of matter, possesses a certain extension or magnitude. It is impossible to form a conception of matter, however minute may be the article, without connecting with it the idea of its having certain bulk, and filling a certain extent of space. In common phraseology, we express this property of bodies by the word *size* or *volume*.

The next property demanding our attention is the *figure* of bodies. Figure or form is the result of extension, for we cannot have the idea of a body possessing length and breadth, without its having some kind of figure, however irregular. The volume of a body has no relation to its figure. Bodies which have the same figure may possess very different volumes; and bodies may have the same volume, but possess very different figures. Thus, two masses of matter may have the same volume, although the one be round and the other be square.

Matter is divisible into parts, and these parts may again be subdivided into other parts. By this is meant *divisibility* or separability. To the practical subdivision of matter there seems to be no assignable limit; and many of the instances of it which may be found in philosophical investigations almost exceed credibility. The thinnest part of a soap-bubble, which is a thin shell of water and the matter of soap, does not exceed in thickness the 2,500,000 part of an inch. The useful arts, also, furnish many striking examples; but it is in the organized world that the most astonishing proofs of the extreme divisibility of globules, or particles of matter, are to be found.

Animalcules—that is, animals which are so small as to be invisible to the naked eye, and which, by means of microscopes, are seen floating in water—are in some cases so minute, that it would require a million of them to form the bulk of a grain of sand. As these animalcules possess, in every case, a perfect organization to enable them to perform all the functions of life, the smallness of their different parts, and the extreme minuteness of the particles of matter which compose them, are too exquisite to be made the subject of calculation: the imagination is lost in the contemplation of their wonderful economy. The effluvium or odour which excites the sensation of *smell*, consists of an incalculable number of particles of matter floating in the atmosphere, and so minute as to be altogether invisible to the eye. These particles are not more remarkable for their inconceivably small size than for the length of time which they will remain in suspension in the atmosphere, or in connection with some particular place. The effluvium given forth by a single grain of musk has been known to perfume a large apartment for twenty years, and yet at the expiry of that period there was no sensible diminution of the little mass of matter from which the smell had proceeded.

The diffusion of particles of matter invisible to the naked eye, is also obvious in the case of the melting of a piece of sugar in our tea; the solid mass of the sugar disappears, and the particles of which it was composed are diffused in the liquid. There is a similar diffusion of particles of salt in the ocean. When we look through a glass full of sea water, we perceive that it is pure and limpid; but if we pour the water into a vessel on the fire, and boil it, we shall at length discover that, while the liquid has escaped in the form of vapour, the particles of salt it held in solution remain incrusted on the vessel.

Particles of matter are never destroyed or lost, although they may disappear from our immediate observation Under certain circumstances, the particles may again be collected into a body without change of form. Mercury, water, and many other substances, may be converted into vapour, or distilled in close vessels, without any of their particles being lost. In such cases, there is no decomposition of the substances, but only a change of form by the heat; and hence the mercury and water assume their original state again on cooling. When bodies suffer decomposition or decay, their elementary particles, in like manner, are neither destroyed nor lost, but only enter into new arrangements or combinations with other bodies. When a piece of wood is heated in a close vessel, such as a retort, we obtain water, an acid, several kinds of gas, and there remains a black, porous substance, called charcoal. The wood is thus decomposed, or destroyed, and its particles take a new arrangement, and assume new forms; but that nothing is lost is proved by the fact, that if the water, acid, gases, and charcoal, be collected and weighed, they will be found exactly as heavy as the wood was, before distillation. In the same manner, the substance of the coal burnt in our fires is not annihilated; it is only dispersed in the form of smoke, or particles of culm, gas, and ashes or dust. Bones, flesh, or any animal substance, may in the same manner be made to assume new forms, without losing a particle of the matter which they originally contained. The decay of animal or vegetable bodies in the open air, or in the ground, is only a process by which the particles of which they were composed change their places and assume new forms.

The decay and decomposition of animals and vegetables beneath the surface of the earth, fertilize the soil, which nourishes the growth of plants and other vegetables; and these, in their turn, form the nutriment of animals. Thus is there a perpetual change from death to life, and from life to death, and as constant a succession in the forms and places which the particles of matter assume. Nothing is lost, and not a particle of matter is struck out of existence. The same matter of which every living animal and every vegetable was formed in the earliest ages, is still in existence. As nothing is lost or annihilated, so it is probable that nothing has been added, and that we ourselves are composed of particles of matter as old as the creation. In time, we must in our turn suffer decomposition, as all forms have done before us, and thus resign the matter of which we are composed, to form new existences.

Inertia means passiveness or inactivity. Thus, matter is perfectly passive in submitting to any condition in which it is placed, whether of rest or motion. When at rest, it shows an inability or reluctancy to move; and when in motion, it shows an equal inability or reluctancy to come to a state of rest. It is obvious that a rock on the surface of the earth never changes its position in respect to other things on the earth. It has of itself no power to move, and would therefore for ever lie still, unless moved by some external force. Now, it is just as true that inert matter has no power to bring itself to rest when once put in motion, as that it cannot put itself in motion when at rest; for having no life, it is perfectly passive both to motion and rest, and therefore either state depends entirely upon external circumstances.

Many instances might be given of the tendency which matter has to remain in the condition in which it happens to have been already placed. The following are among the most instructive:—When the sails of a ship are loosened to the breeze, slowly and heavily at first the vessel gets into motion, but gradually its speed increases, as the force by which it is impelled overcomes the inertia of its mass. A great force is necessary at first to set a vehicle in motion; but when once this is effected, it goes onward with comparative ease, so that, in fact, a strong effort is necessary before it can be stopped. If a person be standing in it when it is suddenly set a going, his feet are pulled forward, whilst his body, obeying the law of inertia, remains where it was, and he accordingly falls backwards. On the other hand, if the vehicle be suddenly stopped, and the individual be standing in the same position as formerly, the tendency which his body has to move forward—for it acquired the same motion as the carriage by which it was borne along—will cause him to fall in the opposite direction.

The following is a familiar example of the inertia of matter:—Upon the tip of the finger let a card be balanced, and a piece of money—say a shilling—laid upon it. Let the card then be smartly struck, and it will fly from beneath the coin, leaving it supported upon the finger. This arises from the inertia of the metal being greater than the friction of the card which passes from beneath it.

Coursing, or hare-hunting, affords a striking illustration of inertia. In that field sport, the hare seems to possess an instinctive consciousness of the existence of this law of matter. When pursued by the greyhound, it does not run in a straight line to the cover, but in a zigzag one. It *doubles*, that is, suddenly changes the direction of its course, and turns back at an acute angle with the direction in which it had been running. The greyhound, being unprepared to make the turn, and therefore unable to resist the tendency to persevere in the rapid motion which it has acquired, is impelled a considerable distance forward before it can check its speed and return to the pursuit. But, in the mean time, the hare has been enabled to shoot far ahead in the other direction; and although a hare is much less fleet than a greyhound, by this scientific manœuvring it often escapes its pursuer. Those who have witnessed horse-racing, may have observed that the horses shoot far past the winning-post before their speed can be arrested. This is also owing to the inertia of their bodies.

We have now arrived at a most important property, *attraction*, which it is desirable should be carefully studied. It is a fundamental law of nature, ascertained by Sir Isaac Newton, that every atom or particle of matter has a tendency to approach or to be attracted towards another atom or particle. This forms one of the leading principles in modern natural philosophy. Experience and observation demonstrate that this power of mutual attraction pervades all material things, and, though unseen except in its results, is ever present with us—is the cause of particles of matter adhering to each other, and forming solid masses—of these masses assuming in many instances a round or globular form—of the falling of bodies to, and their stability on, the earth—and is one of the causes of the whole of the planetary bodies moving in their paths in the heavens.

Attraction is of different kinds, although some of these may be merely modifications of others, and has received different names according to the circumstances under which it acts. The force which keeps the particles of matter together, to form bodies, or masses, is called *attraction of cohesion*. That which inclines different masses towards each other, is called *gravitation*, or *attraction of gravitation*. That which causes liquids to rise in tubes, or in very confined situations, is called *capillary attraction*. That which forces the particles of different kinds of matter to unite, is called *chemical attraction*. That which causes the magnetic needle to point constantly towards the poles of the earth, is *magnetic attraction*. And that which is excited by friction in certain substances, is known by the name of *electrical attraction*.

Attraction of cohesion acts only at insensible distances, as when the particles of bodies apparently touch each other. This kind of attraction may be described as the quality in nature which causes matter to cohere or stick together. It is much stronger in some bodies than in others. It is stronger in the metals than in most other substances, and in some of the metals it is stronger than in others. In general, it is most powerful among the particles of solid bodies, weaker among those of fluids, and least of all, or almost entirely wanting, among elastic fluids, such as air and the gases. Thus, a small iron wire will hold a suspended weight of many pounds, without having its particles separated; the particles of water are divided by a very small force, while those of air are still more easily moved among each other. These different properties depend on the force of cohesion with which the several particles of these bodies are united.

When the particles of a body can be suspended in the air in a fluid state, they will, if not under the attractive influence of some other body, arrange themselves, by virtue of the same law, around a centre, and take a spherical or round form. Thus, a small quantity of dew suspended on the point of a thorn or leaf, becomes a globule, because in that case the attraction of the particles towards their own centre is greater than the attraction of any neighbouring body. Tears running down the cheeks, drops of rain, and hail are all examples of this tendency in insulated fluid bodies to assume the globular form. When two perfect globules of mercury are brought into contact, they instantly unite together, and form one spherical drop. The manufacture of shot is also a striking illustration. The lead is melted and poured into a sieve, at the height of about two hundred feet from the ground. Each stream of lead, immediately after leaving the sieve, separates into little globules, which, before they reach the ground, are cooled and become solid: thus is formed the shot used by sportsmen. To account for the globular form in all these cases, we have only to consider that the particles of matter are mutually attracted towards a common centre, and in liquids, being free to move, they arrange themselves accordingly. In consequence of this law of nature, it is considered probable that the planetary bodies, including our earth, were originally in a fluid state—that, in that state, they unavoidably assume a spherical form, and were then hardened into their present consistency.

The force by which small tubes, or porous substances, raise liquids above their levels, is called capillary attraction, from *capilla*, the Latin word for a hair. In a wet tea-cup, or other vessel containing liquid, you may perceive the liquid at the sides rising above the level of that of the other parts of the surface; this is caused by attraction. If two glass plates be brought very near each other, so as to stand parallel with their flat sides in almost mutual contact, and then their lower end be dipped into a vessel of water, the fluid will rise up between the plates, and the height to which it rises will be greater the nearer the plates are to each other. The water rises very little on the outsides of the plates, for this attraction is insensible at even moderately small distances. If a glass tube, with an exceedingly small or capillary bore, be dipped in water, the fluid will rise in the interior of the tube; and the smaller the bore, the higher does the water ascend.

A great variety of porous substances are capable of this kind of attraction. If a piece of sponge or a lump of sugar be placed, so that its lowest corner touches the water, the fluid will rise up and wet the whole mass. In the same manner, the wick of a lamp will carry up the oil to supply the flame, though the flame is several inches above the level of the oil. If the end of a towel happens to be left in a basin of water, it will empty the basin of its contents; and, on the same principle, when a dry wedge of wood is driven into the crevice of a rock, and afterwards moistened with water, as when the rain falls upon it, it will absorb the water, swell, and sometimes split the rock.

It is this kind of attraction which is supposed to be one of the causes of springs of water in the earth. The water creeps up by capillary attraction through porous beds of sand, small stones, and crevices of rocks, and in this manner reaches the surface even at great heights. The lower parts of the walls, and also the earthen floors of cottages, are in the same manner apt to become damp, by the attraction of the moisture upwards from the ground. Hence the necessity for clearing away all wet earthy matter from the foundations of houses.

Besides these varieties of attraction, there are, as already said, chemical, magnetic, and electric attraction, but as these are respectively alluded to under the heads Chemistry and Electricity in the present series of treatises, they do not require particular notice here, and we proceed to consider the kind of attraction which seems to unite all ordinary masses and particles of matter. Reference is here made to the *attraction of gravitation*.

As the attraction of cohesion unites the particles of matter into masses or bodies, so the attraction of gravitation tends to force those masses towards each other to form others of still greater dimensions. The force of attraction increases in proportion as bodies approach each other, and by the same law it must diminish in proportion as they recede from each other. Attraction, in technical language, is inversely as the squares of the distances between the two bodies; that is, in proportion as the square of the distance increases, in the same proportion attraction decreases, and so the contrary. Thus, if, at the distance of 2 feet, the attraction be equal to 4 pounds, at the distance of 4 feet it will be only 1 pound; for the square of 2 is 4, and the square of 4 is 16, which is 4 times the square of 2. On the contrary, if the attraction at the distance of 6 feet be 3 pounds, at the distance of 2 feet it will be 9 times as much, or 27 pounds, because 36, the square of 6, is equal to 9 times 4, the square of 2. The intensity of light is found to increase and diminish in the same proportion. Thus, if a board a foot square be placed at the distance of one foot from a candle, it will be found to hide the light from another board of two feet square, at the distance of two feet from the candle. Now, a board of two feet square is just four times as large as one of one foot square, and therefore the light at double the distance being spread over four times the surface, has only one fourth the intensity.

The gradual diminution of attraction as the distance increases, is exemplified in the following table. In the upper line, the distance is expressed by progressive numbers; in the lower corresponding squares the diminution of attraction is indicated by the common arithmetical fractions.

Distance	1	2	3	4	5	6	7	8	and so on
Attraction	1	$\frac{1}{4}$	$\frac{1}{9}$	$\frac{1}{16}$	$\frac{1}{25}$	$\frac{1}{36}$	$\frac{1}{49}$	$\frac{1}{64}$	and so on

It is here seen, that at the distance of 8, the attractive force is diminished to a 64th part of what it was at 1.

The attractive force of matter is also in proportion to the numbers of the atoms of matter which a body contains: the attraction, therefore, does not proceed from the mere surface of a body, but from all the particles which individually compose it. Some bodies of the same bulk contain a much greater quantity of matter than others: thus, a piece of lead contains about twelve times as much matter as a piece of cork of the same dimensions; and therefore a piece of lead of any given size, and a piece of cork twelve times as large, will attract each other equally. The attractive power of any mass acts from the centre. At all equal distances from the centre, the attractive power is equal; for instance, in a body perfectly spherical, the attraction to the centre would be the same at all parts of the surface. The distance of the centre of a sphere from its surface is called the *semi-diameter* of that sphere—that is, the half of its thickness. At a point as far from the surface of a sphere as its semi-diameter, its attractive power is diminished to a fourth. At three distances, the attraction is a ninth; at four distances, a sixteenth; and so on. When we wish, therefore, to ascertain the relative amount of the attraction which any mass of matter exercises over another, the rule is, to inquire how many semi-diameters of the one the other is distant from it, and then to multiply that number by itself. The result shows how many times the attraction at this distance is less than at the surface of the former. The moon, for instance, is distant 240,000 miles from the earth, or as much as sixty semi-diameters of the earth; 60 multiplied by 60 gives 3600; consequently, the attraction exercised by the earth upon the moon is a 3600th part of what it would exercise upon the same mass at its own surface. If the earth were a perfectly spherical body, its attraction would be equal everywhere at the level of the sea. As the surface at the pole is thirteen miles nearer the centre than the surface at the equator, the attraction is stronger at the former than at the latter place: it gets proportionally weaker as we advance towards the equator, on account of the increase of distance from the centre. Hence, a mass of iron which is considered a pound weight in Britain, would be less than a pound on the coast of Guinea, and more than a pound in Greenland, for weight is only a result of attraction. If we ascend a mountain, the effect is the same as if we proceed towards the equator: we are always getting farther from the centre of attraction, and consequently weights become lighter. On the top of a hill four miles high, a ball of four thousand pounds' weight would be found to be two pounds lighter.

Pressure downwards, or weight, is in philosophical language termed GRAVITY, and under that head it is hereafter treated, in connection with the phenomena of falling bodies.

The attraction of bodies is mutual, and in proportion to the quantity of matter they contain. Therefore, any body, however small, exerts some degree of attraction upon the mass of the earth. Any body which comes immediately under our observation, is so small in comparison to the earth, that its attractive force is altogether unappreciable; but if the body were of great density, and of dimensions approaching to those of the earth, then we should see the earth rise to meet the body, or fall towards the body. The heavenly bodies, when they approach each other, are drawn out of the line of their paths or orbits, by mutual attraction. It is found by experiment, that a plumb-line suspended in the neighbourhood of a mountain, is sensibly attracted towards the mountain from the true vertical line. The mutual attraction of matter is exemplified by the diminution of the weight of bodies as we penetrate into the earth. At the depth of a mile, a body weighing a pound would be found to be lighter than at the surface. This is in consequence of the attraction of the matter of the shell of the earth, which is exterior to the point, being nothing, in consequence of the attractions of its particles on this point counteracting each other; and hence the only efficient attraction on it arises merely from the smaller sphere below the point; and, therefore, the nearer the point is to the centre, the less is this internal sphere, and the less therefore is its attraction on the point. Were we to proceed to the centre of the earth, we should there find that weight altogether ceased, because the attractive power would be equal on all sides. Were there a cavity at the earth's centre, the body would hang suspended in space.

The attraction of the earth's mass performs an important function, in binding the atmosphere, which is an elastic fluid, around the surface of our planet, and in causing the air to perforate every open crevice and pore in the superficial substances of the globe. The attractive force, in this respect, produces what is called *atmospheric pressure*, the air being pulled or pressed down by a force equivalent to about 15 lbs. on the square inch, at the level of the sea, and diminishes in proportion to the distance above that common level.

THE REPULSIVE QUALITY IN MATTER—HEAT.

While attraction tends to unite and compress the particles of matter, there is another and equally universal principle known in familiar language by the appellation of *heat*, the tendency of which is to keep the particles of matter at a certain degree of expansion. Heat is often, in scientific works, named *caloric*, from the Latin word for heat. Heat pervades all things, but some in greater degrees than others. Even ice has been found to contain a certain portion of heat. In fact, there is no such thing in nature as positive cold. The things which seem cold to us, are only under a low degree of heat.

The absolute nature of this universal principle is unknown. We only know it by its effects, and the sensations it produces. Some have conjectured that it is a fluid; others think it is a quality or affection of matter, resulting from electrical action. From its producing no sensible difference in the weight of any substance, it has been called an *imponderable body*. When the heat of any particular substance, as ice, stone, or wood, is not sensible to us, it is called latent (that is concealed) heat. We may very readily detect its presence in a piece of wood or metal by rubbing or friction. If a button, for instance, be rubbed on a table, it will soon become too hot to be held by the fingers. In like manner, the axle of any carriage-wheel soon becomes hot, unless the friction is prevented by grease.

Heat, in its extreme form, becomes fire. Thus, if an ungreased wheel be rapidly turned for a long time on its axle, so much heat will be excited that both wheel and axle will burst into a flame. The effects of powerful friction are known to savage nations, among whom it is common to produce fire by rubbing two sticks together. Two pieces of flint struck together, or a flint struck hard upon a piece of iron, evolve sparks of fire. By such means, many important purposes are served; for instance the discharge of fire-arms. Fire can also be evolved from the common atmosphere, by compressing a quantity of it suddenly in a tube, at the bottom of which a piece of tinder has been placed. The evolution of heat by these means, and other circumstances, lead to the conclusion that heat is an element mixed up with the atoms of matter, which it serves to keep at a lesser or greater distance from each other. Thus, as we squeeze the pores of a sponge together, and disengage the liquid which they held in cohesion, so, when squeezing or rubbing a portion of matter, do we disengage the heat which it retained amongst its component atoms. In all cases of the development of heat by pressure, hammering, and friction, the cause is the squeezing together of atoms which had been kept asunder by the latent fluid, and which fluid must, as a matter of necessity, come forth and make itself sensibly felt or seen.

Heat, then, is a principle of *repulsion* in nature, and in this capacity its uses are as obvious as those of terrestrial gravitation, to which it apparently acts as a counterpoise. The force of attraction is so powerful, that, unless for a counteracting principle of repulsion, all bodies would hasten into close contact; there would be no air, no water, no vegetable or animal life; all would be a uniform dead solid mass, and the earth itself might perhaps be reduced to a small portion of its present bulk.

Heat, by pervading all things, modifies attraction, and, according to circumstances, regulates the density or solidity of bodies. Hence we possess in nature a beautiful variety of substances, some solid and hard, like stone and marble; others soft, or of the jelly form; a third class liquid, like water; and a fourth kind aëriform, or gaseous. Heat expands most bodies in proportion as it is increased in quantity, and they become solid in proportion as it is withdrawn. Water may thus be either expanded into the form of vapour or steam, or hardened into ice. When withdrawn, the process of *cooling* is said to take place; *cold* being simply a state of abstraction or comparative absence of heat.

Heat is diffused or communicated by *conduction* and *radiation*. When it passes slowly from one portion of matter to another in contact with it, it is said to be conducted; and the process, in scientific language, is termed the *conduction of caloric*. Metals are the best conductors, then liquids, and lastly, gases. Gold, silver, and copper, are the best conductors among solids; glass, bricks, and many stony substances, are very bad conductors; and porous spongy substances, as charcoal, hair, and fur, are the worst. Clothing is generally made of bad conductors, that the heat of the body may not be conducted quickly to the surrounding air. Furnaces, where great heat is required, are built with porous bricks, which are very effectual in preventing the escape of heat, and do not readily communicate the fire to adjacent bodies.

Heat is said to radiate when it is emitted from a fire or from the rays of the sun, and affects the atmosphere or substances at a distance from its source. Radiant heat is absorbed when it falls upon bodies having painted or rough surfaces, such as are presented by bricks and other porous solids, by many kinds of stony matter, and numerous animal and vegetable substances, and makes them warmer as it is taken up. But brilliant and polished metallic surfaces absorb little heat; they reflect or turn it back again. Heat, as already mentioned, can be brought into action in most substances, by percussion and rubbing. It is also produced by the burning of certain inflammable substances, as coal and wood; and in this manner its chief purposes in domestic economy are effected. But the most remarkable source of heat is the sun; though whether this luminary is a burning mass, throwing off warmth like a common fire or red-hot ball, or produces the effect by some peculiar and unknown operation, is as yet uncertain. Heat, besides being produced by the sun's rays, and by the friction and combustion of inanimate substances, is evolved by chemical action, a familiar example of which is observable in fermentation. It is by means of a natural chemical action in connection with the circulation of the blood, that heat is resident and sustained in most living animals. A stoppage of the circulation of the blood, as every one knows, leads to an absence of animal heat, or a very considerable degree of coldness. On the contrary, quick circulation of the blood, and active muscular motion, as well as rubbing, produce heat. In these cases of motion and rubbing, the heat seems to be in a great measure evolved by the momentary compression of the parts.

Heat is unequally distributed over the globe. At and near the equator, where the rays of the sun are sent in the greatest degree of directness, the greatest heat prevails. In the parts of the earth adjacent to the north and south poles, he transmits his rays so slantingly as to have little power; and there, accordingly, the air is seldom of a genial mildness. The higher we ascend in the air, the colder it becomes; the summits of very high mountains are always covered with snow. In penetrating into the body of the earth, after gaining a certain depth, the heat becomes greater in proportion as we descend. The interior of the globe is by many believed to be at a very elevated degree of heat, if not in a state of ignition. On the surface, great expanses of sea tend to equalize and temper the degrees of heat and cold in their neighbourhood, and great continents have the contrary effect.

The degrees of heat and cold in the atmosphere are called its temperature; and for ascertaining this correctly, with reference to a standard, a very ingenious instrument has been invented. This is called the *thermometer* (a word signifying heat-measurer). It is a glass tube with a bulb at the bottom, into which mercury or quicksilver is put, with a scale of figures along the tube to mark the rising of the quicksilver. This instrument differs from the barometer, in as much as the quicksilver is sealed up close from the air. The atmospheric heat, however, affects the metallic fluid in the bulb, and, according to its warmth, causes it to expand and rise in the tube. The degree of temperature is indicated by the figures to which it ascends.

Fig. 1.

Our common thermometer has a graduation from No. 1, near the bulb, to 212, the degree of heat of boiling water. In the scale of figures, 32 is marked as the freezing-point—that is to say, when the mercury is at the height of 32, water freezes; and the more it is below that point, the more intense is the frost: 55 is reckoned moderate heat, and 76 summer heat, in Great Britain: 98 is the heat of the blood in the average of living men.

The rising of mercury in the table of the thermometer offers a familiar example of the repulsive power of heat in expanding or dilating bodies. Common experience affords many such examples. A bar of iron is longer and thicker when hot than when it is cold. The iron rim of a wheel slips easily into its place when hot, and grips or binds fast when it becomes cool. When heated from 32 to 212, air expands 3-8ths of its volume, alcohol 1-9th, water 1-22d, and hammered iron 1-273d. In these, and all similar instances, the expansion arises from the fluid of heat lodged among the atoms of matter pressing outwards on all sides, according as it is excited.

When the temperature of the atmosphere falls below the freezing-point (32), which it does principally from the weakness of the sun's rays in winter, the phenomenon of frost, or freezing, ensues. Freezing is a process of congelation, or properly crystallization, produced by the withdrawal of heat, and by which water assumes the form of ice. When the temperature of the atmosphere rises above the freezing-point, the ice melts, and is resolved into its original elements. When the temperature of the atmosphere is below the freezing-point, the particles of water which are upheld in the clouds are frozen in their descent, and reach the earth in the form of flakes of snow. If this freezing take place after the particles have become united into rain-drops, we have hail instead of snow. When the descending flakes of snow come into a temperature above the freezing-point as they approach the earth, they are apt to melt, and in such a case fall in the shape of sleet, which is half-melted snow or hail.

Heat has a constant tendency to preserve an equilibrium in all situations; and hence its diffusion through nature, and many of the ordinary phenomena in relation to temperature. When we touch a cold substance with our hand, a portion of the heat of the hand rushes into the substance, and leaves the hand so much deficient of its former heat. On the same principle, when we touch a substance which is warmer than the hand, some of the heat rushes into the hand, and renders it hot. When we pour a quantity of hot water into that which is cold, an equalization of the two temperatures immediately ensues. When the air at any particular place becomes heated or rarefied, it ascends by virtue of its greater lightness, leaving a vacancy which the neighbouring air rushes in to supply. This is one of the chief causes of winds. The same principle is observable in the case of heated apartments. If the door of a heated room be thrown open, a current of cold air immediately rushes in to supply the deficiency in the rarefied atmosphere.

Evaporation is always accompanied by the withdrawal of heat, or production of cold, when no heat is directly applied; the heat necessary for the production of the vapour is then derived or radiated from surrounding objects, as is mentioned above in the case of dew forming on plants.

In the great operations of nature, the withdrawal of heat to produce intense cold, and the application of heat to produce great warmth, ordinarily take place gradually. Thus, although water freezes at a temperature of 32, it is some time before frost is completely effectual in changing the aspect and condition of liquid bodies; and when the temperature rises a few degrees above 32, after a frost, the ice and snow which have been formed do not vanish immediately; indeed, ice will remain unthawed for several days after the temperature has risen some degrees above the freezing-point. By this slow process, either in the absorption or evolution of heat, the animal and vegetable worlds are not liable to the injury which would ensue from instantaneous changes in the condition of their elementary fluids.

Water is increased in volume by freezing, which circumstance explains the ordinary phenomena of the bursting of water-pipes, and other similar occurrences, during frost. When a vessel of moderate strength is filled with water, its expansion, when it is converted into ice, by exposure to a freezing temperature, causes the vessel to burst. If the vessel is not brittle, but possessed of considerable tenacity, as a leaden water-pipe, the rupture will seldom be observed during the continuance of the frost while the water remains in a solid state, but it readily appears when thaw takes place, as the water is then forced out with a velocity corresponding to the vertical height of the column of water in the pipe. The fissures of rocks, too, are widened by the freezing of the water which may happen to lodge in them before frost; and this process, therefore, is a powerful agent in the disintegration of rocks. Portions of steep banks, also, from a similar cause, tumble down after thaw; for the moisture in them expands when frozen, and thus rends them to pieces, which, however, during the frost, are bound together as by cement, and fall down whenever thaw dissolves the moisture.

Heat has a powerful effect in causing certain bodies to shrink and diminish in volume. This happens with those substances which do not liquefy, such as wood and clay. The contraction arises from the heat carrying off the watery particles from the bodies, and thus allowing the constituent atoms to come more closely together. As wood becomes drier, its fibres are sometimes split asunder, so as to emit loud cracking noises, which, in the case of household furniture, are ascribed by the ignorant to supernatural causes.

Heat is further treated of under the articles Chemistry, Pneumatics, and Meteorology.

ACCIDENTAL PROPERTIES OF MATTER.

Having shown how the beautiful and extensive variety of form in bodies—solid, liquid, gaseous, and the different modifications of them—are to be traced to the operation of chiefly two great leading principles in nature, attraction and repulsion, we have now to mention the peculiar forms or characters which bodies assume from the influence of these and other causes, and which are usually classed under the term *accidental properties of matter*. The following are these properties:—Density, Porosity or Rarity, Compressibility, Elasticity, Dilatation, Hardness, Brittleness, Malleability, Ductility, and Tenacity.

Density signifies closeness of texture, or compactness. Bodies are most dense when in the solid state, less dense when in the condition of liquids, and least dense of all when gaseous or aëriform. In this manner the degree of density is in agreement with the closeness of the atoms to each other. The density of bodies may generally be altered by artificial means, as is afterwards mentioned. The metals, in particular, may have the quality of density increased by hammering, by which their pores are made smaller, and their constituent particles are brought nearer to each other.

The more dense in substance that a body is, it is the more heavy or weighty. In speaking of the density of different solid and liquid bodies, the term *specific gravity* is used to denote the comparison which is made. Thus, the specific gravity of a lump of lead is greater than an equal bulk of cork; or the specific gravity of water is greater than that of an equal quantity of spirituous fluid. For the sake of convenience, pure distilled water, at a temperature of 62°, has been established as a standard by which to compare the specific gravity or relative weights of bodies. Water, as the standard, is thus said to be 1. When, therefore, any body, bulk for bulk, is double the specific gravity of water, it is called 2, and so on to 3 and 4 times, up to 22 times, which is the specific gravity of platinum, the heaviest known substance. In almost every case of comparison there are fractional parts, and these are usually written in figures, according to the following arrangement: Fractional parts are divided into tens, hundreds, thousands, and so on. If, in addition to the figure expressing the main part of the specific gravity, there be one other figure, with a dot or point between them—thus 2·5—the additional figure signifies tenths, and the body is two times and five-tenth parts of a time more dense or heavy than water. If two figures occur—thus, 10·40—hundredths are signified, and the body is ten times and forty-hundredth parts of a time heavier than water. If there be three figures, thousandths of parts of a time are meant; if four figures, ten thousandth parts; and so on. Common air is sometimes taken as a standard with which to compare gases, being a more simple mode of comparing the relative weights of aërial substances. But all the solids and liquids are estimated with reference to water as the standard.

Any body of greater specific gravity than water, will sink on being thrown into water; but it will float on the surface, if its specific gravity be less than that of water. A body, such as a piece of wood, after floating a certain length of time on water, will imbibe such a quantity of liquid that its specific gravity will be gradually increased, and in the course of time it may sink to the bottom.

Porosity is the quality opposite to density, and means that the substance to which it is applied is porous; that is, full of small pores or empty spaces between the particles, and that the body is comparatively light. The instances of porosity are numerous in every department of the material world, but those which are connected with animal and vegetable bodies are the most remarkable. Bone is a tissue of pores or cells, and, when seen through a microscope, may be said to resemble a honeycomb. Wood is also a tissue of cells or tubes. If the end of a cylinder of straight wood be immersed in water, whilst the other is forcibly blown into, the air will be found to pass through the pores of the wood, and rise in bubbles through the water. When a gas is comparatively light, it is said to be *rare*, or to possess *rarity*.

By *compressibility* is meant that quality in virtue of which a body allows its volume to be diminished, without the quantity or mass of matter being diminished. It arises, of course, from the constituent particles being brought nearer to each other, and is effected in various ways. All bodies are less or more capable of being diminished in bulk, which is a conclusive proof of their porosity. Liquids are less easily compressed than solid bodies; nevertheless they, to a small extent, yield, and go into smaller bulk by great pressure. The water at the bottom of the sea, by being pressed down by the superincumbent water, is more dense or compact than it would be at the surface. Atmospheric air and gases are much more easily compressed than liquids, or even than many solids. Air may be compressed into a hundredth part of its ordinary volume. When at this state of compression, it has a great tendency to expand and burst the vessel in which it is confined.

Some bodies have the power of resuming their former volume or shape when the force which diminished it is withdrawn. This quality is termed *elasticity*. Steel is one of the most elastic of metallic bodies, but its elasticity is not nearly so great as that of India-rubber, which, though twisted, drawn out, or compressed in different ways, always resumes its original form. The aëriform fluids, such as atmospheric air, and the gases, are all exceedingly elastic; and so are liquids, such as water, but to a smaller extent.

Dilatability is that quality of bodies by which they are enabled to be expanded or enlarged in their dimensions, without any addition being made to their substance. *Hardness* is the quality which is the opposite of softness, and does not depend so much on the density of the substance, as the force with which the particles of a body cohere, or keep their places. For instance, glass is less dense than most of the metals, but it is so hard that it is capable of scratching them. Some of the metals are capable of being made either hard or soft. Steel, when heated to a white heat, and then suddenly cooled, as by immersion in water, becomes harder than glass, and when cooled slowly, it becomes soft and flexible. *Brittleness* is that quality by which bodies are capable of being easily broken into irregular fragments, and it belongs chiefly to hard bodies. Iron, steel, brass, and copper when heated and suddenly cooled, become brittle. *Malleability* is the quality by which bodies are capable of being extended by hammering. Some of the malleable metals are gold, silver, copper, zinc at the temperature of boiling water, lead, iron, and some others. Some of the metals possess the opposite quality of brittleness. Gold is the most malleable of all metals, and it may be hammered so thin as to be translucent, or permeable to light. By *ductility* is understood that property by which metals may be drawn to wire. The most malleable metals are not the most ductile. Tin and lead may be rolled into thin leaves, but cannot be drawn into wire. The most ductile metal is platina, which can be drawn into wire as fine as the threads of a cobweb. *Tenacity* is the quality by which bodies are not easily torn asunder. Steel is the most tenacious of all substances; a wire of this metal, the hundredth of an inch in diameter, will support a weight of 134 lbs.; while one of the same size of platina will sustain only 16 lbs., and one of lead only 2 lbs.

MOTION AND FORCES—GENERAL EXPLANATIONS.

Motion is the changing of place, or the opposite of rest.

Matter, according to the definitions which have been given of its properties, is substance devoid of life and volition, and which is perfectly passive, or inert. It has been described as possessing the property of inertia, and in this respect it is said to possess an unwillingness or reluctance to move, but these phrases are only figurative, and are used for the purpose of conveying a forcible idea of the passiveness of its character. It is also, in consequence of this property of inertia, or passiveness to submit to any condition to which it is subjected, that a body, when once in motion, will continue to move continually with the same velocity and in the same direction, till it is disturbed by some external cause.

Any instance of [illegible] comes under our observation, is only rest in a *relative*, not an *absolute*, sense; that is, it is rest as relates to the earth, but not rest as relates to the universe; for though the stone which falls to the ground lies at rest on the earth, the earth is always in motion, and therefore the stone is no more at rest than the insect which sits upon a moving wheel is at rest. Hence, in speaking of bodies coming apparently to a state of rest, we must always recollect, that it is only relative, not positive or absolute rest. It is supposed that there is no such thing as absolute rest in creation. All the planets are in motion round the sun; and the sun itself has a motion on its own axis; it is also believed by many astronomers that the sun has an onward or progressive motion in space, besides its rotatory movement; and thus, perhaps, revolves round some distant centre, with all its planets in its train.

Common experience would lead to the conviction that rest is more natural for matter than motion; but this conviction is founded on a limited consideration of circumstances. The reason why we see ordinary moving bodies coming to a state of rest—such as a wheel stopping after having been whirled on its axle, a ball stopping after rolling on the ground, or an object falling to the earth after being thrown upwards—is, that they are sooner or later arrested in their progress by the earth's attraction or their own gravity, by the friction or rubbing against some other body, or by the opposition presented to them by the atmosphere. Except for these three prevailing causes of impediment and stoppage, all bodies set in motion would go on moving for ever. Taking this expanded view of things, and dismissing the erroneous impressions arising from what is obvious only to our limited experience, we find that there is nothing more remarkable in perpetual motion than in perpetual rest.

It is only, however, in the great works of creation, or the heavenly bodies, that perpetual motion is observable. The planetary bodies are under the ever-acting impulses of centrifugal and centripetal forces, and are not impeded by friction, or by the atmosphere, for they move in space, or in a comparative vacuum. Many ingenious attempts have been made to produce perpetual motion on mechanical principles in terrestrial objects, but they have all necessarily failed, as no human effort can destroy gravity in bodies, or altogether prevent friction in movement.

In regard to bodies on the earth, of which a state of rest is the ordinary condition, motion is produced by certain agencies, or impelling causes, either belonging to the phenomena of nature or to art. The property of capillary attraction causes a motion in liquids under certain circumstances; the winds blow, and cause motion; rivers, in flowing down their channels, and the action of the tides, likewise produce motion; thus, there exist many natural causes of motion, which are taken advantage of by man in the economy of arts and manufactures. Motion in the animal economy is produced by a principle of life; but of the nature of this kind of motion mankind are ignorant, and nothing here requires to be said regarding it. The causes of motion which have to engage our attention are those which consist of *forces*, whether natural or artificial, and which forces have the property of impelling inanimate objects from a state of rest to a state of motion, of stopping them when in motion, or of altering the character of their motion. These forces are also called powers.

Motion, according to the mode in which the force acts, is susceptible of innumerable variations. According as the moving body is affected, it may move rapidly or slowly; proceed in a straight line, turn in a circle, or curve; it may move with uniform or irregular speed, or be retarded or accelerated. The body may also move upon or in respect of another body which is also moving. Some of these peculiarities in motion will immediately engage our attention; meanwhile, it has to be explained, that, for the sake of convenience in language, and accuracy in the application of terms, certain words are used to define the nature of motion in bodies, and the forces affecting them.

Motion is said to be *common* to two or more bodies when they move in contact or together; or when, though not in contact, they are carried along in a similar manner, and with the same velocity; that is, when they have a motion in common, or participate in the same motion. Motion is said to be *absolute*, when a body actually moves from one point of space to another, or when it moves towards, or when it passes, another which is at rest. Therefore, setting aside the idea of the earth moving, we should say that a vessel moving on the sea has an absolute motion, while the land is fixed or stationary. Motion is said to be *relative*, when the motion of one moving body is considered in reference to that of another moving body. Thus, if two bodies move in the same direction, their relative motion is the difference of their motions; if they move in opposite directions, it is the sum of their separate motions.

When a force, applied to any material object, is resisted or counteracted, so that no motion ensues, it is called a *pressure*; and forces so counteracted are said to *balance* each other, or to be in *equilibrium*.

The degree of speed in the motion of bodies is called *velocity*. Velocity is measured by the space or distance passed over, with an invariable motion, and in a given time, as one second. Thus, if a body, in one second, with an invariable motion, pass over twenty feet, its velocity is said to be twenty feet per second.

When a motion is invariable, it is said to be *uniform*; if it be gradually increasing, it is said to be *accelerated*; and if it gradually decrease, it is said to be *retarded*.

A force is said to be an *accelerating* or *retarding* force, according as it produces an accelerated or retarded motion.

Forces are either *instantaneous* or *continued.* The former is an impulse, like a stroke; the latter acts without intermission. When a continued force remains always of the same intensity, it is called a *constant* force. Other continued forces are said to be *variable.*

A body, in moving, possesses a force which is called its *momentum,* or *motal force.* Momentum is very different from velocity. A light body and a heavy body may move at the same velocity, but the momentum of the light body will be small in comparison with that of the heavy one. The light one, on coming to a state of rest, will perhaps fall harmlessly on the ground, while the other, by its momentum, will strike *forcibly* on the earth, or destroy any object which opposes it. Momentum is proportionate to the mass and velocity of bodies, and, by multiplying the weight by the number of feet moved over per second, we find that the momentum is the product. Thus, if a body of twelve ounces move with a velocity of twenty feet per second, its momentum is (twelve times twenty) two hundred and forty. In ordinary language, the term *impetus* is used to signify the violent tendency of a moving body to any point.

Before entering upon a consideration of motion as produced by ordinary forces, it will be appropriate to describe the effects produced upon bodies when simply falling—that is, moving downwards towards the earth, when the supports which upheld them are withdrawn.

THE PHENOMENA OF FALLING BODIES—WEIGHT.

Attraction, as already explained, is a force inherent in nature, by which particles and masses of matter are drawn towards each other. This force, it has also been stated, increases in proportion to the quantity of matter which the attracting body contains, and it also increases as the bodies approach each other. Further, it has been mentioned that this powerful and subtile quality in matter is the cause of the falling or drawing of bodies downwards towards the earth, and thus produces what is termed *weight* or *gravity.* Gravity, then, is simply the tendency which any substance has to press downwards in obedience to the law of attraction, as exemplified in the phenomena of bodies falling from heights to the ground, when the supports which upheld them are removed.

All falling bodies tend directly towards the centre of the earth, in a straight line from the point where they are let fall. If, then, a body be let fall in any part of the world, the line of its direction will be perpendicular to the earth's centre. Consequently, two bodies falling on opposite sides of the earth, fall towards each other. Suppose any body to be disengaged from a height opposite to us, on the other side of the earth, its motion in respect to us would be upward, while the downward motion from where we stand, would be upward in respect to those who stand opposite to us, on the other side of the earth. In like manner, if the falling body be a quarter, instead of half the distance round the earth from us, its line of direction would be directly across or sidewise, that is, at right angles with the lines already supposed.

It will be obvious, therefore, that what we call *up* and *down* are merely relative terms, and that what is down in respect to us, is up in respect to those who live on the opposite side of the globe. Consequently, *down* everywhere means towards the centre of the earth, and *up* signifies from the centre of the earth. The velocity or rapidity of every falling body is uniformly accelerated, or increased, in its approach towards the earth, from whatever height it falls, if the resistance of the atmosphere be not reckoned. If a rock be rolled from the summit of a steep mountain, its motion is at first slow and gentle, but as it proceeds downwards, it moves with perpetually increased velocity, seeming to gather fresh speed every moment, until its force is such that every obstacle is overcome; trees and rocks are dashed from its path, and its motion does not cease until it has rolled to a great distance on the plain.

The same principle of increased velocity in bodies as they descend from a height, is illustrated by pouring treacle, honey, or any thick syrup, from an elevated vessel. The bulky stream, which is perhaps two inches in diameter where it leaves the vessel, is reduced to the size of a straw or thread on reaching its destination; but what it wants in bulk is made up in velocity, for the small thread-like stream at the bottom will fill a vessel just as soon as the large and slow moving stream at the outlet; the velocity is indeed so great, that the stream has not time to sink at once into the mass below, but falls in overlaying folds.

From the same principle, a person may leap from a chair without danger; but if he jump from the housetop, his velocity becomes so much increased, before he reaches the ground, as to endanger his life by the fall.

It is found by experiment, that the motion of a falling body is increased, or accelerated, in regular arithmetical progression. In other words, in every second of time during its descent, it acquires an additional rate of speed, the rate regularly increasing by the accumulation of the preceding additions.

It is ascertained that a dense or compact body, when falling freely, passes through a space of 16 feet 1 inch during the first second of time. Leaving out the odd inch for the sake of even numbers, we find that the space fallen through in a given time is determined by the following arithmetical computation.

Ascertain the number of seconds which a body occupies when falling. Take the square of that number (that is, the number multiplied by itself), and multiply the square by 16, which is the number of feet fallen during the first second, and the result is the amount of feet which the body altogether falls. For example, if a ball occupy 3 seconds in falling, we take the square of 3, which is 9; then we multiply 9 by 16, which gives 144 as the result, and that is the number of feet fallen. Again, if we find that the ball occupies 4 seconds in falling, we take the square of 4, which is 16, and multiplying 16 by 16, the result is 256, which is the number of feet fallen. And so on, always following the same rule of computation.

It is not always easy, by the above mode of calculation, to arrive at a correct result as to the height fallen by bodies, and all that can be expected is an approximation to a true result. This arises from bodies being of different bulks, and receiving different degrees of opposition from the atmosphere in their descent. It is a common supposition that large and heavy bodies fall more quickly than small and light ones. This opinion, which was maintained even by philosophers, until Galileo rectified the mistake, perhaps originates in the error of confounding *momentum* with *velocity.* Be this as it may, it is now an ascertained truth in science, that all bodies, of whatever density, fall with the same velocity. Thus, a ball containing a pound of lead falls with the same velocity as a ball containing an ounce. This equality in the rate of falling is, however, disturbed by the quality of figure and bulk of bodies. A solid ball of gold will fall more quickly than the same quantity of gold beat out into a thin leaf, because in the case of the leaf the resistance from the atmosphere on a large surface impedes the descent. Thus the atmosphere prevents bulky and porous substances from falling with the same velocity as those which are compact.

If the atmosphere were removed, all bodies, whether light or heavy, large or small, would descend with the same velocity. This fact is ascertained by experiments performed with the air-pump.

When a piece of coin, for instance a guinea, and a feather, are let fall at the same instant of time, from a hook which has held them at the top of the exhausted receiver of an air-pump, they are observed to fall at an equal rate, and to strike the bottom at the same moment. Hence it is demonstrated, that were it not for the resistance of the atmosphere, a bag full of feathers, and one of coins, would fall from a given height with the same velocity, and in the same space of time.

It has been stated that the attraction of gravitation increases in proportion to the quantity of matter which the attracting body contains. Thus, the mass of our planet, the earth, exerts a force of attraction which produces the phenomena of weight, and the falling of bodies with a certain velocity.

In consequence of the different size and density of the sun and planetary bodies, attraction is much stronger in some of them than others, and consequently the weight of bodies differs in each. On the surface of the sun, our pound weight would weigh upwards of 27 pounds, and a body would fall upon it 434 feet the first second. On the surface of Jupiter, our pound would weigh about 2 pounds 4 ounces. And on the surface of the moon, our pound would weigh only the fifth part of a pound.

As a body in descending to the earth receives increasing accessions to its velocity during every successive second, so when a body is projected upwards from the surface of the earth, its velocity decreases in the same proportion, till it comes to a state of momentary rest, when it instantly begins to descend with a gradually increasing velocity, which at any point in the descent is equal to its velocity at the same point when ascending. In this calculation, however, we omit the influence of the atmosphere, which would cause the final velocity in the descent to be less than the original velocity with which the body was projected upwards.

THE CENTRE OF GRAVITY.

Terrestrial gravitation, as already explained, does not act on the mere surface of bodies, or according to their bulk, but is exerted in reference to all the particles or atoms individually which compose the mass of a body. As the earth is nearly of a spherical form, its attraction is the same nearly as if it proceeded entirely from the centre. On account of the great size of the earth, compared with that of any ordinary body at its surface, its attractive force acts in straight lines, sensibly parallel, proceeding from the earth's centre. In the case of liquids, in which the atoms slightly cohere, the atoms have liberty to spread themselves over the earth, and to seek the lowest situation for repose. In the case of solids, a different operation is observable. In them, the particles of matter stick so closely together, that they are not at liberty to obey the law of gravitation individually, but rally, as it were, round a common centre, upon which the force of attraction may be considered to act for the general behoof. This centre is called the *centre of gravity*, the *centre of inertia*, or the *centre of parallel forces*.

Every solid body or dense mass possesses a centre of gravity, which is the point upon or about which the body balances itself, and remains in a state of rest, or equilibrium, in any position. The centre of gravity may be described as a point in solids which always seeks its lowest level, in the same manner that the lowest level is sought for by water; for it is only by propping up the body, that the centre of gravity is prevented from displaying the same mode of action. The centre of gravity in round, square, or other regular shaped bodies, of uniform density in all their parts, is the centre of these bodies. When a body is shaped irregularly, or when there are two or more bodies connected, the centre of gravity is the point about which they will balance each other.

Any square or angular body which we may place on the ground, will remain stationary, or safely at rest, provided an ideal line, drawn from its centre of gravity, and passing to the ground in a direction perpendicular to the earth's surface, fall within its base, as in fig. 2. A point below A is the centre of gravity; and from that point the line of direction goes downward to B, which is within the edges of the base. An object of this form, and so placed, will stand.

Fig. 2.

If the line of direction from the centre of gravity falls without the outer edge of the base, as in fig. 3, from A to B, then the object will not remain balanced on its base; it will fall over, and attain some position in which the line of direction falls within the boundary of the base on which it stands. By keeping this simple principle in view, stability and safety will generally be secured in the erection of objects of art, such as houses, monumental edifices, spires, and obelisks, as well as in the lading of coaches, carts, and other vehicles, and the piling of timber or any kind of goods in heaps. In every instance, the base ought to be sufficiently broad to admit of the line of direction from the centre of gravity falling within it.

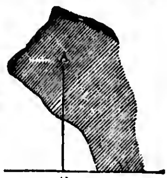


Fig. 3.

A small degree of experience seems to point out the propriety of erecting all kinds of structures with a base wide enough to secure stability; nevertheless, in opposition both to experience and the simple principles of science, we often find that stage-coaches are laden in such a manner that their centre of gravity is liable to too great a change of position, and that they are overturned, to the personal injury, and even loss of life, of the passengers. The error in these instances consists in raising the centre of gravity too high. At first, perhaps, the centre of gravity is so comparatively low, that, in the case of swaying to a side, the line of direction would fall within the edge of the wheel, and no danger would ensue; but it is common to go on piling masses of goods or luggage, or placing a number of passengers on the roof of the vehicle, so that the centre of gravity becomes considerably elevated; so high, indeed, that when the carriage is swayed, or jolts to one side, the line of direction is thrown beyond the wheel, and the vehicle will consequently fall over. In the annexed cut, fig. 4, a loaded vehicle is represented crossing an inclined plane, or we may suppose that its wheel on one side has come in contact with a stone S, which has raised it above the level of the other wheel, so as to incline the body of the vehicle very considerably from the horizontal. The centre of gravity is represented in two different positions, a lower with the line of direction L C, and a higher with the line of direction U C. Had the vehicle not been high laden, the line of direction would have remained as L C, and as it falls within the wheel or base, the vehicle would have maintained its balance; but being now laden to a considerable height, the line has risen to about the

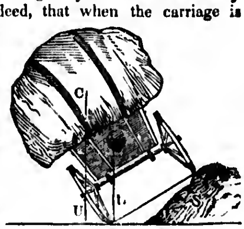

Fig. 4.

place where it is marked descending from C to U, beyond the base; consequently the vehicle must overturn.

There are instances in which bodies will not be overturned, although the line of direction falls considerably beyond the base. These exceptions to a common rule are observable in the case of rapidly and smoothly moving bodies, in which centrifugal force acts as a counterpoise to the weight of the body. A familiar example of this kind occurs in the case of skaters, in making their circular turns on the ice, in which they bend or lean greatly beyond the perpendicular position without falling. A notice of this peculiarity in moving bodies will engage our attention, under the head Centrifugal Force.

The tendency which leaning bodies have to fall, may also be counteracted in some measure by the cohesion of parts. Thus, there are many instances of walls, steeples, and towers, inclining sensibly from the vertical line, and yet, by the strength of the cement which binds them, they have stood for ages.

Whatever raises the centre of gravity, or narrows the base, allows the line of direction to pass more easily without it, and diminishes the stability. Hence the imprudence of rising up in carriages or boats, when in danger of being upset; and hence, as we have just mentioned, the danger of high-loading of vehicles. Lately an improvement has been effected in stage-coach building, by which a chief part of the load is placed as low as the axle of the wheels; and by this means the danger of overturning is almost entirely averted.

The centre of gravity of a body is not always in the substance of the body. Thus, the centre of gravity of a circular ring is in the centre of the circle; of an elliptic or oval ring, in the centre of the ellipse; and of a hollow cylindric tube, it is in the imaginary axis of the tube. In a drum, for instance, the centre of gravity is a point in the centre of the drum, where there is nothing but air.

When a circular object is placed on level ground, or a horizontal plane, it remains at rest on a point of its surface, because the line of direction from its centre, which is its centre of gravity, falls perpendicularly downwards to the point on which it is in contact with the earth and at rest; and because it could not possibly get its centre of gravity nearer the earth by changing its position. When a similar circular object is placed on an inclined plane, it will not remain at rest, but roll over, because the line of direction from its centre of gravity falls perpendicularly downwards in front of the point on its surface which touches the plane. On this account it rolls over, as if it were seeking a spot on which it might have the line of direction from its centre of gravity passing through its point of contact with the earth. Hence a circular body continues rolling down an inclined plane till it find a level spot on which the line of direction passes through its point of rest.

In a bar of iron, six feet long and of equal breadth and thickness, the centre of gravity is just three feet from each end, or exactly in the middle. If the bar be supported at this point, it will balance itself, because there are equal weighs on both ends. This point, therefore, is the centre of gravity. If a bar of iron be loaded at one end with a ball of a certain weight, then the centre of gravity will not be at the middle, but situated near the heavy end of the bar. But if we attach a ball of the same weight to both ends, the centre of gravity is again in the middle of the bar.

A remarkable illustration of the principles now detailed, is exhibited in the case of the earth and moon. The earth revolves round the sun, in consequence of a cause already explained, namely, the sun's attraction; but instead of the centre of the earth describing the oval or elliptic orbit round the sun, it is the centre of gravity of the earth and moon that describes it. We shall briefly explain the reason for this. The earth, in its course, is encumbered with the moon a body of about the seventieth of its mass; in other words, the moon is like a small ball stuck at one end of a bar, having the earth or a larger ball at the other end—the bar between being the mutual attraction of the earth and moon. On this account, the centre of gravity of the earth and moon is at a point somewhere between the centres of the earth and moon. This point lies not far below the earth's surface. Therefore, if the earth were to fall towards the sun, it would be this point which would proceed most directly towards it.

In suspending an irregularly shaped body from different points successively, we may learn where the centre of gravity of the body is placed, by observing that the line of direction in each case passes through the same point, which point is the centre of gravity. For example, let a painter's palette, which is an irregularly shaped body, be suspended from the thumb-hole, as in the annexed cut, fig. 5, and the line of direction will necessarily be from A to B. Next suspend it from a point at D, and a new line of direction will be obtained, crossing the line A B. The place where the two lines intersect, is thus the centre of gravity. The point of suspension, on being removed to C, will give the same place of intersection in the original line of direction; and a similar result will follow any other change of the suspension point.

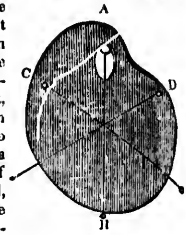

Fig. 5.

In the various natural structures displayed in the animal and vegetable kingdoms, the centre of gravity is always so situated, as to produce a just equilibrium and a harmony of parts. Every animal is properly balanced on its limbs, and every tree has a tendency to grow in a direction perpendicular to its base, whether it grow from a level or an inclined plane. Some animals are enabled to move in opposition to the law of gravity, as, for instance, flies creeping on the ceiling of an apartment; but in such cases, other powers in nature are exerted to preserve the secure footing of the animals.

THE PENDULUM.

Gravity, which causes bodies to fall, also causes them to swing backwards and forwards, when suspended freely by a string or rod from a point, and when once moved to a side, to give them an occasion of falling. A body suspended in this manner is called a Pendulum.

Pendulums usually consist of a rod or wire of metal, at the lower end of which a heavy piece or ball of brass or other metal is attached. When a pendulum swings, it is said to oscillate or vibrate; and the path which its ball pursues in swinging, from its resemblance in figure to an inverted arch or bow, is called its arc. In the accompanying cut, fig. 6, a pendulum of the most common construction is represented. A is the axis or point of suspension. B is the rod. C is the ball, or a round flattish piece of metal, which is fastened to the rod by a screw behind, and by which screw it can be raised or lowered on the rod. D D is the path or arc which the ball traverses in swinging. When the pendulum is at rest, it hangs perpendicularly, as here represented, and the place which the ball is seen to occupy is called the point of rest.

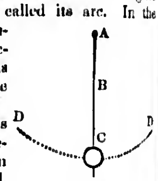

Fig. 6.

The pendulum remains at rest till its ball is drawn aside to allow it an opportunity of swinging on its axis. Being raised to any height on one side, and set at liberty, the ball, by the force of gravity, has a tendency to fall to the ground; but being confined by the suspending rod it is compelled to make a sweep to that point where it was formerly hanging at rest, immediately beneath the point of suspension. But it does not stop here; it has acquired a velocity sufficient to carry it onward in an ascending course to nearly as high a point on the opposite side as that from which it was let fall. Of its o ac-cord, it again falls downwards in the same arc, a rises to near the point where it set off; and thus, itself, continues to swing to and fro, or vibrate, for a certain length of time, till its force is expended, and it finally comes to a state of rest in its original dependent situation under the point of suspension.

At every sweep of the pendulum (when not meddled with, or assisted by any external force), the length of the path or arc traversed by the ball is in a small degree diminished. This arises from two causes—the obstruction offered by the atmosphere, and the friction on its axis or point of suspension. These causes, therefore, sooner or later, bring the pendulum to a state of rest, unless external force of some kind continues to be applied to urge it to sustain its action.

The ball of a pendulum in swinging, as has been mentioned, describes the figure of an arc. This arc is a certain portion of a circle. The extent of this portion depends on the force exerted in setting the pendulum in motion, or in drawing it aside to let it fall. A circle being divided by mathematicians into 360 degrees or parts, the ball may be made to swing over five, ten, twenty, or any other number of degrees under 180, which is half a circle. The extent of the arc traversed under ordinary circumstances, is from ten to twenty degrees.

A pendulum with a long rod vibrates slower than one with a short rod. The time does not become longer, however, in exact proportion as we extend the rod. The vibration, it must always be recollected, is analogous to the falling of bodies. The spaces fallen through by a body in 1, 2, 3, or 4 seconds, are not in proportion to 1, 2, 3, 4, and so on, but in the proportion of 1, 4, 9, 16, 25, and so on, or the squares of the time occupied in falling. In the case of pendulums, it is found that their lengths are as the squares of the times of vibration. Thus, if the times occupied by one vibration of two pendulums be 1 and 2 seconds respectively, the lengths of the pendulums will be as 1 and 4; so if the time of one vibration of several pendulums be as 1, 2, 3, 4, their lengths are as 1, 4, 9, and 16.

The vibrations of the pendulum being produced by terrestrial gravitation, it follows, as a natural result, that, if the force of gravitation be weakened, so will the tendency of the ball of the pendulum to fall or swing be weakened. This result is distinctly observable in different parts of the earth. At the equator, the earth, as already mentioned, bulges out to a thickness of 26 miles on the diameter, or 13 miles from the surface to the centre; and as the attraction of gravitation proceeds from the centre, the force of this attraction is consequently weaker at the surface at the equator than it is at the surface at the poles. At every part of the surface between the equator and s, there is a proportionate increase of gravity. Be the effect produced by the greater distance of the surface from the centre at the equator, centrifugal force, which is strongest at the equator, assists in weakening the attractive force at that place.

In consequence of these combined causes, a pendulum of a given length vibrates more slowly at the equator than at the poles. In proportion as we advance on the surface of the earth from the equator towards the poles, so does the pendulum swing or vibrate more quickly. In order, therefore, to preserve uniformity of speed in pendulums at different parts of the globe, that is, in order that they may all vibrate in one second, their length must be regulated according to the distance of the places from the equator. Thus each degree of latitude has its own length of pendulum.

From a knowledge of these laws we are enabled, by this instrument, not only to detect certain variations in that attraction in various parts of the earth, but also to discover the actual amount of the attraction at any given place.

To compare the force of gravity in different parts of the earth, it is only necessary to swing the same pendulum in the places under consideration, and to observe the rapidity of its vibrations. The proportion of the force of gravity in the several places, will be that of the squares of the velocity of the vibration. Observations to this effect have been made at several places, by Biot, Kater, Sabine, and others.

The uniform vibration of the pendulum has rendered it useful in regulating the motion of clocks for measuring time. In the common clock, a pendulum, connected with the wheel-work, and impelled by weights, or a spring, regulates the motions of the minute and hour hands on the dial-plate, by which the time of day is pointed out. If no pendulum were employed, the wheels would go very irregularly. The pendulum is regulated in length, so as to vibrate sixty times, each time being a second, in the space of a minute. At each vibration, it acts upon the tooth of a wheel, which turns the rest of the machinery. In order that the pendulum may vibrate neither quicker nor slower than sixty times in a minute, in the latitude of London it must measure 39 inches and about the 7th of an inch from the point of suspension to the centre of oscillation. A pendulum at Edinburgh would require to be a small degree longer. The greatest possible nicety is required in the adjustment of the length, for a difference in extent amounting to the 1000th part of an inch, would cause an error of about one second in a day. Therefore, to make a pendulum go slower by one second a day, it must be lengthened by the 1000th part of an inch; and to make it go quicker, it must be shortened in the same proportion.

It is possible to cause short pendulums to regulate the movement of clocks the same as long pendulums; and this is done in cases where long pendulums would be inconvenient, or inelegant in appearance. This is accomplished by shortening the pendulum to a fourth of its ordinary length, by which it beats or vibrates twice instead of once in a second. The wheel-work is constructed to suit this arrangement.

THE LAWS OF MOTION.

Motion, as al y mentioned, is the changing of place, or the opposite of rest. According to the general explanations which have been given, it appears that motion in bodies is as natural as rest, and that matter passively submits to remain in either of these states in which it may be placed, provided no external force or obstacle interfere to cause an alteration of condition. These and other fundamental laws of nature, in relation to rest and motion of matter, are laid down by Sir Isaac Newton in the following three propositions:—

1st. Every body must persevere in its state of rest, or of uniform motion in a straight line, unless it be compelled to change that state by forces impressed upon it.

2d. Every change of motion must be proportional to the impressed force, and must be in the direction of that straight line in which the force is impressed.

3d. Action must always be equal and contrary to reaction; or the actions of two bodies upon each other must be equal, and their directions must be opposite.

These propositions we shall treat separately. In the first of the series there are three points requiring consideration, namely, the permanency, the uniformity, and the straight line of direction of motion in bodies.

As was formerly observed, it is impossible to show either permanency or uniformity of motion in bodies upon or near the earth; for all moving bodies are sooner or later brought to a state of rest by the force of attraction, friction, and the opposition of the atmosphere. It is only, therefore, in the case of the great works of nature, or planetary bodies, that the laws of motion are most clearly and fully illustrated.

The tendency of a body to move in a straight line from the point whence it set out, is as much a property of matter as the uniformity of motion. If we conceive the idea of a body impelled into a state of motion by any given force, and at the same time conceive the idea that there is no obstacle to interrupt it, no attractive force to bend it aside, we shall then fully understand that a moving body must, as a matter of necessity, from its property of inertia, proceed in a straight line of direction—it must go on in an even path for ever.

CENTRIFUGAL FORCE AND CIRCULAR MOTION.

Bodies in flying round a centre have a tendency to proceed in a straight line, and this principle of motion, as already mentioned, is termed *centrifugal force*. Examples of this tendency are very familiar to our observation. When we whirl rapidly a sling with a stone in it, and suddenly allow the stone to fly off, it proceeds at first sensibly in a straight line, but is gradually pulled to the earth by attraction. In turning a circular grindstone rapidly with water in contact with it, we perceive a rim of water first rising on the stone and next flying off; and the more rapidly we turn the stone, so does the water fly off with the greater force. In grinding corn by two rapidly turning stones playing on each other, the grain poured in at an opening at the centre is quickly shuffled towards the edges of the stones, and expelled in the condition of meal or flower. If we put some water in a vessel, and rapidly turn it in one direction, we shall find that the water endeavours to escape, and rises up to the edges of the vessel, leaving a deep hollow in the middle. The tendency to fly off from a centre is made use of in the manufacture of pottery: Soft clay being placed on a revolving wheel, it quickly spreads towards the circumference of the machine, and is guided or moulded by the hand of the potter into the required form. In forming common crown or window-glass, advantage is also taken of the principle of centrifugal force. A thick round mass of glass, softened by heat and fixed at the middle on an iron rod, being made to turn rapidly round, first in one direction, and then in the opposite, and continuing this alternating rotary motion till the glass becomes cool, is found to spread out into a large, thin, circular plate. From this plate, square panes of glass are afterwards cut.

In the same manner as solid bodies laid on a whirling table are thrown off, so water in a vessel which is caused to spin round in any way, as on the centre of a horizontal wheel, instead of lying at the bottom, is raised all round against the sides of the vessel.

Equestrians, in performing their feats of horsemanship, always incline their bodies inwards when standing on a horse which is running round a circle. Centrifugal force having a tendency to impel them outwards, is thus counteracted by the inward leaning, and forms a species of support to their overhanging bodies. A horse running in a circle, or quickly turning a corner, naturally adopts the same counteracting posture, and leans inwards. A skater, in moving in a circular or curvilinear path on smooth ice, also leans inwards, so much so, that if he were to stand still in this posture, he would inevitably fall on his side; but centrifugal force, which has a tendency to impel his body outwards from the curve, or in a straight line of motion, sustains him, as it does the equestrian, and he therefore moves gracefully and safely in the circular path which his fancy directs. In this and other instances, we find the force of gravity overcome by centrifugal force. It is in obedience to this principle, that the earth bulges out to the thickness of 26 miles upon the circumference at the equator, where the whirling motion is most rapid

Thus, centrifugal force is the tendency to fly off in a straight line, or at a tangent, from motion round a centre; and the power which prevents bodies from flying off, and draws them towards the centre, is, as already mentioned, called *centripetal*, or *centre-seeking* force. All bodies moving in circles are constantly acted upon by these opposite forces, as may be exemplified by the annexed cut, Fig. 7. A is a point to which a string with a ball at the end of it, B, is attached. On forcing the ball B into motion, it will describe a circle round the point A, in which case the string is the centripetal force. The ball in whirling, however, having a continual tendency to fly off, if it be disengaged from the string at C, will go in a straight line, C D; if at E, it will go in the line E F; if at G, in the line G H; and so on, at every point in the circle.

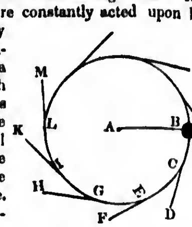

Fig. 7.

The mutual action of centrifugal and centripetal forces, in the case of circular motion, proceeds according to a certain ratio. If the mass of the revolving body be increased, its distance from the centre and velocity remaining the same, its centrifugal force will be increased in the same proportion. If the distance from the centre be increased, while the mass and the time of revolution remain the same, the centrifugal force will also be increased in the same proportion. If the number of revolutions performed in a given time be twice as many, the distance and mass being unchanged, the centrifugal force will be four times as great; if three times as many, the force will be nine times as great; if four times as many, it will be sixteen times as great; and so on in the same proportion. The masses of the planets, and their distances from the sun, being various, the forces which affect them are also similarly varied.

The line round which a body performs a motion of rotation, is called an *axis*. This axis may be only imaginary, like that of the earth; or real, as the axle of a wheel. The body may revolve about two projecting pins or pivots resting in sockets, in which case its axis is a straight line joining the pivots; or it may turn on a cylindrical rod of small diameter, passing through the body, like a wheel on its axle. It is evident that every point of the body, during its revolution, will describe a circle, the centre of which is a point in the axis of the body.

In the turning of a wheel on its axis, that part which is at the greatest distance from the centre, has the greatest velocity; and at this extremity of the circumference the centrifugal force is greatest. For example, in the representation of a wheel with arms radiating from a centre, Fig. 8, the velocity is greater at the extremity of the arm, at A, than it is at B, half the distance from the centre. But the point B goes round as often as the point A, having a smaller circle to traverse.

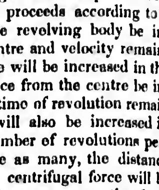

Fig. 8.

In this manner, the velocity of revolving bodies must always, as a matter of necessity, increase in proportion to the distance from the centre of motion. Hence a comparatively small centrifugal force near the centre is prodigiously increased towards the circumference. By increasing the force, and adding to the velocity of a revolving body, the centrifugal force becomes so great that it will in some cases overcome the cohesiveness in the material in the body, and causes it to break and fly off in pieces. When grinding-stones are thus whirled with great rapidity, they are apt to be destroyed, flying in pieces, to the extreme danger of those who are using them.

Bodies movable on an axis of rotation are submitted to different kinds of forces. They are generally distinguished by the duration of their action into instantaneous and continued forces. If the body which sustains an action of the former kind be quiescent and free, it will move in the direction in which the impulse is given with uniform motion. If, however, the force impressed upon it be incapable of setting it in motion, then it receives a shock, the effect of which is called *percussion*. A continued force produces a continued effect. If the body be free and previously quiescent, this effect is a continual increase of velocity. If the body be so restrained that the applied force cannot put it in motion, the effect is a continued pressure on the points or lines which sustain it.

A solid body which is movable upon a fixed axis, is susceptible of no motion, except one of rotation upon the axis. If it be submitted to the action of instantaneous forces, one or other of the following effects must ensue:—1. The axis may resist the forces, and prevent any motion. 2. The axis may modify the effect of the forces, sustaining a corresponding percussion, and the body receiving a motion of rotation. 3. The forces applied may be such as would cause the body to spin round the axis even were it not fixed, in which case the body will receive a motion of rotation, but the axis will suffer no percussion.

What has been just observed of the effect of instantaneous forces, is likewise applicable to continued ones. 1. The axis may entirely resist the effect of such forces, in which case it will suffer a pressure which may be estimated by the rules for the composition of force. 2. It may modify the effect of the applied forces, in which case it must also sustain a pressure, and the body must receive a motion of rotation which is subject to constant variation, owing to the incessant action of the forces. 3. The forces may be such as would communicate to the body the same rotatory motion if the axis were not fixed. In this case the forces will produce no pressure on the axis.

The power of centrifugal force in rapidly whirling bodies, may be rendered so great as to overcome the force of gravity. In whirling a sling with a stone in it, the stone does not fall out of its place in the sling. The following is a more striking example:—Place a jug of water on the inside of the rim of a wheel a few feet in diameter; then, beginning gradually, set the wheel in rapid motion, and it will be observed that the jug retains its place, whirling round in a perfectly stable manner, and that even the water in it is not spilled. Thus, gravity, or the tendency to fall downwards, is overcome by centrifugal force. If the jug were placed in a situation in the wheel, near the centre of motion, where the centrifugal force is weak, it would at once fall to the ground.

LAWS OF PROJECTILES.

Bodies, on being projected by any impulsive forces, are called *projectiles*, and are observed to pursue a curvilinear or bent line of direction in their motion. The bending from the straight line is produced by the force of gravity, and "the change is proportional to the impressed force." A ball projected from a cannon, a stone thrown by the hand, and water spouted from a confined vessel, furnish familiar examples of curvilinear motion.

It is a remarkable law of motion, that whether the force which projects a body be great or small, the body, if thrown horizontally, will reach the surface of the earth from the same height, in the same space of time, not calculating resistance of the air. For example, if two guns are fired from the same spot, at the same instant, and in a horizontal direction, one of the balls falling half a mile, and the other a mile distant, it will be found that the ball which proceeds the greatest distance takes precisely the same time to reach the ground which the other does. The time of flight, as it is called, of two balls will be the same in whatever directions and with whatever velocities they are fired, provided they reach the same height. The reason for the same length of time being occupied in falling by both balls, is, that they are both carried downward at the same rate by gravity. Hence, a ball dropped perpendicularly from the top of a high tower, does not reach the ground sooner than a ball shot from the same height to the distance of one or more miles in a horizontal direction.

In projecting bodies through the atmosphere, great advantage, in point of distance, is gained by impelling them from heights, because a ball thrown from a high situation to a lower, reckoning its whole course, is more aided than retarded by gravity. When the ball is projected from a lower situation to a higher, it is in the first place retarded by gravity in its ascent, and the acceleration afterwards by gravity being less than this previous retardation, it consequently does not go so far, or has not such a wide range, as if projected from a height. Skilful generals, in bombarding towns at a safe distance, take advantage of this law of projectiles.

We are now prepared for the consideration of one of the most important principles in dynamics, namely, the law of motion which governs a body after receiving a projectile impulse.

A projectile exhibits a composition of motion, namely, a horizontal motion forward, when thrown in that direction, produced by the impressed force; and a descending motion, produced by gravity, or the earth's attraction. These two motions are unequal; they are not at the same velocity. The horizontal motion is uniform, while the descending motion, according to the law of gravitation in relation to falling bodies, is accelerated. The consequence is, that the projectile, as already mentioned, pursues a curved line of direction, the convex side of the curve being uppermost.

The degree of curvature of the line of motion depends on the amount of the original projectile force. The law is, the greater the projectile force, or the greater the original velocity of the object, so is the sweep of the curve proportionally greater.

Let us suppose that the projectile force is sufficient to carry a cannon ball ten miles; this will give a very wide curve, allowing that the ball is shot from a lofty situation But let us add to the projectile force, and send the ball double the distance, and the curve is now exceedingly wide. If we in this manner go on adding to the projectile force, we at length give the ball such a motal force, that it will go quite round the world; instead of describing portions of curves, it will describe a whole circle.

This conducts us to a most extensive result. We have at once placed before us a reason why the planetary bodies should have assumed curvilinear paths in relation to the sun. The original projectile force which they received in connection with the force of gravitation, has obliged them to pursue curved lines in their motion; and once being disengaged, they have, by a balance of centrifugal and centripetal forces, continued to travel in circular, or, properly speaking, elliptical orbits—the ellipticity being caused by a want of exact uniformity between the forces which affect them.

ACTION AND REACTION.

We proceed to a consideration of the first clause in the third proposition of Newton—"Action must always be equal and contrary to reaction."

Action is the impression of force. A blow is action; pressure is action. Reaction is resistance; but the word resistance does not fully convey the meaning of reaction, which properly signifies the action of striking or pressing back, even although the body struck or pressed upon do not move. When a man strikes a hammer upon a fixed stone, the stone strikes the hammer at the moment of contact as much as the hammer strikes it. But if the stone be not fixed, and be liable to be easily upset, then its reaction is less, and it acquires a momentum. When a boy throws his ball against the wall of a house, the wall reacts on the ball, and causes it to rebound; but if the boy throw his ball at a pane of glass with the same force, the glass, having the power to resist only a portion of the force, gives way before it. In this case, if we suppose the ball to possess the action or force of 4, and the glass to possess the reaction of 2, the ball passing through the glass loses 2 in its force, and retains the remaining 2. If it then came against another pane possessing a reactive power of 2, it would not break the glass, and, its force being now spent, it would fall to the ground. Thus, "action and reaction are equal."

A story is told of a person who, from his knowledge of the law of action and reaction, betted that he would lie down on the ground and allow an anvil to be placed upon his breast, and that any one might strike the anvil with as much force as he was pleased to exert. In this case, the person who made the offer was quite safe, provided he could support the weight of the anvil; for if a blow were given with the utmost force by a comparatively light body, as a hammer, though it would communicate nearly double its momentum to the anvil, yet the anvil, being so heavy, would acquire so small a velocity that the shock given to the person would be insensible. Were a freestone of the same weight as the anvil used, it would give a still less shock, for the action and reaction of perfectly elastic bodies is twice as great as that of inelastic bodies. Iron has more elasticity than stone.

It is by reaction acting contrary or in opposition to action, that the movements of living objects are rendered effectual. When we walk on the ground, the ground resists the pressure, and we feel ourselves steadied. A bird in flying pushes itself onward by the flapping of its wings against the partially resisting medium of the atmosphere. The partially resisting force of water, in the same manner, allows a fish to propel itself by its tail and fins. A sailor in rowing a boat causes the oars to push against the water, and, the water partially resisting the force, motion is communicated to the boat. In pushing a boat from the shore, the firm ground has such a power of reaction, that we are able to give the boat much greater momentum than if we pushed only against water. If we go into the boat and try to move it, by merely pressing against some part of its fabric, no motion whatever is produced, for the action and reaction are equal. The whole force employed must be rendered greater than the reaction, otherwise no motion can be communicated to the body.

When two bodies come into collision with each other, as in the case of two bodies moving in a straight line, but opposite course, to each other, the law of action and reaction being equal, will not be clearly illustrated, unless the collision be in the direction of the centre of gravity or inertia of the two—in common language, unless the blow be *fair*. The centre of gravity in cases of this kind, is called the *centre of action*, or *percussion*. For example, when we strike a ball with a club, fairly against its side opposite to its centre of gravity, it is impelled to considerable distance; but if we strike it above this central point, a part of the force is expended in vain, or lost, and the ball moves but a comparatively short distance. Experience has demonstrated that the centre of action in hammers should be in the head or striking part; and, therefore, in striking with these instruments, the blow may be given with every advantage. But when an attempt is made to strike with an object in which the centre of action is at a place short of its extreme point, for instance, a common iron poker, a part of the action is expended towards the hand of the person who strikes, and he feels a disagreeable jarring sensation in his arm.

This definition of the centre of action applies only to the motion of bodies in a straight line. In the case of revolving bodies, the centre of action or percussion is a point in it, to which if an immovable obstacle be applied, the body will remain at rest without any tendency to move in any direction, and the axis will receive no shock. In straight rods, or bodies of any form, suspended as pendulums, the centre of oscillation is the same as the centre of action in revolving bodies.

MOTION IN ELASTIC BODIES.

In reference to the effects of collision, bodies are divided into three classes—hard, soft, and elastic. A hard body is one that suffers no change of form by the action of any force. A soft body is one that undergoes a change of form by this means. An elastic body suffers a momentary change of form by the action of any force impressed upon it, and immediately springs back, or recovers its original form. The first two classes are styled *inelastic* bodies.

If two equal inelastic bodies be moving with equal velocities in opposite directions, and come in collision, each will destroy the onward motion of the other, and, consequently, both will be reduced to a state of rest. If there be any elasticity in the bodies, they will, according to their degree of elasticity, rebound from each other, and a positive process of reaction will be exhibited. By this means there will be at once a counteraction and transmission of force. As above stated, when the bodies are perfectly elastic, the action and reaction are double that of inelastic bodies.

An example of the transmission of force or motion from one body to another, while the transmitting bodies remain at rest from their mutual counteraction of the force communicated, may be seen in the case of a row of billiard balls, which possess a certain elasticity. Place six billiard balls in a row on a smooth plane, and let them all be pretty close to each other, or even in contact. Then give a smart blow to the first ball, or, as we may call it, No. 1; it will instantly strike against No. 2, which will communicate the force to No. 3, and from 3 it will be given to 4, and from 4 to 5, and from 5 to 6. None of the balls, however, will sensibly move from the spot in which it rests, except the last of the row, which, having no ball to impinge upon, will roll away, and thus expend the force communicated by the blow upon No. 1. An experiment of this kind is generally performed upon a number of elastic balls of a small size, suspended in a row by threads, as in fig. 9, in which case there is no friction to interrupt the process of action and reaction.

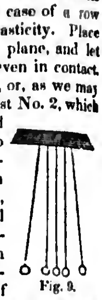

Fig. 9.

REFLECTED MOTION.

A body projected by a single force proceeds in a straight line till a new force act upon it, and send it on a new line of direction. When a moving body is thus impelled into a new line by striking against some body, its motion is said to be *reflected*.

Examples of reflected motion are very common—as, for instance, when a rolling ball encounters an opposing stone in its path, in which case it flies off obliquely in a new direction; when we throw a thin piece of slate along the surface of a river, and make it skip from point to point; or when an apple, in falling from a tree, touches a lower branch in its descent, and rebounds in a slanting direction to the ground.

It is found by experiments, that moving bodies observe certain laws in respect to the line of direction they pursue in rebounding or being reflected from any impediment with which they happen to come in contact. In the accompanying cut, fig 10, the line A B is a level marble slab. C is an ivory ball, which being thrown towards the slab in the direction of C E, is reflected in the direction E D. Thus the two angles F and G are exactly equal; and it is demonstrated, that a perfectly elastic ball striking a smooth wall or floor makes the same angle in leaving the point where it strikes that it does in approaching it.

Fig. 10

Whatever be the angle at which the ball strikes the smooth fixed surface, the same rule will be observed to be followed. This is exemplified in fig. 11. If the ball be dropped perpendicularly from L to K, it will rebound and return to L. If sent in the line H K, it will rebound or be reflected to I. The angle which a ball makes with the perpendicular line in going from H to K, is called the *angle of incidence;* and the angle which it makes in rebounding from the point at K to I, is called the *angle of reflection.* These angles are always equal.

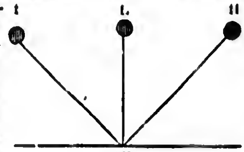

Fig. 11.

A calculation of the angles of reflected motion is necessary in the case of presenting a shield or other object to ward off a missile or blow from the person. If the angle be too acute, that is, if the blow be too point-blank, the shielding object may be damaged, or perhaps destroyed; while if the angle be obtuse, the object which gives the blow will slide off harmlessly.

If a billiard-player strike a ball perpendicularly against the cushion, it will return in the same direction. If, however, he strike the ball at an angle against the side of the table, it will rebound or fly off at an opposite angle. Suppose a ball to be placed half way up the side of an oblong table, and to receive sufficient force in such a direction as would make it strike the centre of the end of the table, the ball will fly off at an angle, and approach the side of the table opposite to that from which it was put in motion. By a knowledge of these laws, the billiard-player often makes a ball fly from one corner, strike the centre of the table, and reach the corner parallel to that from which it was struck. A similar kind of skill is required by those who handle the bat at the game of cricket.

COMPOSITION OF MOTION AND FORCES.

Hitherto we have spoken only of the motion of a body as produced by a single impulsive force, and turned aside or reflected by another force acting upon it; we have now to consider the subject of compound motion and force, or motion and force produced by two or more forces acting on a body in different directions at the same time.

If two or more forces act on a given point of a body, at certain angles, a single force may be found which would produce the same effect. This single force is technically called the *resultant* or *equivalent.* For instance, a wind blowing from the north-west, and a current setting from the north-east, both acting on a ship and tending to carry it with equal velocities in their own directions, the ship will be found to move in an intermediate direction, as if it were acted on by a single force, like a breeze, from due north.

It is usual, in treating of combinations of mechanical forces, to represent them by diagrams, the various lines of which are significant of the quantity or intensity of the forces, of the directions in which they act, and of the effects produced by them. This explains the reason for illustrating the action of forces by the following figures:—

In fig 12, we have an example of motion produced by two forces acting on a body from different directions. A is a ball, which, having received a blow at B, is proceeding onward to C. At the point A, while on its course, it receives a blow equal to the former, which second blow would have been alone capable of carrying it to E in the same time that the first blow would have carried it to C. This new force, by changing the direction of the original motion, causes the ball to move in a line towards F, and the effect is the same as if the ball had been at first sent in the direction of A F by a single force. Practically, it would be difficult to regulate blows with such nicety as to produce this line of motion, but in the theory of forces the law is as it has been stated. The line A F in the figure here drawn is termed the *diagonal of the square.*

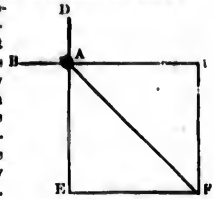

Fig. 12.

Should the constituent forces be of different magnitudes, then the figure described may be a parallelogram, or oblong, as in the annexed cut, fig. 13. The force here, in the direction A B, is double that of the cross force C D, by which means the ball describes a diagonal line to F, and so forms a parallelogram, when we draw all the lines connected with the experiment. The parallelogram thus formed is called the *parallelogram of forces.* The two given forces acting in the directions E B, E D, are called *components,* and the single force in the direction E F is the *resultant.* The process of finding a single force equivalent to two or more forces, is called the *composition of forces.*

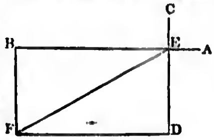

Fig. 13.

The process of finding forces which will produce a motion equal to that of a single force, is called the *resolution of forces.* The following are examples:—

If a boat D E M floating on a river be pressed downwards in the line M C by a current, two forces, P and Q,

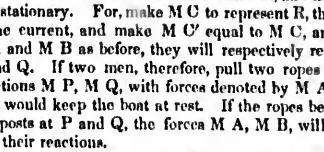

Fig. 14.

acting in the directions M P, M Q, may be found that will counteract the influence of the current, and keep the boat stationary. For, make M C to represent R, the force of the current, and make M C' equal to M C, and find M A and M B as before, they will respectively represent P and Q. If two men, therefore, pull two ropes in the directions M P, M Q, with forces denoted by M A, M B, they would keep the boat at rest. If the ropes be tied to two posts at P and Q, the forces M A, M B, will represent their reactions.

Let H M be a canal boat, M P the rope by which it is drawn by a horse attached to it at P. The force of

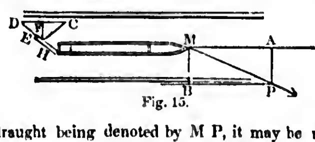

Fig. 15.

the draught being denoted by M P, it may be resolved into M A and M B, of which only M A is effective in drawing the boat forward; the other force M B tends to turn the head of the boat in the direction M B. This last force must therefore be counteracted, which is effected by means of the helm H E turned to an oblique position. When the boat is in motion, the water, being at rest, produces a resistance or pressure against the helm. If C D denote the resistance, it may be resolved into H D and H C, of which H D produces no effect on the helm; therefore C H is the only effective pressure. Again, C H may be resolved into C F and F H, the latter of which tends to turn the stern of the boat in the direction F H, and thus counteracts the force M B, by tending to turn the boat round in an opposite direction; and the part C F tends to move the boat backwards, and thus, counteracting a part of the force M A, it retards the progress of the vessel. The two forces F H, M B, would move the boat sideways, or laterally, to the side of the canal; but this can be prevented by giving the helm a little more obliquity, for, from the length and shape of the vessel, it is much more easily moved in the direction of its length than of its breadth.

Let T P be a ship, S L its sail, W A the direction of the wind and its pressure on the sail. W A can be resolved into A B perpendicular to the sail, and B W parallel to it, the latter of which has no effect in pressing on the sail; therefore A B is the effective pressure on the sail. Were the vessel round, it would move in the direction B A. Let B A be resolved into C A and B C, the former C A acting in the direction of the keel or length of the vessel, or in the direction C A, and the latter perpendicular to it, or in the direction of the breadth. The former pressure C A is the only pressure that moves the vessel forward, the other B C makes it move sideways. From the form of the vessel, however, this latter force B C produces comparatively little lateral motion; any that it does occasion is called *lee-way*. By turning the helm, the vessel may be made to turn round in any direction by the pressure of the water upon it, if the vessel has also at the same time progressive motion.

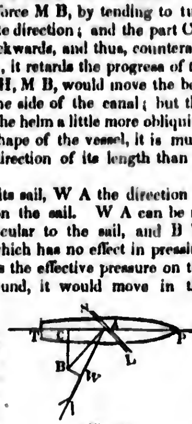

Fig. 16.

COMMON MOTION.

Motion, as has been stated, is called *common*, when participated in by two or more bodies. Thus, all things on the earth, including the atmosphere, have a motion in common with the earth; a person riding in a chaise has a motion in common with the chaise; a person in a moving vessel at sea has a motion in common with the vessel.

For convenience, we shall, in treating of this branch of our subject, use the terms larger and smaller body—the larger being understood to be the body on which the force to produce motion is immediately impressed, and the smaller being the body which is carried along by the body which has received this impression of force.

A large body is in motion; it is moving in a certain direction, at a certain velocity; every thing on it, or small body connected with it, partakes in its motion, and has a tendency to proceed in the same direction, and at the same velocity.

It appears strange that there should be a communication of motion from the larger body to the smaller, without the immediate intervention of impressed force on the smaller, but a little examination shows that such must necessarily be the case. The larger body has received the impulse to move, and this impulse is transmitted through the whole mass of the body, including all the small objects on its surface, and those which are any way connected with it in its propulsion. When a man is walking on the deck of a ship which is moving at the rate of ten miles an hour, he perhaps imagines that he has no more motion than if he were walking on the solid ground. But it would be incorrect for him to think so. His body, and every thing about his person, have received an impulse from the vessel; he possesses a velocity of ten miles an hour as much as the planks of the vessel do, and this onward motion he cannot divest himself of, as long as the ship continues to move at this rate of speed, or as long as he continues in connection with it.

On account of this participation of motion in all bodies moving in connected masses, it is observed that all objects whatever keep their proper places in or about the large moving bodies with which they are in contact, and hence no confusion takes place in the relative situation of objects on the earth by its motion. For example, when we leap from the ground, the earth does not slip away from below us; if we ascend in a straight line of direction, we fall down exactly upon the same spot whence we arose. When a man falls from the top of a mast of a moving vessel, he falls upon the deck upon a spot directly under the point whence he fell; the vessel does not leave him. When we are sitting in the cabin of a moving vessel, and let a small object drop from our hand to the floor, it falls on a point on the floor immediately below, the same as if it had been dropped in a house on solid ground; the floor does not leave it behind. When we are sitting in a rapidly moving coach, and in a similar manner let an object fall, it descends in the same manner to the bottom of the coach. The reason for these phenomena is that already mentioned—the small objects possess a motion derived from the larger; this common motion, or *motal inertia*, as some authors call it, is retained by the small objects during their descent, so that, while descending, they are also going forward; in other words, they display a composition of motion—a horizontal motion and a descending perpendicular motion.

One of the most beautiful examples of common motion, is that which is exhibited by an equestrian standing on a horse which is running round a circle, while he at the same time throws oranges from his hand and catches them in their descent. Notwithstanding his rapid motion, the oranges which are thrown into the air do not fall behind; they return regularly to his hand. To counteract centrifugal force, he leans greatly inward; but this does not alter the law of motal inertia, which causes the oranges to return. He throws them almost sidewise in an inward slanting direction, and yet they come readily back to him. The reason for these phenomena is, that the oranges participate in the forces by which he himself is impelled and sustained.

Small bodies which have derived a motal inertia from a larger, continue to possess this motal inertia after leaving the larger, until they meet with some new impression of force sufficient to alter their condition. If they were not pulled to the earth by attraction, and were not opposed by the atmosphere, they would go on moving in a straight line for ever. When we drop a ball from the window of a moving coach, it continues to go forward as if it were still in the coach, till it meet the ground when it is stopped; thus, its motal inertia is destroyed. If we attempt to leap from a moving body, such as a coach or a boat, we continue to possess the motion which we previously had, until we touch the earth, when we receive a shock by the destruction of our motal inertia. But if we leap from one moving body to another moving body which is going near it, on the same level, in the same direction, and at the same velocity, we sustain no shock, because the body upon which we leap possesses the same condition of motion as that which we possess.

When a man, standing on the ground, shoots at a bird on the wing, he requires to follow its motion by keeping his gun moving when presented at it; but if he be standing on the deck of a ship sailing at the rate of ten miles an hour, and point his gun at a bird flying in the same direction and at the same velocity as the ship, then he placed in the same condition as the bird; he does not require to move his gun, as if following the bird. In taking aim at a bird on the wing from the solid ground, it requires considerable skill to prevent the shot from proceeding to a point behind the bird, because the shot is entirely destitute of motal inertia on being fired, unless it be previously put in motion. But a bullet on leaving a gun which is moving at the same rate as the bird, and in the same direction, keeps going on in the direction of the bird, because it retains the motion it had in common with the gun. The bullet in this case does not go in the direction of the gun, but obliquely, so as to keep up with the motion of the bird, so that the same effect is produced as if the shot had been fired from a fixed gun on land to a fixed point in the air in advance of the bird. Should the bullet be fired from a gun in a moving vessel, for instance a ship sailing westward to a fixed point on land, then a certain allowance must be made for the motal inertia of the bullet; it must be fired a little eastward, and the motal inertia will carry it westward to the object.

Objects falling from bodies moving in an onward direction to those which are at rest, are regulated by the same law that governs projectiles. The falling objects, as formerly mentioned, are affected by two motions—one in a horizontal and the other in a descending direction. When these motions are unequal, the falling body describes a curve in its descent, the convex side of the curve being uppermost. Thus motal inertia and the motion produced by projectile impulse are the same thing; and hence, powerful centrifugal force in the sun, sufficient to disengage a portion of its mass, would be equivalent to a projectile impulse from it as a fixed body.

In consequence of the general participation of common motion in all things connected with a moving body, there can be no consciousness of motion in the living beings carried about by it, provided the motion be perfectly smooth, and there be no means of observing bodies which are at rest. Thus, on account of our possessing a motion in common with the earth, which moves with perfect smoothness, we can neither see nor feel the earth moving. We, however, see the sun, which seems to us to be in motion in reference to the earth, but which, by various means, we know to be at rest; and hence we are assured of the earth's diurnal rotation on its axis, and its annual or planetary motion round the sun. In the same manner, a person sitting in the cabin of a smooth-sailing ship, and not looking out at the windows, cannot, by his mere sensations, tell that the vessel is moving; but if he look at the shore, which is at rest, he is immediately sensible of the progressive motion of the vessel.

In looking from a moving body, as from the earth to the sun, from a ship to the shore, or from a coach to objects on the wayside, a delusive feeling prevails that it is not the body you are upon, but the body which is at rest, that is really moving—going in a direction contrary to that of the body you are connected with. This is in consequence of our possession of motion in common with the moving body. We are under an influence, or in a condition, that renders us incapable of seeing our own motion; and hence the error which the sense of vision leads us to commit, is left to be rectified by an exertion of the understanding.

[WORKS ON NATURAL PHILOSOPHY.

One of the best general views of this subject is Herschell's admirable "*Discourse on the Objects, Advantages, and Pleasures of the Study of Natural Philosophy*," originally published as a part of Lardner's Cabinet Cyclopædia; and reprinted in a cheap form by the Harpers. Among the best works on the history of Natural Philosophy are, Fischer's "*History of Physics since the Revival of Letters*" (in German, Gottingen, 1801, 6 vols.), and Playfair's "*Dissertation on the Progress of Mathematical and Physical Science since the Revival of Letters*," prefixed to the Encyclopædia Britannica, and continued by Leslie. Arnott's "*Elements of Physics*" (Am. ed. with additions by Dr. Hays, Philadelphia, 1829), is a well written and excellent popular treatise. "*The Scientific Class Book*," edited by Walter R. Johnson, Esq., is an excellent compendium. Dr. Reynell Coates's "*First Lines of Natural Philosophy*" (Philadelphia, 1846), is a very ably written popular treatise, illustrated by 264 well engraved embellishments. This book has the advantage of bringing the science down to its present state, and giving the result of all its recent improvements and discoveries. Daniell's "*Illustrations of Natural Philosophy*," and Euler's "*Letters on Natural Philosophy*," edited by Brewster, are highly interesting and delightful works, uniting the attractions of elegant style and great felicity of illustration with thorough scientific knowledge.

In prosecuting the study of Natural Philosophy, the learner will find his progress greatly facilitated by the use of Brande's "*Encyclopædia of Science and Art*," lately reprinted by the Harpers, in which the terms of science are accurately explained and illustrated.—*Am. Ed.*]

MECHANICS—MACHINERY.

GENERAL DEFINITIONS.

THE application of the laws of motion and forces to objects in nature or contrivances in the arts, forms the branch of Natural Philosophy usually treated under the head MECHANICS, MECHANICAL POWERS, or ELEMENTS OF MACHINERY.*

Machines are, under all denominations or circumstances, only instruments through which power may be made to act. They only convey, regulate, or distribute, the force or power which is communicated to them from some source of motion, and never create or generate power. But although a machine does not create power, or give more power than it has received, it practically applies the power which has been communicated to it, in so convenient and easy a manner, that a result ensues almost as surprising as if it had actually generated the whole or a portion of the power it exhibits.

The main purpose required in mechanical operations is to overcome, oppose, or sustain, a certain resistance or force. This purpose is obtained by applying another species of force. According to the usual phraseology, the resistance or force to be overcome is called the *weight*, and the force which is applied is called the *power*.

The ability of applying force by the human hands, without the aid of instruments or machines, is very limited. In almost all our operations of art, it is found necessary to call in the aid of instruments or machines of some kind. All the instruments which mankind have adopted for their use—from the piece of stick with which the savage scratches the ground as a plough, to the most elegantly finished piece of mechanism—act upon certain fixed principles in nature, which a long course of experience and scientific investigation has developed.

The mechanical powers which exhibit the working of these principles, are strictly only three in number, namely,—1. the *Lever*; 2. the *Pulley*, or *Cord*: 3. the *Inclined Plane*. These may be called the Primary Mechanical Powers; and from two of them, the Lever and Inclined Plane, other three are formed, as follow—1. *Wheel* and *Axle*, from the *Lever*: 2. *Wedge*, from the *Inclined Plane*; 3. *Screw*, from the *Inclined Plane*. These may be called the Secondary Mechanical Powers. The six altogether form the elements of every species of machinery, however complex.

OF LEVERS.

The lever is one of the most important and extensively used of all the mechanical powers, and its operation exhibits some of the leading principles in mechanics.

A lever is a rod, or bar of iron, wood, or any other material, which is movable upon or about a prop or fulcrum, or about a fixed axis. It is called a *lever*, from a French word, signifying to raise, and has been applied to instruments for raising or lifting weights.

Three elements contribute to the operation of the lever—the *power*, the *fulcrum*, and the *weight*. The power is the force applied, the fulcrum is the prop or support, and the weight is the resistance or burden to be lifted. The terms *power* and *weight* have merely a reference to the manner in which the machine is used; strictly, both the power and weight are *forces* the same in character and action.

There are three kinds of levers, differing according to the relative situation of the power, fulcrum, and weight. Each of these kinds consists of a straight bar, and in theoretical calculations is supposed to be in itself destitute of any gravity or degree of heaviness. In theory, also, the forces which are applied are supposed to act at *right angles* to the fulcrum.

In the first or most simple kind of lever, "the fulcrum is disposed between the power and the weight." In the second kind, "the weight is disposed between the power and the fulcrum." In the third kind, "the power is disposed between the weight and the fulcrum."

In the first kind of lever, "the fulcrum is disposed between the power and the weight." Figure 1 is an example. A to B is a straight bar, resting on a prop or fulcrum F. From A to F is the long arm of the lever, and from F to B is the short arm. P is the power, or a certain force drawing down the extremity of the long arm at A. W is the weight suspended from the extremity of the short arm at B. The object is to cause P, which is supposed to be a small weight, to balance or overcome W, which is supposed to be a weight much heavier. Practically, the force of a man pressing upon the extremity of the handle of the lever at A, will effect with ease, in lifting the heavy weight W, what it would require a much greater force to accomplish by pressing upon the long arm at a point half way betwixt A and the fulcrum.

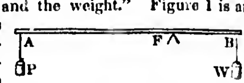

Fig. 1.

This is more clearly exemplified in fig. 2, which represents a lever placed conveniently for raising a square block W, which is the weight. On pressing down the extremity of the long arm of the lever at A, the point of the short arm B raises the block. F is an object lying on the ground to press against as the fulcrum. As in the case of fig. 1, "the force of a man pressing upon the extremity of the handle at A, will effect with ease, in lifting the weight W, what it would require a much greater force to accomplish by pressing upon the long arm at a point half way betwixt A and the fulcrum."

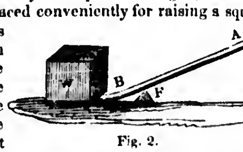

Fig. 2.

The principle in mechanics which produces this phenomenon is very simple, and is explained by what is called the Law of Virtual Velocities, or, from its general application, the Golden Rule of Mechanics.

This law or rule is, *That a small weight, descending a long way in any given length of time, is equal in effect to a great weight descending a proportionally shorter way in the same space of time.* In other words, what is gained in velocity or time, is lost in expenditure of power.

Another way of stating this important law is as follows:—*In the case of equilibrium, if a motion be given to the mechanical power, then the power multiplied by the space through which it moves in a vertical direction, will be equal to the weight multiplied by the space through which it moves in a vertical direction.*

This principle, which applies to every mechanical movement in the case of equilibrium, has been illustrated by a reference to the property of attraction of gravitation. What is called weight is only an effect of

* In scientific works, the term *mechanics* is usually restricted to the action of *solids*, while *mechanical* or *mechanically* is applied to the action of both solids and fluids. For example, the wearing away of stone by the action of the water, is said to be *mechanical action*, or that the water acts *mechanically*.

gravity on the atoms of matter. In figurative language, every atom is drawn towards the earth by an invisible line or cord of attraction; and when one atom rises or falls ten inches, the same quantity of attraction is drawn out from, or sent back to the earth, as if ten atoms were to rise or fall only one inch.

Thus, by a proper mode of applying the power, we may cause a weight of one pound, by moving through a space of ten feet, to raise another weight of ten pounds, moving through a space of one foot; or (the reverse) by a weight of ten pounds moving through the space of one foot, we may make a single pound move through the space of ten feet. But by none of the mechanical powers shall we be able, by moving a weight of ten pounds through one foot, to move a single pound through eleven feet; nor, by a single pound moving through a space of nine feet, shall we be able to raise a weight of ten pounds through one foot.

Neither by the power of the lever, therefore, nor by any other of the mechanical powers, can we make any absolute increase of the power which is applied. In other words, the quantity of power expended in any great and instantaneous effort, is exactly the amount of the power which has been previously accumulated. All that we can do to procure mechanical advantage, is to accommodate the velocity, force, or direction of the applied power, to the purposes which we may have in view.

To apply this principle to the lever: in figs. 1 or 2, a small force at A is equal to double the force exerted at a point halfway betwixt A and the fulcrum, yet, in both cases, the same amount of mechanical power is expended. A slight push downwards at A, by being continued for one minute, is equal to a push of double the force at a point halfway towards the fulcrum, continued for the same time. Any amount of force, therefore, can be exerted with ease at the extremity of the long arm of the lever, provided we choose to make the arm long enough and strong enough.

It may possibly be said that it would be as expeditious to push down the extremity of the long arm of the lever, as to push down the arm at the point nearer the fulcrum. Practically, in small levers this may be the case; but when levers of considerable length have to be used, and a succession of depressions and raisings are necessary, it will be found that more time is spent in working with a long than a short lever. For when the sweep of the lever is inconveniently long, the person using it has to move his body quickly up and down over a larger space, and is sooner fatigued. For this reason, although a boy with a long lever may balance as great a weight as a man with a shorter one, yet, in raising weights successively by it, the boy would be sooner fatigued.

It is a general rule that "the force of the lever increases in proportion as the distance of the power from the fulcrum increases, and diminishes in proportion as the distance of the weight from the fulcrum diminishes." In making calculations to ascertain the proportions to be observed betwixt the power and the weight, regard must be paid to the respective lengths of the long and short arms of the lever. We must also fix what are to be the units of weight and distance, and let them be the same on both ends. If we state inches to be the unit of length of the short arm, inches must be the unit of length of the long arm; and in the same manner, if ounces be made the unit of weight of the short arm, ounces must be made the unit of power of the long arm.

Rule.—Multiply the weight by its distance from the fulcrum; then multiply the power by its distance from the same point; and if the products are equal, the weight and the power will balance each other.

Example First.—Suppose a weight of 100 pounds on the short arm of a lever, at the distance of 8 inches from the fulcrum, then another weight or power of 8 pounds would be equal to this, at the distance of 100 inches from the fulcrum. Because 8 multiplied by 100 produces 800, and 100 multiplied by 8 produces 800—and thus the weight and the power would mutually counteract each other.

Example Second.—Suppose we wish to calculate what power should be employed at the end of the long arm of the lever to balance a given weight at the end of the short arm. We multiply the weight by the length of its arm. This gives us a product; then divide that product by the number of inches in the long arm, and the result or quotient is the power. Thus, a weight of 10 pounds, multiplied by 10 inches as the length of the short arm, gives a product of 100. If the length of the long arm be 20, we find how many twenties are in 100, and there being 5, consequently 5 pounds is the power. In this instance, the mechanical advantage is two to one—that is, the power is twice as small as the weight.

The common spade used in delving in gardens offers a similar example of simple lever power, when employed in raising the earth from its place to turn it over. Fig. 3 represents an equally familiar example, namely, a wood-sawyer or carpenter moving a log of

Fig. 3.

timber from its place, by means of a long pole or beam of wood. Stone masons use a lever of iron of this description, called a crow-bar.

The power of the first kind of lever is frequently seen to operate in machines or instruments having two arms. The most common examples of this nature are pincers, scissors, and similar instruments. In the pair of scissors here represented, the two limbs are seen to be joined together with a rivet at the centre, which is the fulcrum of both.

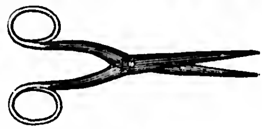

Fig. 4.

A common scale beam for weighing, used by shopkeepers, is an example of the first kind of lever, formed with two arms of equal length, and suspended over the centre of gravity, so that the two extremities balance each other. See fig. 5. S is a string or line suspending the beam A B at a central point F, which is the fulcrum. The point of suspension, or pivot, is sharpened to a thin edge, so as to allow the arms to rise or fall with as little friction as possible when any thing is put in the scales.

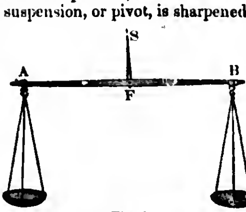

Fig. 5.

There is another kind of balance called a *steelyard*, which consists of a lever with arms of unequal length, and acts upon the principle of distance from the fulcrum on the long arm compensating for weight on the short arm, as already defined. Fig. 6 is a representation of the steelyard balance. C is the fulcrum or pivot by which the beam is suspended, and freely plays as on an axis. A is the short

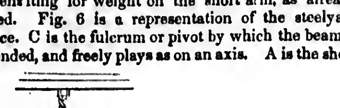

Fig. 6.

arm, and the opposite end is the long arm. W is the scale for the reception of the article to be weighed. The long arm is graduated into divisions by marks, each mark denoting by a figure a certain number of pounds or ounces. P is a weight of a certain heaviness, and being movable by a ring, it can be slipped along the bar to any required point. The same weight is always used, and thus constitutes one of the principal conveniences of this kind of balance. In proportion as the article to be weighed in the scale W is heavy, so is the weight P slipped along to a greater distance from the fulcrum; and when it is brought to a point where it balances the article, the figure on the bar at that point indicates the amount of the weight. If P be one pound, and if, when suspended from the division at 6, it balance the weight at W, it is evident that the weight will be six times P, or 6 pounds. And so on with all the other divisions.

The steelyard, though not so ancient as the common balance, is of considerable antiquity. It was used by the Romans, and has long been in use among the Chinese. Neither the common balance nor the steelyard are suitable for showing the varying weight or heaviness of an article at different latitudes of the earth's surface, because the weights employed are equally affected with the attraction of gravitation and centrifugal force, as the article to be weighed. For this reason, the difference of weight resulting from the causes mentioned, can only be demonstrated by a balance formed of a spring of elastic metal. By suspending the article from the spring, it pulls it out to a certain extent, and so indicates the weight on a graduated scale on the instrument. As the spring acts the same in all latitudes, it serves as a fixed and unalterable power, while the article to be weighed is liable to an alteration in its weight or heaviness according as it is brought near or carried from the equator.

In the lever of the second kind, the weight is placed between the power and the fulcrum, as in fig. 7. The line from A to B is the long arm, B to F is the short arm. W is the weight, and P is the power. The object required by this lever is to lift the weight W by raising the extremity of the lever at A. In this, as in the case of the first kind of lever, the power is increased in proportion to its distance from the fulcrum.

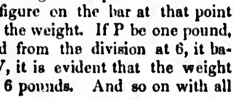

Fig. 7.

Examples of this kind of lever power are common. One of the most familiar is that of a man pushing or lifting forward a bale of goods, as represented in fig. 8, in which the bale or weight W presses against the lever between the power P and the fulcrum F.

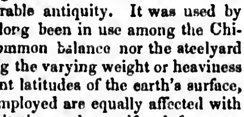

Fig. 8.

Another example of the second kind of lever is that of a man using a wheelbarrow, as represented in fig 9. A point in the wheel of the barrow where it presses on the ground, is the fulcrum. The body of the barrow, with its load, is the weight. And the two handles, lifted or held up by the man, form the power.

Fig 9.

In proportion as the man shortens or lengthens the handles in holding them, so does he increase or diminish the weight he has to sustain.

Two men carrying a load between them on a pole, is also an example of the second kind of lever. The load may either rest upon or be dependent from the pole. In the case of two porters carrying a sedan chair by means of two poles, the load or weight is partly above and partly below the line of the lever. In the case of porters carrying a barrel slung from a pole, as in fig. 10, the weight is altogether below the lever. In both instances the principle is the same. Each man acts as the power in moving the weight, and at the same time each man becomes a fulcrum in respect to the other.

Fig. 10.

If the weight hang fairly from the centre of the pole, each man will bear just a half of the burden; but if the weight be slipped along to be nearer one end of the lever than the other, then the man who bears the shorter end of the pole supports a greater load than the man who is at the long end. The weight increases precisely in proportion as it advances towards him. Sometimes, when a man and a boy are carrying a handbarrow between them, the man, in order to ease the weight as much as possible to the boy, holds by the arms of the barrow near to where they join the loaded part.

In yoking horses to the extremities of cross bars in ploughs, coaches, or other vehicles, care requires to be taken to hook the cross bar to the load at its centre, otherwise one horse will have to pull more than the other.

An inflexible beam resting on supports or fulcra at its two extremities, acts similarly as a lever of the second kind. Should no weight be appended to its centre, the weight of the material itself, when the extension is considerable, will be enough to bend it down, and even to break it. Extended flexible cords or chains are from this cause always bent down in the middle, no power of extension being able to overcome the gravity of the materials, which will give way before they can be rendered perfectly straight. The bended string of a boy's paper kite is an example of this powerful influence of gravity of materials.

The instrument used for cracking nuts (fig. 11) is an example of the second kind of lever with two arms or limbs. The fulcrum is the joint which connects the two limbs; the nut between them is the weight or resistance; and the hand which presses the limbs together, in order to break the nut, is the power. As each limb is a lever, a double lever action takes place in the operation.

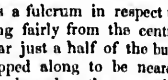

Fig. 11.

The oar of a boat in rowing is a lever of the second kind. The hands of the sailor who pulls constitute the power; the boat is the weight to be moved: and the water against which the blade of the oar pushes, is the fulcrum.

The second kind of lever is sometimes employed as an instrument of pressure. The point of the short arm is, for example, pushed into a crevice or hole in the wall, the fulcrum is the object to be pressed, and at the extremity of the long arm a heavy weight is applied. In this rude but efficacious manner are cheeses pressed in some parts of the country.

In the lever of the third kind, the power is placed between the weight and the fulcrum (fig. 12). The fulcrum is at the extremity of the short arm at F; the weight W is dependent from the extremity of the long arm at A; and P is the power.

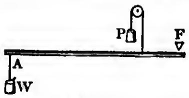

Fig. 12.

In this kind of lever, the power acts with considerable disadvantage, or with small effect; but this disadvantage is compensated by an opposite advantage, which is frequently of great importance in the operations of both nature and art. The advantage consists in the velocity with which a small power will cause the extreme point of the long arm of the lever to move over a great space. This lever, therefore, whether in nature or art, is used only when a great space has to be traversed quickly by the long arm; but in this case the power must always be greater than the weight.

An example of this kind of lever is found in the footboard of the turning-lathe (fig. 13). The foot of the workman presses lightly on the board or plank near the end which rests on the ground, or fulcrum, and causes the opposite extremity of the board to move in a downward direction over a considerable space. A spring over head, or a crank, pulls the board up again by means of a string S; the workman again presses it downward, and so a constant action of the string or cord which works the lathe is easily produced.

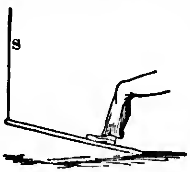

Fig. 13.

A man wielding a flail with two hands, and similar instances of using weapons, are also examples of the third kind of lever action. A similar action was observable when we use fire-tongs; a small motion of the fingers near the joint of the instrument causes the legs, which are two levers, to open or shut over a considerable space.

Before the peculiar advantages of this kind of lever became known, or were appreciated, it was called the *losing lever*.

The movements in the limbs of animals are generally produced by the action of this kind of lever power.

When several levers of the simple kinds are connected together, and are made to operate one upon the other, the machine so formed is called a compound lever. In this machine, as each lever acts with a power equal to the pressure on it of the next lever between it and the power, the force is increased or diminished according to the number or kind of levers employed.

Fig. 14 represents a compound lever, consisting of three simple levers of the first kind, placed in a line, and each working on its own fulcrum. The desired object of the machine is for a small force or power at P, to move or balance a large weight at W. The same rule applies, in calculating the action of this combined lever, which has already been given for the simple lever—namely, "Multiply the weight on any lever by its distance from the fulcrum; then multiply the power by its distance from the same point, and if the products

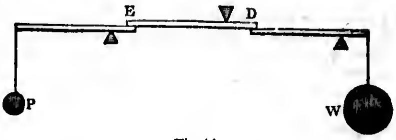

Fig. 14.

are equal, the weight and the power will balance each other." Or, for the form of lever in the figure, "Multiply the length of the long arm by moving the power, and multiply that of the short one by the weight, or resistance."

It is supposed that the three levers in the figure are of the same length, the long arms being six inches each, and the short ones two inches each; required—the weight which a moving power of 1 pound at P will balance at W. In the first place, 1 pound at P would balance 3 pounds at E; we say 3, because the long arm being six inches, and the power 1 pound, 6 multiplied by 1 is 6; and the short one being 2 inches, we find that there are 3 twos in 6, therefore 3 is the weight. The long arm of the second lever being also 6 inches, and moved with a power of 3 pounds, multiply the 3 by 6, which gives 18; and multiply the short arm, being 2 inches, by a number which will give 18; we find that 9 will do so (9 twos are 18); therefore 9 is the weight borne at the extremity of the short arm of the second lever at D. The long arm of the third lever being also 6 inches, and moved with a power of 9 pounds, multiply the 9 by 6, and we have 54; and multiply the short arm, being 2 inches, by a number which will give 54; we find that 27 will do so (twice 27 is 54); therefore 27 is the weight borne at the extremity of the short arm of the third lever. Thus 1 pound at P will balance 27 pounds at W; or 1 ounce at P will balance 27 ounces at W—the proportions being always alike, whatever denomination of weight we employ.

In this instance, the increase of power is comparatively small, because the proportion between the long and short arms is only as 2 to 6, or 1 to 3. If we make the proportions more dissimilar, as 1 to 10, or 1 to 20, the increase of force becomes very great. For example, let the long arms be 18 inches each, and the short ones 1 inch each, and 1 pound at P will balance 18 pounds at A, and the second lever would be pushed up with a power of 18 pounds. This 18 being multiplied by the length of the lever 18, gives 324 pounds as the power which would press down the third lever. Lastly, multiply this 324 by the length of the lever 18, and the product is 5832 pounds, which would be the final weight at W which 1 pound at P would raise.

The following is a general rule for calculating the advantages of a compound lever consisting of any number of levers, whether equal or not:—Call the arms of the different levers next the power the *arms of power*, and the other arms the *arms of weight*; then, if the lengths of the arms of power and the power itself be successively multiplied together, the product will be equal to the continued product of the arms of weight and the weight, when the power and weight are in equilibrium.

A similar result to that of a combination of levers might be produced by only one lever, provided it were long enough, but the operation would be both clumsy and inconvenient. By combining levers, and making them act one upon another, great weights may be balanced within a small compass, and with an exceedingly small power. On this account, machines are constructed with combinations of levers, for weighing loaded carts and other heavy burdens. The cart is wheeled upon a sort of table placed level with the ground, beneath which the levers are arranged; and a small weight placed on a scale attached to the extreme point of the first lever, balances the load, which rests on the table above the last lever. This species of weighing-machine is often to be seen at toll-bars.

In the foregoing examples of lever powers, the levers or bars are supposed to be straight, and the powers and weights, or forces, are supposed to act at right angles with them.

Levers are frequently *bent* in their form, for purposes of convenience, and the powers and weights often act *obliquely*, or not at right angles.

In calculating the mechanical advantage of bent levers, the chief matter of consideration is *obliquity* in the direction of the applied power and weight. Obliquity in the action of the forces generally diminishes the mechanical advantage.

Whatever be the form of the lever, or the direction of the power and the weight, the mechanical advantage of the power or the weight is always represented by *a line drawn from the fulcrum, at right angles to the direction in which the forces are respectively exerted.*

Fig. 15 is a bent lever, with the power of P hanging from A, and the weight W hanging from B. In this case, both the power and the weight act at right angles to an ideal line, drawn as from E to G across the fulcrum, which strikes the lines of direction of the forces at right angles.

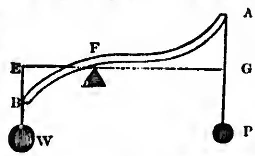

Fig. 15.

OF THE WHEEL AND AXLE.

A lever has been defined to be "a rod or bar of iron, wood, or any other material which is movable upon or about a prop or fulcrum, or about a fixed axis." The illustrations which have been given, show the lever only in its character of a simple bar, which is movable in some part "upon or about a prop or fulcrum." It is now to be shown how it acts when movable upon or about a fixed axis. When a lever is movable upon an axis, and is susceptible of being turned completely round, it assumes the character of the diameter of a wheel.

In fig. 16, the simple rudiments of a wheel are represented. A and B are the two arms of a bar or lever playing upon a fixed axis at F, and which axis is the fulcrum. If we push down A, we raise B, or if we push down B, we raise A. In this manner the situation of the power and the weight is transferable from one end to the other, as in the beam of a common balance, without altering the equilibrium.

Fig. 16.

Fig. 17 is a representation of a wheel in a state more advanced to completion. Here the arms A B are connected with the arms D C, both at the centre F, and by means of the circumference or rim of the wheel. By reason of this union of parts, the central axis at F becomes the common fulcrum for every portion of the wheel; therefore, from the centre to any point of the circumference is an arm of a lever, although the line of that lever be not marked or seen, as in the case of a distinct spoke.

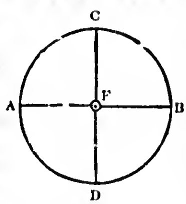

Fig. 17.

A line through the centre from one side of the circumference of a wheel to the opposite side, is a diameter; from the centre to any part of the circumference, is the semi-diameter or radius. The arms or spokes are said to radiate from a centre. The circumference is sometimes called the periphery.

Besides wheels with axes in the centre, there are wheels with axes not in the centre, called eccentric wheels. At present, however, we are treating only of wheels having their axes in the centre.

Wheels with a central axis may be rendered available as levers in various ways, according to the placing of the weight or resistance. The plan commonly pursued consists in giving to the wheel an axle which is fixed to its arms, and placing a weight near the axle or fulcrum, to work against another weight at the circumference.

Thus a machine is formed called the Wheel and Axle, which constitutes one of the simple mechanical powers founded on the lever.

The machine termed the wheel and axle consists of a wheel fixed upon an axle or spindle, which axle turns horizontally on its two ends in upright supports. See fig. 18. The fulcrum of the machine is common to both the wheel and the axle, and is the centre of the axle. A is the wheel, B is the axle, and H is a handle with which the machine may be turned. By turning the wheel, the axle is also turned, and a rope being fixed to the axle, with the weight W hanging at its extremity, the turning of the wheel causes the axle to wind up the rope, and so lift the weight. If, instead of turning the wheel with the hand, we wind a rope round the circumference of the wheel, in a contrary direction from that in which the axle rope is wound, and also hang a weight of a certain heaviness, P, to its extremity, then the draught or pulling of the wheel rope in unwinding, will turn the axle, and so wind up the axle rope with its weight. In this manner, one power works against another, exactly as in the case of the lever. By properly apportioning the two powers in correspondence with the diameters of the wheel and the axle, the one power or weight may be made to balance the other power or weight, so as to produce an equilibrium of the machine.

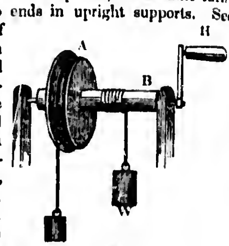

Fig. 18.

The wheel and axle form what is called a *perpetual lever.* Common simple levers act only for a short space, or by reiterated efforts, so as to be adapted for lifting an object from one place to another on the ground. The perpetual lever, formed by the wheel and axle, turns round without intermission, and is therefore suitable for lifting weights attached to a rope, through a considerable space upward from the ground without stopping.

Fig. 19 is a representation of the machine endwise, and shows how the lever operates. The line going across the machine from A to B represents the line of the lever. A is the situation of the power, F is the centre or fulcrum, and B is the situation of the weight; therefore, from A to F is the long arm, and from F to B is the short arm of the lever. In other words, the long arm is half the diameter of the wheel, and the short arm is half the thickness or diameter of the axle.

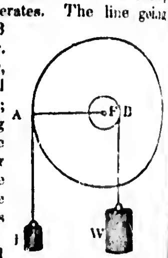

Fig 19

By widening the wheel, and so lengthening the long arm of the lever, the smaller will be the power necessary to overcome the weight on the axle or short arm; but what is gained by this mechanical advantage is lost by the circumstance that the power must descend through a pro pr rtionally greater space in order to raise the same weight through the same space in the same time.

To find what forces will balance each other, let the same rules be followed as those formerly given for the simple lever. Multiply the weight by its distance from the fulcrum (that distance is half the diameter of the axle); then multiply the power by its distance from the same point (that is, half the diameter of the wheel), and if the products be equal, the weight and the power will balance each other. Thus, a power of one pound at or depending from the circumference of a wheel of twelve inches in diameter, will balance a weight of twelve pounds at or depending from the circumference of an axle one inch in diameter.

Note.—No allowance is made in these calculations for the overlaying of the rope in winding, which affects the length of both the long and the short arm; but this is a matter of practical, not of theoretic import.

The principle of the wheel and axle, or perpetual lever, is introduced into various mechanical contrivances which are of great use in many of the ordinary occupations of life. One of the simplest machines constructed on this principle, is the common windlass for drawing water by a rope and bucket from wells. Coal is lifted from the pits in which it is dug, by a similar contrivance, wrought by horse or steam power.

The capstan in general use on board of ships for hauling or drawing up anchors, and for other operations, is an example of the wheel and axle, constructed in an upright or vertical, instead of a horizontal, position. In fig. 20, one of these capstans is represented. The axle is placed upright, with the rope winding about it, and having a head pierced with holes for spokes or levers, which the men push against to cause the axle to turn. This is a powerful and convenient machine on shipboard; when not in use, the spokes are taken out and laid aside.

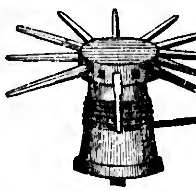

Fig. 20.

An illustration of the wheel and axle, in a combined form, is afterwards given in the case of the crane.

OF CORDS AND PULLEYS.

The pulley, or cord, is one of the primary mechanical powers. A pulley is a wheel, with a groove in its circumference, and is suspended by a central axis. In fixed pulleys, a flexible cord, which is made to pass over and hang from the upper part of the groove, has at one extremity a certain weight to be raised, and at the other extremity a power is attached for the purpose of pulling.

There are two kinds of pulleys, the fixed and movable. The annexed cut, fig. 21, represents a fixed pulley. A is the wheel, B is the beam or roof from which the wheel is suspended. P is the power hanging at one end of the rope, and W is the weight at the other end. This kind of pulley is called a fixed pulley, because it does not shift from its position.

Fig. 21.

The fixed pulley possesses no mechanical advantage. The wheel is merely a lever with equal arms, and therefore the cord which passes over these arms gains no advantage. To raise a pound weight from the ground at the one end of the cord, the power of one pound must be exerted at the other.

The object of the single fixed pulley is not to save power, but to give convenience in pulling. For instance, by pulling downwards, a weight may be raised upwards, or by pulling in one direction, a load may be made to proceed in another. The same object might be gained by drawing a cord over a fixed post or pivot, but in this case the friction of the cord would chafe or injure it; the wheel or pulley is therefore a simple contrivance to prevent friction, for it turns round along with the cord.

The movable pulley is in form the same as the fixed pulley, but instead of being placed in a fixed position from a beam or roof, it hangs in the cord which passes under it, and from it the weight is suspended. In fig. 22, a movable pulley is represented. A is a hook in a beam to which one end of a cord is fixed. B is the movable pulley, under which the cord passes and proceeds upwards to C, a fixed pulley, from which it depends to P, the power or the hand pulling. The fixed pulley C is of no further use than to change the direction of the power. W is the weight hanging from B.

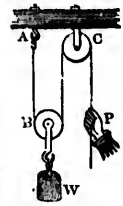

Fig. 22.

The movable pulley possesses a mechanical advantage. The first point to be observed is, that the weight hangs in the cord; second, that the weight presses down each side of the cord equally—that is, it draws as hard at A as at C or P; third, that the consequence of this equal pressure is the halving of the weight between the two ends of the cord. The *halving of the weight* is therefore the mechanical advantage given by the movable pulley.

Example.—If the weight W be ten pounds, five pounds is borne by A, and five pounds by P. The case is precisely the same as that of two boys carrying a basket between them. The basket is the weight, and each boy, with his hand upholding the handle, bears only half the load, whatever it may be. If, instead of holding by the handle, the boys slip a cord beneath it, and each take an end of the cord, the case is the same.

In order to save expenditure of power in lifting weights by pulleys, it is always contrived to cause some inanimate object, as for instance a beam or roof, to take a share of the weight, leaving only a portion to be borne by the person who pulls. But in this, as in all cases of mechanical advantage, the saving of power is effected only by a certain loss of time, or a longer continuation of labour. To lift a weight one foot from the ground, by the movable pulley, a man must pull up the cord two feet; therefore, to lift a weight, it will take double the exertion to draw it up a given height in a given time without the pulley, than it would require with the intervention of the pulley.

As the power which a man can exert by his hands, is able to overcome a weight greater than the weight of his own person, this circumstance may be taken advantage of in a very peculiar manner, through the agency of the fixed pulley. As represented in fig. 23, a man may seat himself in a loop or seat attached to one end of a cord, and passing the cord over a fixed pulley above, may pull himself upwards by drawing at the other end of the cord. By adding a movable pulley and another fixed pulley to the apparatus, the exertion of pulling would be diminished one half. An apparatus of this nature, having two fixed pulleys and one movable pulley, is used by house masons and other artisans, in making repairs on the fronts of buildings.

Fig. 23.

The principle upon which pulleys act, is the distribution of weight throughout the different portions of the cord, so as to lessen the power necessary to be exerted by the operator. And along with this principle is the changing of the direction of the power for the sake of convenience in pulling.

According to ordinary language, the mechanical power of which we are treating is called the power of the pulley; but, in reality, as has been just shown, the pulley has no power in itself. The power of the machine is in the cord. *It is in the equal tension of the cord through its whole length, by which the weight is distributed upon intervening points, that the machine offers any mechanical advantage.*

In all cases in which cords are drawn tightly, so as to hold objects in close contact, the same species of power or mechanical advantage is exemplified. For instance, in drawing a cord in lacing, or a thread in sewing, this distribution of power is observable. If all the power which is distributed throughout the sewing of a single pair of strong shoes, were released and concentrated in one main draught, it would, in all likelihood, be a power sufficient to lift one or two tons in weight.

Technically, the wheel of a pulley is called a *sheave;* for protection and convenience this sheave is ordinarily fixed with pivots in a mass of wood called a *block;* and the ropes and cords are called a *tackle.* The whole machine, fully mounted for working, is termed a *block and tackle.* By causing a wheel and axle to wind up the cord of a block and tackle, the power of the lever is combined with that of the pulley in the operation.

There is no assignable limit to the power which may be exerted by means of pulleys. The machine may be constructed to raise with ease any weight which the strength of materials will bear, provided the combination is not so complex as to exhaust the power by the friction produced.

The power of pulleys is increased by a combination of wheels or sheaves in one tackle. There are different kinds of combinations or systems of pulleys. In some there is only one fixed pulley, and in others there are several.

The following are examples of different combinations of pulleys:—

Figure 24 represents a compound system of pulleys, by which the weight is distributed through four folds of the same cord, so as to leave only a fourth of the weight, whatever it may be, to be raised by the operator. In this illustration, the cord number 1 bears one-fourth of the weight; the cord number 2 bears a second fourth; the cord number 3 bears a third fourth; and the cord number 4 bears a fourth fourth. Here the mechanical advantage ceases. For although the cord number 4 passes over the topmost fixed pulley down to the hand of the operator, no more distribution of power takes place; this topmost pulley being of use only to change the direction of the power. The person who pulls has thus only a quarter of the weight to draw. If the weight be one hundred pounds, he has the labour of pulling only twenty-five pounds.

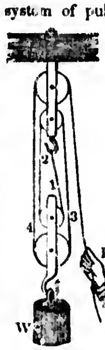

Fig. 24.

Thus it is observable that the diminution of weight is in proportion to the number of movable pulleys. To calculate the expenditure of power or diminution of weight, therefore, we have only to multiply the number of movable pulleys by two, and the product shows the power to be exerted. Two movable pulleys multiplied by two, gives 4; therefore a fourth of the weight is the power required, and so on. The addition of a single movable pulley to any system of pulleys, at once lessens the apparent weight one-half, or, in other words, doubles the effect of the power; but every such addition causes more time to be spent in the operation, there being at every additional fold of the cord more cord to draw out, and also more friction to overcome.

In the annexed system of pulleys, Fig. 25, a series of movable pulleys, with different cords, are made to act successively on one another, and the effect is doubled by each pulley. At the extremity of the first cord, a power of one pound depends. This cord, marked 1, by being drawn below a movable pulley, supports two pounds—that is, 1 pound on each side. The next cord, marked 2, in the same manner supports four pounds, or 2 pounds on each side. The next cord, marked 4, supports 8 pounds, or 4 pounds on each side. Thus, 1 pound at P supports 8 pounds at W. If another movable pulley were added, the 1 pound at P would support 16 pounds, and so on.

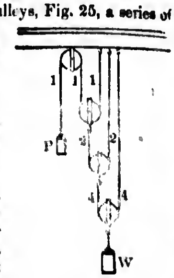

Fig. 25.

In working pulleys, the power must be applied in a line perpendicular to, or parallel with, the weight; that is, straight above the weight, in order to produce the full efficiency of direct force. If the power be applied obliquely —do not draw fair up—there will be a loss of power in proportion as the line of draught departs from the perpendicular.

Pulleys are used chiefly on board of ships, where blocks and tackle are in constant requisition for raising and lowering the sails, masts, and yards. They are likewise in considerable use by house-builders and others, in connection with the wheel and axle, for raising or lowering heavy masses of stone and other articles.

Fig. 26 is a representation of a system of pulleys, commonly used in practical operations. Three movable pulleys are enclosed in the block A, and three fixed pulleys are enclosed in the block B. Suppose, therefore, that the weight W, in this case, is six hundred pounds, the hand P pulls it upwards by exerting a force of one hundred pounds. A combination of pulleys resembling this is used in turning kitchen jacks. The weight in sinking draws off the cord from a spindle, by which motion the jack is turned. In order that a considerable weight falling slowly through a comparatively small height may keep the jack in motion for a long time, as many as ten or twelve movable and fixed pulleys are used.

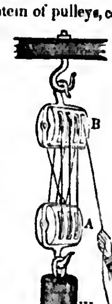

Fig. 26.

OF THE INCLINED PLANE.

A horizontal plane is a plane coinciding with that of the horizon, or parallel to it; when the plane is not level or horizontal, but lies in a sloping direction, with one end higher than the other, it is said to incline, or is called an inclined plane. Fig. 27 is an example.

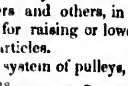

Fig. 27.

The inclined plane, as already stated, is a primary mechanical power. The object which is accomplished by it is the raising of weights to considerable elevations, or the overcoming of resistance by the application of lesser weights and resistances; or, making a small power overcome a greater.

To raise a load of a hundred pounds to an elevation of fifty feet by a direct perpendicular ascent, and without using any mechanical advantage, the power exerted must be a hundred pounds, or equal to the weights to be overcome. If, instead of raising the load directly upwards, we raise it by the gradual ascent of an inclined plane, the power required is less than a hundred pounds, and the diminution is in proportion to the smallness of rise in the inclined plane. But this saving of power, as in all other instances of mechanical advantage, is accomplished only by a corresponding loss of time.

In drawing a load, as, for instance, a loaded carriage, along a horizontal plane, the resistance to be overcome is chiefly the friction of the load upon the plane. If there were no friction or impediment from inequalities of surface, and if the load were once put in motion, it would go on moving with the smallest possible expenditure of power.

In drawing a load up an inclined plane, ordinary friction has to be overcome, and also the gravity of the body, which gravity gives it a tendency to roll down to the lowest level. In this constant impulse to descend, it is not at liberty to pursue the same line of descent as bodies falling freely from heights. It falls or rolls down as much less speedily than a free falling body (omitting the loss by friction) as the length of the inclined plane is greater than its height. A freely descending body falls about 16 feet in the first second; and a body rolling down an inclined plane, rolls just as many feet the first second as the number of feet of inclination is in sixteen feet. If the inclination be one foot in sixteen, the body rolls down one foot, and so on.

Any body in being drawn up an inclined plane, by a power parallel with the plane, presses at right angles with the plane. The common expression is, that the reaction of the plane upon the object is perpendicular to the plane. When an object, as a ball, rests upon a horizontal plane, its pressure is at right angles with the plane; or, what is the same thing, the reaction or resistance of the plane is at right angles with it. This is seen in Fig. 28, in which a ball is represented lying on a level plane, with the line of pressure A passing down to B, which line is at right angles with the plane.

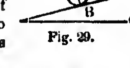

Fig. 28.

Suppose, then, that the end of the plane at C is elevated to D, as in Fig. 29, so as to form a slope; in this case the line of pressure of the ball on the plane is also moved, so as still to be at right angles with the inclination.

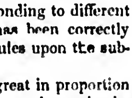

Fig. 29.

The power which is required to be sustained for the purpose of overcoming friction or inequalities of surface on level planes, is for the purpose of drawing the load up or over the inequalities.

The amount of the power corresponding to different weights and inclinations of the plane has been correctly ascertained, and the following are the rules upon the subject:—

First.—The quantity of weight is great in proportion to the inclination of the plane; consequently, so is the difficulty of raising greater, and the rate of elevation or motion slower.

Second.—To overcome the weight or resistance and the slowness of movement, a corresponding increase of power must be given.

Third.—The smaller the inclination, so is the pressure of the weight on the plane the greater.

Fourth, or Special Rule of Calculation.—Whatever is the unit of inclination in a given length, the same is the unit of weight that can be lifted, and the unit of power to be exerted.

If the inclination of a road be *one* foot in ten, *one-tenth* is called the unit of inclination; hence, *one-tenth* part of the nominal weight of the load has to be lifted; and a power to draw this one-tenth part of the load has to be exerted. Or, to put the case in other words:—If the road rise one foot in ten, there is in the ten only one foot of perpendicular height to be lifted through; and the weight at any point of the ten feet is only a tenth of what it would be if it were to be lifted through a perfect perpendicular ascent of ten feet.

The reason is now perceived why a small power overcomes a greater in the case of draughts upon inclined planes. The load is, as it were, lifted by instalments. Partly supported as it advances, and always supported more completely the smaller the inclination, the weight of the burden is apparently lessened by merely taking the rise gradually and slowly.

If we suppose a case of two roads, the first rising one foot in twenty, and the second rising one foot in fifty, a loaded carriage will be found to go over the fifty feet of the one with precisely the same expenditure of power that would be required to make it go over the twenty feet of the other—that is, always providing that friction and other circumstances are alike.

Figure 30 represents a supposed case of two inclined planes of the same height, but different slopes, meeting together at the top, with a weight resting on each, P and Q, hanging by a string, which passes over the pulley M. If the length of the longest plane from A to M be two feet, and that of the shorter from B to M be one foot, then two pounds at Q, on the short side, will balance four pounds at P, on the long side, and so on in this proportion, whether the planes be longer or shorter.

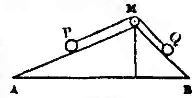

Fig. 30.

In this manner, weights moving on two adjoining inclined planes may be adjusted so as to balance each other, although the inclinations be different; and they are so made to act on various sloping railways connected with public works, where one wagon descending on one plane is made to draw up another wagon on another plane.

An inattention on the part of our forefathers to these exceedingly simple principles of mechanical science, led them to form roads over steep hills, pursuing, as it was imagined, the best routes, because they were the straightest in a forward direction. In modern times, this error has been avoided by enlightened engineers, and roads are now constructed with as few risings and fallings as possible. When roads have necessarily to be carried to the summits of heights, they are very properly made either to wind round the ascent, or to describe a zig-zag line of direction.

The drivers of carts are aware of the saving of labour to their horses by causing them to wind or zig-zag up steep roads instead of leading them directly forward.

The inclined plane is resorted to for a saving of labour in many of the ordinary occupations of life. By it loaded wheelbarrows are with comparative ease wheeled to considerable elevations in house building and other works of art; hogsheads are rolled out of or into wagons, and ships are launched into or drawn from the water, the inclined plane being as useful in giving facilities for letting down loads as in drawing them up.

It is also by inclined planes that we reach the higher floors of a house from the ground, or attain other elevations. For all such purposes, the inclined plane is formed with steps to ensure our safe footing. All stairs or flights of steps are inclined planes. A ladder forms a steep inclined plane.

OF THE WEDGE.

The inclined plane has been described as being fixed or stationary, as, for instance, a common ascending road, or a sloping plank, upon which the weights are moved. It has now to be viewed as a *movable plane*, in which form it suits many useful purposes.

When an inclined plane is movable, and the load or weight which it affects is at rest, it receives the name of a wedge. The wedge is, therefore, a mechanical power, founded on the principle of the inclined plane.

The wedge is an instrument or simple machine, consisting of a solid body of wood, iron, or some other hard material, and is triangular in form. See Fig. 31. Here the wedge is seen to taper from a thick end or head at B to a thin edge or point at A. This, however, is only the more common form of the wedge. It is made with sides of various angularities or degrees of slope, and, in some cases, it possesses a flat and a sloping side. When it slopes on both sides, it consists of two inclined planes joined together; and when one of its sides is flat, it acts as only one inclined plane. The wedge is employed as an instrument for cleaving solid masses asunder, to compress bodies more closely together, and to move great weights through small spaces. Fig. 32 is a front view of a wedge in the act of splitting asunder a piece of timber. The power employed to force the wedge forward, is either repeated blows with a mallet or hammer, or the gradual pressure of a weight. In general, the power is applied by rapid strokes, or quick applications of some kind of external pressure.

Fig. 31.

Fig. 32.

The rules for calculating the power of the wedge are similar to those for the inclined plane. In proportion as the inclination or angularity is great, so is the resistance greater, and the power must be greater to overcome it. Thus, if the wedge be of short dimensions and thick at its head, it will require a greater power to move it than if it be long and thin in its form.

The resistance offered to the wedge of equal sides, when the pressure is equally applied, is, as in the case of the inclined plane, at right angles with the sides. See fig. 33, in which the oblique cross lines represent the direction of the pressure passing at right angles through the sides, and meeting at the centre.

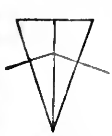

Fig. 33.

It is difficult to calculate the precise power of the wedge, for much depends on the force or the number of blows which may be given to it, together with the obliquity of the sides, and the power of resistance in the object to be split. In the splitting of timber, for instance, the divided parts act as levers, and assist in opening a passage for the wedge.

The wedge is the least used of the simple machines, but the principle upon which it acts is in extensive application. Needles, awls, bodkins, and driving nails, are the most common examples. Knives, swords, razors, the axe, chisel, and other cutting instruments, also act on the principle of the wedge; so likewise does the saw, the teeth of which are small wedges, and act by being drawn along while pressed against the object operated upon.

The principle of the inclined plane, which is the basis of that of the wedge, is particularly observable in the action of the razor and the scythe, both of which cut best by being drawn along the materials against which they are applied. When the edge of a scythe or razor is examined with a microscope, it is seen to be a series of small sharp angularities of the nature of the teeth of a saw.

The principle of the wedge operates in the case of two glass tumblers, one placed within the other, as in fig. 34. A very gentle pressure applied to the uppermost tumbler would be sufficient to burst the lower. At every little advance of the uppermost tumbler, it acts more and more as a lever power on the rim of the lower, and at last overcomes the resistance, and fractures the vessel.

Fig. 34.

OF THE SCREW.

The screw is the fifth, and usually the last mentioned mechanical power. Like the wedge, it is founded on the principle of the inclined plane.

The screw consists of a projecting ridge winding in the form of an inclined plane, and in a spiral direction, round a central cylinder or spindle, similar to a spiral rod winding round a precipitous mountain. Fig. 35 is a representation of a common strong screw used in various mechanical operations. The projecting ridge on the spindle is technically called the *thread*. The thread is not always made in this square projecting form; it is frequently sharpened to a single thin edge, as in fig. 38, but does not affect the principle of the machine.

Fig. 35.

One circumvolution or turn of a thread of a screw is, in scientific language, termed a *helix* (plural *helices*), from a Greek word signifying winding or wreathing. The spiral winding of the thread is called the *helical line*.

The helices of a screw do not necessarily require to have a central spindle. They may form a screw of themselves, and do so in the case of the common corkscrew (fig. 36). A screw of this pointed or tapering form, in penetrating a substance, possesses the advantage of the inclined plane in three ways—first, by the gradual thickening of the substance of the thread from a sharp point; second, the gradual widening; and, third, the gradual ascending, of the thread.

Fig. 36.

The screw acts on the principle of the inclined plane, and this is obvious from the consideration of the nature of the threads. If we were to cut through the turns of the threads straight from top to bottom, and draw them out to their full extent, each separate and retaining its own inclination, we should find that they were so many inclined planes. In the annexed cut, fig. 37, one entire turn of the thread is thus drawn out, reaching from *b* to *a*, and is seen to form an inclined plane. If not drawn out it would wind down to *c*; therefore, while a weight is raised by one turn of the screw over the limits of one thread, or from *c* to *b*, it has actually been carried up the inclined plane from *a* to *b*.

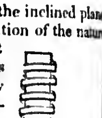

Fig. 37.

The screw has no power by itself. It can operate only by means of pressure against the threads of another screw which overlaps it and holds it. This exterior screw, which is technically called a *box* or a *nut*, consists of a block with a central tube cut out in spiral grooves so as to fit with perfect exactness to the screw which has to work in it. Fig. 38 represents both screws in combination. M is the box or nut through which the screw passes. L is a lever inserted in the head of the screw, for the purpose of turning it.

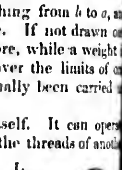

Fig. 38.

The object required by the use of the screw is to apply force or pressure. To produce the intended effect, either the outer or inner screw, that is, either the nut or the screw, must be fixed. If the screw be fixed at one extremity, say at the top, to a solid body, the nut may be turned round it so as to move from the bottom to the top; and if the nut be fixed, held fast by some solid body, the screw in the same manner may be turned round till it reach its extremity. Thus, either the point of the screw, or the nut, may be forced in such a way as to squeeze or press any object presented to them.

Practically, the screw is never used as a simple machine; the power being always applied by means of a lever, passing either through the head of the screw, or through the nut. The screw, therefore, acts with the combined power of the lever and inclined plane; and, in investigating the effects, we must take into account both these simple mechanical powers, so that the screw now becomes really a compound machine.

In the inclined plane, as has been seen, the less it is inclined, the more easy is the ascent, though the slower is the process of rising to a certain elevation. In applying the same principle to the screw, it is obvious that the greater the distance is betwixt the threads, the greater or more rapid is the inclination, and consequently, the greater must be the power to turn it under a given weight. On the contrary, if the thread inclines downwards but slightly, it will describe a greater number of revolutions in a given space, so as to diminish the distance betwixt the threads, and the smaller will be the power required to turn the machine under a given weight. Therefore, the finer the screw, or the nearer the threads to each other, the less the power will require to be for a given resistance.

Suppose a case of two screws, one having the threads one inch apart, and the other half an inch apart; then, the force which the first screw will give with the same power at the lever, will be only half that given by the second. The second screw must be turned twice as many times round as the first, to go through the same space. At the lever of the first, two men would raise a weight to a given height, by making one revolution; while at the lever of the second, one man would raise the same weight to the same height, by making two revolutions.

It is apparent, that the length of the inclined plane up which a body moves in one revolution, is the circumference of the screw, and its height the interval between the threads. The proportion of the power would therefore be—"as the circumference of the screw is to the distance between the threads, so is the weight to the power." By this rule, the power of the screw could alone be found, provided the action of the machine was not affected by the lever which works it. As that is the case, the circumference described by the outer end of the lever employed is taken instead of the circumference of the screw itself.

The rule by which the true force of the screw is calculated, is, by multiplying the circumference which the lever describes by the power. Thus—*The power multiplied by the circumference which it describes, is equal to the weight or resistance multiplied by the distance between the two contiguous threads.* Hence, the efficacy of the screw may be increased, by increasing the length of the lever by which it is turned, or by diminishing the distance between the threads. If, then, we know the length of the lever, the distance between the threads, and the weight to be raised, we can readily calculate the power; or, the power being given, and the distance of the threads, and the length of the lever known, we can easily find the weight which the screw will raise.

Suppose the length of the lever to be forty inches, the distance of the threads one inch, and the weight 8000; required—the power, at the end of the lever, to raise the weight. The lever being 40 inches, the diameter of the circle which the lever describes is double that, or 80 inches. Reckoning the circumference at thrice the diameter (though it is a little more), we multiply 80 by 3, which gives 240 inches for the circumference of the circle. The distance of the threads is one inch, and the weight 8000 pounds. To find the power, multiply the weight by the distance of the threads, and divide by the circumference of the circle.

$$\begin{array}{r} 8000 \text{ weight} \\ 1 \text{ distance} \\ \hline 240)8000 \\ \hline 33\frac{1}{3} \end{array}$$

Thirty-three and a third is the product, and it would require that power or number of pounds to raise the weight. This, however, is only in theory. In practice a third of the amount of power would require to be added to overcome the friction of the machine.

In the ordinary working of the screw, velocity is incompatible with great power. This is a truth, however, which applies only to a screw with one thread. There is a way of making a screw, by which great velocity and power may be combined. This is done by forming the screw with two, three, or more threads. To understand how this is accomplished, we have only to conceive the idea of a screw with one thread, very wide betwixt its turns, and then imagine one or two other threads placed so as to fill up the intervals; thus composing a fine close screw. And as by this means all the threads descend with equal rapidity, we have a screw which will not only descend with great velocity but which will apply a very great degree of pressure. A screw of this nature is used in the printing press, by which a pressure of a ton weight is applied instantaneously by a single pull of a lever.

The most common purpose for which the screw is applied in mechanical operations, is to produce great pressure accompanied with constancy of action, or retention of the pressure; and this quality of constancy is always procurable from the great friction which takes place in the pressure of the threads on the nut, or on any substance, such as wood, through which the screw penetrates.

The common standing-press used by bookbinders for pressing their books, affords one of the best examples of the application of the screw to produce great pressure (fig. 39). The screw A has a thick round lower extremity B, into holes in which the lever is inserted. This extremity B is attached by a socket joint, to the pressing-table C, so that when the screw is turned in one direction, the table sinks, and when turned in another, the table rises. The books D lie upon a fixed sole S, and are thus between the table and the sole. H is a cross beam above, in which is the box or overlapping screw to give the necessary resistance.

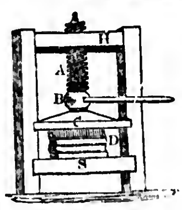

Fig. 39.

MECHANICAL COMBINATION AND STRUCTURE.

Mechanical action is applied to the action of forces that produce no change in the constitution of bodies, and is therefore distinguished from chemical or any other species of action, in which change of constitution is less or more effected.

Great changes are continually taking place in nature and art by mechanical action. Mechanical action generally implies movement or change of place, and is most cases alteration of external features and circumstances. The whole of the planetary movements are mechanical; the motions of water and winds are mechanical; and the new appearances produced in art by placing different objects together, are mechanical.

The action of forces upon solids, or mechanical action, is taken advantage of by mankind for the production of numerous useful results in the arts. And success in attaining these results depends in a great measure upon the knowledge we have of the principles of mechanics, and the skill and care we use in applying them.

When skill, care, and ingenuity, are brought fully into operation for these results, very great wonders are in many instances achieved. But where ignorance or negligence, the object in view may not only be defeated, but very mischievous consequences may take place.

Example first.—If a tall mast or beam break through at two-thirds of its height, and the two fractured ends be simply placed together and tied with a rope, the upper piece will, by the action of a small force, again fall. It will act like *the arm of power of a lever* against the rope, which is the *weight;* and as this weight is inconsiderable, the arm of power will preponderate. But if we take the two pieces and saw each of them lengthwise, so as to make four pieces, and then, as represented in fig. 40, lay a short piece alongside of a long piece, and another long piece on the top of the first short piece, with the second short piece opposite to this second long piece, the whole will be effectually *spliced* together; in such a case, with the aid of an overlapping rope, the beam will in all likelihood be stronger than it was before it was fractured. The cause of its being stronger, at least of its remaining firm, is, that the weaker part at one side is supported by a stronger part on the other side. Thus by skilfully taking advantage of certain forces acting in connection with solids, we are able to rear a structure of the utmost possible strength.

Fig. 40.

Example second.—If a man, in making repairs upon the outside of a building, project a plank from a window for the purpose of standing upon it, and if he proceed to place himself near the outer extremity of the plank, without having placed a sufficient counterbalancing weight at its inner extremity, he will assuredly be precipitated to the ground, and perhaps killed; because the *gravity* of his body acted like a *power* on the arm of a lever, while the lever was without a sufficient *weight* to preserve the apparatus in equilibrium. From such neglects of the operation of forces in nature, dreadful consequences frequently ensue.

The study of the operation of mechanical forces, along with experience, teaches that there are certain bulks, positions, and forms of bodies, which produce the greatest strength for purposes of art.

The strength of beams or masses of the same kind and bulk, and fixed in the same manner, in resisting a transverse force which tends to break them, is simply as their breadth, as the square of their depth, and inversely as their length—that is, the thicker and shorter they are, they are the stronger. Thus, if a beam be twice as broad as another, it will also be twice as strong; for the increase of breadth doubles the number of the resisting particles. By making the beam double the depth, the strength is four times as great; because the number of fibres is double and the lever by which they act is also increased.

But this increase of strength, by increasing bulk, has a practical limit. It is found that in increasing the dimensions of a body, or combination of bodies, preserving all proportions the same, *the weight increases more rapidly than the increase of strength, or power of endurance.* This is one of the most important principles in mechanical science, and ought to prevent undue extension in structural arrangements.

Take a block of stone, and fix one end of it into a wall, leaving its other end projecting. By this arrangement of position, each particle of matter in the block acts as a weight pulling downwards as with a lever, the fulcrum of the lever being at the point of support, and the particles of matter in the mass forming at once the arm of power and the weight. Hence, every particle we add to the length of the block beyond a certain length (whatever may be its constitutional strength), we shall certainly cause the mass to break, and fall, from the effect of gravity, upon the outer extremity.

A similar lever action takes effect in the case of blocks or beams supported on both ends, the only difference being, that, in extending them to an undue length, they will break in the middle, or at the weakest point between the two supports.

The strength of a beam supported at both ends is twice as great as that of a beam of half the length, which is fixed only at one end; and the strength of the whole beam is again increased if both ends or fulcra be firmly fixed, as [illegible].

In the case of fibrous or grained materials, as, for instance, wood, the body sustains the greatest pressure when the weight is applied to the grain endwise, or to the beam longitudinally. The nearer that the pressure can be applied to any beam endwise the better. Thus, a beam supports most weight on its upper end, the other end being fixed to the ground, and its strength is next greatest when the pressure is applied to it leaning at top against another beam. This is exemplified in the angular roofs of houses, in which two beams lean against each other like the two sides of the letter A. In arranging beams to support great weights, as in building bridges, each beam is made to push obliquely upward with one end, while it pushes obliquely downward with the other, and thus an extensive combination of beams is firmly supported.

In rearing structures consisting of beams, it is an important point to convert, as far as possible, by mode of erection, cross or transverse strains into longitudinal strains, or into forces acting on the ends of beams, in the direction of their length.

Nature appears to have designed that strength of structure should be accomplished with the least expenditure of material. It is obvious, that, if trees and animals were made many times larger than we now find them, and of the same kinds of substance, they would be borne down by their own weight. Small animals endure greater comparative violence, and perform greater feats of strength, in proportion to their size, than large ones. The largest bulk which a human being can possess in his person, at the same time retaining activity of motion, is not more than is usually seen in well-grown men. Thus, from a simple natural cause, men of very gigantic figure never could have existed on our earth. Men must always have been about the size which they are at present; or, if they were considerably larger, they must have been constituted of much stronger materials, without a corresponding increase of weight.

The same principles relative to mechanical strength apply to contrivances in the arts. As already stated, the strength or power of endurance in a material does not increase in proportion as the weight increases. Hence there is a practical limitation of the magnitude of machines and other structures. For example, a bridge or roof of beams may be very strong when of small or moderate size, but if the dimensions be extended beyond a certain limit, the structure will fall, by not being able to support its own weight.

The strength or power of endurance of pressure up-fixed body, is greatly increased by giving the body a certain form. The strongest form in nature or art is that of an *arch*.

An arch is a skilful disposition of parts, forming a convex and concave side, the convex side being that upon which the pressure is applied. The arch, which takes its name from *arcus*, a Latin word, signifying a *bow*, may be either a portion of a circle or ellipse, or entirely rounded in form. Whether shaped like a bridge, or round tube, or the shell of an egg, the principle which causes the power of endurance of pressure is the same.

The principle of endurance consists in the particles of the arched body bearing upon each other like a series of wedges, thus causing a compression of particles on the concave side of the circle, which enables the mass to bear an enormous pressure on the convex side. Indeed, the greater the pressure is (to a certain extent), perpendicular to the convexity, so also the compression and power of resistance become the greater.

PRACTICAL MACHINERY.

Machines are usually formed of wood, iron, steel, brass, or other durable materials, with sometimes leather and cordage as part of the apparatus. In the construction of every machine, four objects are particularly desirable —1st, Strength or durability of materials; 2d, Simplicity of arrangement of parts; 3d, Exactness of fitting of one part to another; and, 4th, Easiness and correctness of motion. It is a general and well-recognised principle in mechanics, that the *fewer the parts* are in a machine, and the *more simple its construction*, the better.

Machines act from the impression of a certain power or force communicated to them. Whatever be the amount of power they receive, that amount they expend in their action. They cannot in the smallest degree increase the power. They can only convey, regulate, and distribute, the quantity of power which has been communicated to them.

The power communicated to machines is derived from various sources; as, human labour, the power of horses or other animals, the force of wind, water, or steam, or any other active agent which may be found suitable. Sources of power are technically called *moving forces*, or *first movers*.

Of the original impressed power, each moving part of the machine uses a certain portion. If the whole power which enters a machine be supposed to consist of 1000 parts, this large quantity is dispersed in various small quantities through the mechanism; some wheels taking perhaps 10 parts, others 5 parts, a third kind 1 part, a fourth a fractional part, friction another part, and so on, till the whole 1000 parts are expended. In some large cotton, flax, or silk spinning establishments, a single water-wheel or steam-engine turns several thousands of spindles; each spindle, consequently, consumes a minute fraction of the originally impressed power.

Whatever be the nature of the moving forces, it is generally sufficient for all purposes that they produce in the first instance *rotary* or *circular motion*, and either in a horizontal or vertical direction. It is, however, indispensable that the power be of that magnitude which will cause each part of the machine to fulfil its designed office. If the power be too small or weak, the machine will move languidly and ineffectually; and if too great, it will either cause the machine to move too rapidly, or at least power will be expended uselessly. In the application of moving forces, it is always a matter of importance to regulate the power to the precise wants of the machinery.

The circular motion communicated in the first instance to a machine, is, by means of certain contrivances, diffused through the whole organization, and changed into every conceivable direction; some parts being caused to revolve, others to rise and fall, a third kind to move horizontally to and fro, and so forth, in all possible ways. The various parts may also be made to move with any degree of velocity; there being methods of transforming quick into slow motion, or slow motion into quick. Most minute and complex operations are thus performed by machines with a precision which often exceeds the skill of the most expert artisan; but these operations are all necessarily marked by the quality of *uniformity of action*. As machines cannot reason, or act arbitrarily in stopping, moving, or altering their process, according to circumstances, they proceed in a blind routine, whether right or wrong, *mechanically* as it is called, and in every case less or more require the superintendence of reasoning beings. This apparent defect, however, is really advantageous. A machine, by being composed of inanimate matter, destitute of feeling and unsusceptible of fatigue, proceeds unswervingly in its assigned duty, and may be forced to accomplish tasks which it would be both inhumane and impolitic to demand from living creatures.

The purpose of machinery, therefore, is to *lessen and aid human labour*. At an inconsiderable expense, and with a small degree of trouble in supervision, a machine may be made to do the work of ten, fifty, or perhaps as many as five hundred men; and the work so simply effected by inanimate mechanism, serves to cheapen and extend the comforts and luxuries of life to the great body of the people.

The following are the chief elementary parts of machinery:—

WHEELS.

A wheel moving on a central axis is a lever with equal arms radiating from the fulcrum at the centre, and is thus called a perpetual lever.

Wheels may be used in machines simply to transmit power from one point to another. This is done by means of toothed wheels. Projecting teeth or *cogs* are placed all round the circumference of a wheel, and when the wheel is turned, these teeth work upon or press against the teeth of another wheel, and so cause it to turn also, but in an opposite direction. Fig. 42 represents two wheels so working upon each other. As both of these wheels are of the same size, and consequently are levers with equal arms, they do not alter the effect of the power communicated to them.

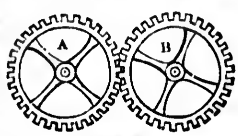

Fig. 42.

The motion of the axle in the wheel B is the same as the motion of the first axle in the wheel A. Thus, power may be *transmitted* from one point to another.

A long and large axle, in wheel-work, is called a *shaft*, and shafts of small dimensions are termed *spindles*. The terminating point of axles, shafts, and spindles, where they rest and turn upon supports, are called their *pivots* or *gudgeons*. The *sockets* upon which the gudgeons bear in turning, are sometimes termed *bushes*

WHEELS AND PINIONS.

When power has to be *accumulated* or increased in its effect in the course of its transmission, a large wheel is made to play upon a small wheel, by which means there is a diversity in the lengths of the levers. Fig. 43 is a representation of a large wheel W, working on a small wheel or pinion P. The wheel is turned by the handle C. In all arrangements in which large wheels are

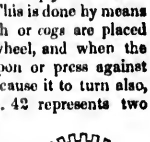

Fig. 43

moved by small wheels, or small wheels by large, the small wheels are called *pinions;* and when these pinions are broad in their dimensions, they are termed *trundles*.

In this combination of a wheel and pinion, a long perpetual lever works against a short perpetual lever, by which a considerable mechanical advantage is gained. The wheel may be supposed to possess 48 teeth and the pinion 6 teeth; hence, by one revolution of the wheel, the pinion turns 8 times, which gives the axle of the pinion eight times the velocity of the axle of the wheel; and if we suppose that the diameter of the wheel is ten times the diameter of the pinion, the power is increased in effect ten times.

Any degree of velocity greater than that of the first rotary motion, may be imparted to the parts of a machine, by making these parts so much smaller than the primary moving parts. Thus, if a large wheel, having a thousand teeth in its circumference, work upon and turn a small wheel having only ten teeth in its circumference, the small wheel will go round one time for every ten teeth of the large wheel which it touches; or in other words, it will go round one hundred times for one time of the large wheel. The respective velocities of wheels in a machine are, in this manner, always proportionate to their diameters, or size, unless when specially arranged to be otherwise.

A combination of wheels acting as perpetual levers, is represented in fig. 44. Three wheels are placed in a row close to each other, and it is supposed they are fixed by three axles to some upright object. On the side of the first wheel A, there is attached a small toothed pinion or wheel F, which, by the pressure of its teeth on the teeth of the second wheel B, causes this second wheel to turn round. The power applied to produce this motion is at the circumference of the first wheel at D. From D then, to the centre of the pinion F, is the long arm of a lever, of which the centre of the pinion is the fulcrum; and from the centre to the ends of the teeth of the pinion is the short arm. The second wheel B having received its motion, the toothed pinion G, which is similarly attached to its side, presses against the teeth of the third wheel C, and so causes it also to turn. In this way a second lever is put in action. And the third wheel, from its circumference to the point from which the weight W depends, is a third lever. As the power or small weight P falls, therefore, from the circumference of the first wheel, the resistance W is raised, with the accumulated force of three levers acting on each other. The line across the figure represents the three levers in action.

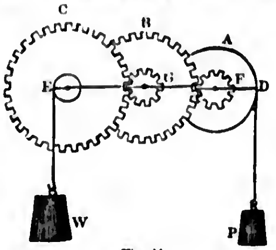

Fig. 44.

To calculate the power or mechanical advantage to be gained by such a machine, suppose the number of teeth on the first wheel to be six times less than the number of those on the circumference of the second wheel, then the second wheel would turn round only once, while the first wheel turned six times. And, in like manner, if the number of teeth on the circumference of the third wheel be six times greater than those on the axle of the second wheel, then the third wheel would turn once, while the second wheel turned six times. Thus, the first wheel will make 36 revolutions, while the third wheel makes only one. The diameter of the first wheel being three times the diameter of the axle of the third wheel, and its velocity of motion being 36 to 1, three times 36 will give the weight which a power of 1 pound at P will raise at W. Three times 36 being 108, one pound at P will balance 108 pounds at W.

WORKING OF TOOTHED WHEELS.

In the working of toothed wheels one upon another, or of wheels working on pinions, it is essential to set them in opposition with such exact adjustment, that the teeth of one will fall into the hollows between the teeth of the other. When the teeth of each do not work with this nicety, they are apt to jar upon and break each other, and so damage the machine. In some cases teeth are made of a round or pointed form at their extremities, by which a very small degree of grinding or pressing on each other takes place. Fig. 45 is an example of a wheel and pinion with rounded and pointed teeth. From the centre of the axis of the pinion L to the centre of the wheel C, a dotted line is marked, called by mechanics the *line of centres*. The dotted circle O O round the pinion, and the dotted circle P P round the wheel, indicate the true point of working or contact of the teeth upon each other. These two circles are seen to join with exactness at A.

Fig. 45.

ALTERING THE DIRECTION OF MOTION.

Motion often requires to be *altered in its direction* in the course of its transmission. For example, rotary horizontal motion requires to impart rotary vertical motion, or rotary vertical motion to impart horizontal motion. By means of a peculiar mode of setting the wheels, and a corresponding peculiarity in the shape of their teeth, any alteration may be effected in the direction of the motion.

Fig. 46 represents a plan of changing the direction of motion. A is a pinion or trundle working with its shaft horizontally on a wheel B, whose shaft is turning vertically. As the case may happen to be, the horizontal movement is causing the vertical movement, or the vertical movement is causing the horizontal movement.

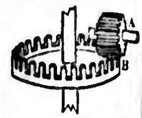

Fig. 46.

BEVEL WHEELS.

Fig. 47 represents a more common plan of changing the direction of motion. The wheels in this case are bevelled. A *bevel* wheel is a wheel with teeth placed in a sloping or oblique direction on its circumference. When two bevel wheels are placed at right angles to each other, their respective teeth work against each other, and so a harmonious joint motion ensues. This is exemplified in the figure, in which a horizontal shaft with a bevel wheel is seen turning a smaller bevel wheel above it, placed on a vertical shaft.

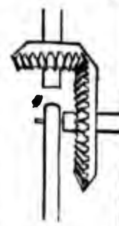

Fig. 47.

TRANSMISSION OF POWER BY BELTS.

A common plan of transmitting power from one point to another, when the interval is considerable, is by a flat leather band, strap, or belt, communicating from a wheel at the source of power to a wheel connected with the machine.

The wheels upon which straps work are usually called *pulleys*. They have flat and broad rims, and these rims have sometimes narrow ledges, to prevent the belt from slipping off. The rims must also be rather rough on their surface, so as to give the belt a sufficient friction or power of pulling in performing its revolutions.

Fig. 48 represents the transmission of power by a belt. A is the first pulley, which has received the power from its source, and C is the second pulley, moved by a belt, which passes over both pulleys. In this case, the motion of A is transmitted by the belt to C, which it causes to turn in the same direction as A. If these two pulleys were of precisely the same diameter, and the belt did not relax or slip, the second pulley would unavoidably go at the same velocity as the first, because the belt has exactly the property of a toothed wheel, and simply transmits the power it has acquired. As C appears to be somewhat smaller than A, it would consequently turn more frequently than A; therefore, we have here an example of the mode of increasing the velocity while transmitting power.

Fig. 48.

SHAFTS AND PULLEYS.

When power requires to be carried to a distance beyond that which belts can conveniently manage, the transmission is effected by a long shaft; and, if it be necessary to change and re-change the direction of the motion, bevel wheels are added. Or the transmission may take place by a long flat chain acting like a belt, but caused to travel over small wheels or pulleys, to prevent the chain hanging down in any part of its course. A chain of this nature is called an *endless chain*.

Motion is often required to be communicated to many different machines, *at different points*, from one source of power. This is effected by means of a shaft and pulleys. From the pulley which receives the first motion, a belt is sent to a pulley fixed upon a shaft, which shaft is generally hung horizontally from the roof over the machines. As the shaft turns through its whole extent, it is able to turn pulleys fixed at any point upon it, and from these pulleys, belts are sent down to pulleys at the respective machines.

Fig. 49 represents an apparatus of a shaft and pulleys. A is the pulley receiving motion from the source of power, and, by means of the belt L, turns the pulley B on the end of the shaft S. At the same time, the pulley D at the opposite end of the shaft is turned. From a pulley on the shaft situated close to B, a belt descends to turn C, and from D another belt descends to turn E. Thus, an extended axle or shaft from C will turn a machine, and an extended axle or shaft from E will turn another machine. The apparatus can turn two machines. Shafts with pulleys, working on the plan now stated, are to be seen at almost every considerable manufactory in which machinery is employed; and the power, by means of bevel wheels and upright connecting shafts, is carried upwards from story to story in a building, giving motion to hundreds of wheels, spindles, and other parts of the mechanism.

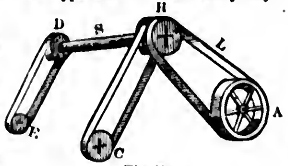

Fig. 49.

CHANGING VELOCITY.

It is sometimes necessary that a machine, or part of a machine, should be propelled with a velocity which is not equable, and is continually changing from fast to slow and slow to fast. This happens in cotton-mills, where it is necessary that the speed of certain parts of the machinery should continually decrease from the beginning to the end of an operation. To effect this, an apparatus is used, as represented in fig. 50. Two cones, or conically shaped drums, are used, having their larger diameters in contrary directions. They are connected by a belt, which is so governed by proper mechanism, that it is gradually shifted along from one extremity of the cones to the other, thus acting upon circles of different diameter, causing a continual change of velocity in the driven cone with relation to that which drives it. The shifting of bands from large to small wheels, and from small to large, has similar effects.

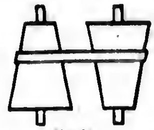

Fig. 50.

PRESERVING REGULARITY OF MOTION BY A VARIABLE FORCE.

In some mechanical contrivances, the force which is applied varies in its intensity, while the wheels of the machinery require to be kept at a uniform speed. This is generally the case when the force is communicated from a steel spring, which, after being wound up, is suffered to relax. Fig. 51 is a spring suited for operations of this kind. It is represented in a state of relaxation, and is wound up into a compact form by means of a spindle fixed to its inner extremity. The coiling of a strip of paper round the finger, and allowing it to unwind itself, is a familiar illustration of the action of a spring of this description.

Fig. 51

The force communicated by the relaxing of the spring varies in its intensity. The force is greatest when it begins to relax, and it gradually weakens till its expansive energy is exhausted. To compensate this defect, a very ingenious plan is adopted, and which is put in operation in the apparatus of the common watch.

Fig. 52 represents the apparatus of motion of a watch, somewhat magnified. The spring is confined in a brass cylinder or barrel B. To this barrel the spring is attached by a slit at its outer extremity. The inner extremity of the spring is fixed by a similar slit to the central axis or spindle. F is a brass cone, broad at bottom and narrow at top, with a path winding spirally round it as an inclined plane. This cone is called the *fusee*, and has also a central axis or spindle K, to which it is fixed. To a point on the lower inclined path of the fusee, a small steel chain C is attached, and the other extremity of this chain is attached to the top part of the barrel. When the spring is relaxed, the chain is almost altogether round the barrel. To set the apparatus in motion, the watch-key is made to turn the spindle K, by which the chain is drawn from the barrel to the fusee, filling up the inclined path to the summit. The chain in leaving the barrel causes it to turn, and consequently to wind up the spring inside. The process of unwinding or relaxing ensues, and now the ingenious plan for regulating the motion is to be remarked. At first, when the force of the spring is greatest, the chain acts upon a small round of

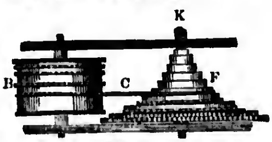

Fig. 52.

the fusee; in other words, it pulls with a small lever—for, as already explained under the head Wheel and Axle, a wheel or round object on an axis is simply a perpetual lever. In proportion as the intensity of the force weakens, and the barrel takes off the chain from the fusee, and winds it about itself, so does the chain act upon a longer lever, or so does it gain a greater lever advantage, by drawing at a wider part of a cone. Thus, the gradual loss of force is counterbalanced by a gradual increase of lever advantage. (The case resembles that of a strong man working with a short lever, and a weak man working with a long lever; both are equal in effect in balancing any resistance.) The wheelwork of the watch is moved by teeth on the lower circumference of the cone.

ALTERNATE OR RECIPROCATING MOTION—ECCENTRIC WHEELS.

Alternate or reciprocating motion is applied to movements which take place continually backwards and forwards in the same path. In most complex machines, both rotary and reciprocating motion occur, and these motions may be converted into each other by various contrivances.

A common contrivance for gradually raising and depressing an object by machinery, is that of an eccentric wheel.

An eccentric wheel is a wheel with an axis not in its centre, but at a point nearer one side than the other. Fig. 53 represents the action of a wheel of this kind. W is the wheel, and A the axis upon which it is fixed. When the axis turns, the wheel turns with it. As the axis never moves out of its place, the wheel necessarily describes a path of gradual rising and falling in its revolutions.

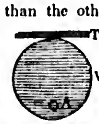

Fig. 53.

Suppose an object, as T, pressing upon the upper edge of the wheel, so as to accommodate itself to the motion, it is obvious that, by the action of the wheel, this object will be alternately raised and allowed to fall. Or suppose that a rod is hung from a point of the wheel near where T rests, it is similarly obvious that the rod would be raised or depressed, according as the wheel turned. Thus a rising and falling motion may be effected by an eccentric wheel.

Eccentric wheels are made of different forms. According as they may be required to act, they are circular, oval, heart-shaped, or pointed at one end, and so forth—the object in each case being to produce alternate motion, by continually altering the distance of some movable part of the machine, from the axis about which they revolve. Technically, the projecting parts of eccentric wheels are called *cambs*.

In some cases, eccentric wheels are not required to perform entire revolutions on their axis. It is perhaps sufficient for the purpose of the mechanism, if they gradually rise to the height of their power, and then, without turning round, gradually descend by retracing their course.

When alternate rising and falling is required *thrice*, by only *one* revolution of an axle, an eccentric wheel is used having three projecting cambs on its circumference, and as each camb comes round, it lifts and lets fall any object presented to it. An example of this apparatus is given in fig. 54. The object required is to work a heavy hammer upon an anvil for beating iron. W is the wheel with the three cambs, and it turns by an axle in upright supports. In turning, each camb, with its rounded or convex side, presses down the end of the handle of the hammer, so as to raise the heavy head H at the opposite end. After pressing down the handle and escaping, the head of the hammer falls with a heavy blow on the anvil A. There it remains till raised up and let fall by the next camb and so on.

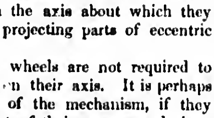

Fig. 54.

OBLIQUE ACTION.

A mechanical advantage, which is frequently of a very serviceable nature, is obtained by causing the points of two straight bars to meet each other, but fixed loosely, so as to be free to move from an oblique to a straight direction, and the reverse. The power consists in bringing the bars to the straight, by which they force asunder or press hard upon any object presented to their outer extremities. In the adjoining figure, the bars are seen first in their oblique position, and next when brought towards a straight. Betwixt the two points a small hollowed piece of metal is inserted, in which the points work, and against which the power is exerted to produce the action. The straightening and bending of the apparatus resembles the action of the knee-joint in animals. The pressure produced by the forcing downwards of the outer extremity of the lower bar (the upper working against a fixed beam), is very easily and rapidly accomplished, and is almost unlimited; and these advantages, as well as the extreme simplicity of the mechanism, have led to the application of the power to the printing-press wrought by the hand, instead of screw pressure.

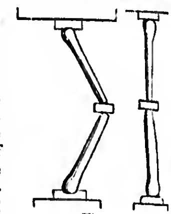

Fig. 55.

CRANKS.

The crank affords one of the simplest and most useful methods of changing an alternate rising and falling motion into rotary motion.

A crank resembles a common handle or winch for turning a machine by the hand; the chief difference being, that a rod or shaft jointed to the handle, and going up and down, works the machine. If the crank be made double, it will turn two wheels or machines.

Fig. 56 represents a double crank in action. S is the rod or shaft ascending and descending, and attached by a joint to the lower part of the crank C, which it alternately pulls up and pushes down, so as to cause the axles W W to turn a wheel at each side. Take away one of the sides of the crank and its support, and the apparatus becomes a single crank.

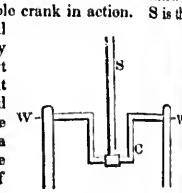

Fig. 56.

Turning-lathes, knife-grinders' machines, and similar apparatus, are usually turned by cranks wrought by an alternate pressing and raising of the foot of the operator; a rod going upwards from the foot-board to the crank, causing the wheel or spindle to go round. The crank has been hitherto indispensable in the action of the steam-engine.

ACCUMULATION.

Power is susceptible of accumulation—that is, of increasing little by little—and of being expended either gradually or in one or more violent efforts; the effort being entirely the concentrated amount of the previous accumulation. The apparently wonderful powers displayed through the agency of levers and other simple machines, are all a natural consequence of an accumulation of any degree of force into a small space;

which effects take place that could never have been accomplished by the original force.

In consequence of this convenient accumulation of power in machines, plans have been devised for establishing *reservoirs of power*, as they may be called, in connection with moving machinery.

A well-known method of accumulating power consists in suspending a heavy body by a chain or strong rope of considerable length—forming, what is called by young persons, a *swing*. This body may be put in motion by a very small degree of power, and will acquire a vibrating motion like a pendulum. By continuing the impulse as the body returns, it will continually acquire greater and greater force, the arcs through which it moves becoming continually larger, until at last it might be made to overcome almost any obstacle. Upon this principle, the battering-rams, or engines for beating down the fortifications of towns in ancient times, were constructed, and the force of their blows was as great as that of a cannon ball; nevertheless, the power of their blows never could exceed the accumulated power of the impulses given to them in order to produce these blows.

The forcible expenditure of accumulated power in the swing apparatus, resembles that which is observable in the case of a person occupying several minutes in bending a spring—that is, accumulating power—and allowing the spring to unbend itself by one violent effort, which effort is nothing more than the giving out of the accumulated power.

A boy taking a race to gain force before making a leap, is another familiar example of accumulating power and expending it instantaneously. The boy is gathering up power at every step he runs, and the force of his leap corresponds exactly with the quantity of the power he has acquired.

In the same manner, the lifting of a hammer, axe, or other instrument, to an elevation as far as our arm can reach, in order to give a blow with good effect, is a method we naturally pursue to gain an accumulation of power.

In contrivances in the arts, power is sometimes accumulated in order to be given out in the form of a rapid and effective blow. This may be done by means of a horizontal bar or lever, poised on a central axis, and loaded at each end with a heavy ball of lead or iron. After communicating to the machine a sufficient power of rotation, it will proceed with an enormous accumulated energy and momentum, till it expend its force either by friction in turning, or upon some fixed obstacle presented to it.

EQUALIZATION—FLY-WHEELS.

In most machines, both the moving force and the resistance to be overcome are liable to fluctuations of intensity at different times, during the operation of working. For instance, when a man turns a winch or handle of a piece of machinery, he is apt to relax in his efforts for an instant from loss of strength, or from an inability to keep his attention closely and uniformly fixed to the labour he has to perform. These relaxations cause an irregularity of motion in the machinery, which are detrimental to the machine and to the work performed. Other moving forces are liable to similar irregularities.

The irregularities in the motion of machinery, from whatever cause they arise, are remedied by giving to each machine a *reservoir of power*, from which force may be given at all times to equalize the motion according as it may be required. These reservoirs of power are usually in the form of *fly-wheels*.

A fly-wheel is generally made of iron, and consists of a heavy rim or circumference, joined to a central axis by cross bar or spokes. In most cases it is placed in close connection with the first moving force, the effect of which it equalizes in its passage to the machine.

FRICTION.

Moving bodies, as machines and wheel carriages, are less or more retarded in their velocity by friction, and the resistance of the atmosphere, while vessels moving on water are retarded by the resistance both of the atmosphere and of the liquid in which they are buoyant.

Friction is an effect of the action of rubbing of bodies one upon another.

This effect is produced by inequalities of surface. No such thing is found as perfect smoothness of surface in bodies. In every case there is, to a lesser or greater extent, a roughness or unevenness of the parts of the surface, arising from peculiar texture, porosity, and other causes; and, therefore, when two surfaces come together, the prominent parts of the one fall into the hollow parts of the other. This tends to prevent or retard motion. In dragging the one body over the other, an exertion must be used to lift the prominences over the parts which oppose them, and this exertion is similar to that of lifting or drawing of bodies up inclined planes or over upright protuberances.

Friction acts as a retarding influence in the action of all mechanical contrivances, and a due allowance must in every case be made for it. In many instances it destroys more than half of the power employed, and seldom destroys less than a third. However small it may be, it sooner or later causes the wearing down and destruction of mechanism, and therefore forms an insurmountable obstacle to the lasting duration of bodies and the perpetuity of motion.

Friction is found to depend on the following circumstances:—1st, The degree of roughness of the surfaces. 2d, The weight of the body to be moved. 3d, The extent of surfaces in certain bodies presented to the action of rubbing. 4th, The nature of the bodies. 5th, The degree of velocity of the motion. 6th, The manner of the motion.

Roughness.—It is of the utmost importance to smooth the surfaces. An apparently insignificant piece of matter, or even particles of dust, will greatly retard the motion of a body. But there is a limit beyond which it would be imprudent to smooth the surfaces of bodies having a close texture. If the surfaces be highly polished and levelled, the bodies will adhere by the effect of attraction of cohesion, even when the atmospheric air is not entirely expelled from between them, and more forcibly when the air is completely expelled. Practically, roads, railways, and similar bodies, cannot be made too smooth.

Weight.—Friction from weight differs in different bodies, and depends on concurring circumstances, as nature of surface, and so forth. Friction always increases in exact proportion as the weight increases, when all other circumstances remain the same. The parts of machinery, therefore, should be made as light as possible, consistent with strength and durability.

Extent of surfaces.—Rough bodies are more easily drawn along when their surface of contact is narrow than when they are broad. For example, it is easier to draw two narrow brushes across each other, than two broad ones of the same weight. Friction may, therefore be diminished in rough bodies by lessening the extent of surfaces in contact. But there is a limit to this diminution. If the moving surface be very thin, and the other soft, the thin surface will plough a groove in the soft one, and thus the friction will be increased, and the machine injured.

Nature of bodies.—It is a remarkable truth that two bodies which are of the same nature, or homogeneous, produce greater friction in movement than bodies which are different in their nature, or heterogeneous. Thu iron working against iron, steel against steel, or brass against brass, causes in each case greater friction and wearing of parts, than when iron or steel is made to work against brass. This circumstance is always attended to in the construction of machinery. Frequently, a small piece of leather is adjusted round an axle, to prevent the metals from coming in contact.

Degree of Velocity.—Friction is a uniformly retarding force, except in the case of small velocities, when it is greater in proportion. The reason for it being greater in small velocities is, that in these cases time is allowed for the prominences of the moving body to sink deeply into the hollows of the surface on which it is moving, which has a retarding effect.

Manner of the Motion.—The least advantageous manner in which one body can be moved upon another, is to cause it to slide or drag. The most advantageous manner is to cause it to roll or turn. The causing of a body to roll instead of to slide, is one of the chief means of diminishing friction. The opposition presented by inequalities of surface to a rolling wheel, is overcome with ease, in proportion to the extent of diameter of the wheel. On a perfectly horizontal plane, the friction of wheels on the plane is very inconsiderable; the chief seat of friction in such cases being in the axles working in their sockets.

Friction is greatly diminished by lubricating the rubbing surfaces with an oily or greasy substance, which substance forms a medium of small soft particles betwixt the bodies, and so prevents the tendency to grind or wear down the surfaces. Water or any similar fluid will also act as a medium to prevent friction, but the effects are only temporary, and would frequently be injurious, as the substance speedily evaporates, and would corrode metals. Practically, fine pure oil is found to be the best unguent for machinery.

One of the first considerations on the part of contrivers of mechanism, should be how to provide for and diminish the effects of friction in their machines. For want of forethought on this important point, thousands of ingenious schemes, which seemed perfect in the form of models and drawings on paper, have been completely frustrated when attempted to be brought into use.

Whatever may be the retarding and frequently inconvenient effects of friction, in reference to the action of mechanism, it is certain that friction is indispensable in the economy of both nature and art, and serves as an essential auxiliary to gravitation. It is a property which is frequently necessary, in order to allow one kind of matter to possess a hold upon another, without actual cohesion. We walk and maintain our erect posture by means of gravitation and action and reaction—in other words, we are held to the earth by gravitation, and our pressure with our feet exemplifies action and reaction; but if there was no such property as friction, we should either stick to the earth by attraction of cohesion, or slide along it as upon the smoothest ice. In order to keep our feet from sliding when on ice, if we received any impulse, we either tie rough substances on our shoes, or scatter ashes in our path; and thus we receive the benefit of friction. It is by friction that rains wear down hills, and that rivers wear away their banks, by which ceaseless process the external configuration of the globe is constantly undergoing a change. The operations in art, of washing, cleaning, scouring, sharpening, polishing, cutting, bruising, beating, and so forth, are all effected less or more by friction. The hold which one fibrous substance has on another, or mutual friction, permits the operations of weaving cloth, twisting ropes and threads, and the tying of one body to another. Thus, friction is of universal service; and the only known instance in nature in which it is not required, and therefore not present, are the movements of the heavenly bodies, which revolve in a vacuum, and are consequently not impeded in their motions.

RESISTANCE OF AIR AND WATER.

Atmospheric air and water are fluids of different densities, and both present an obstacle to the motion of solid bodies through them.

There is a rule in respect to the resistance presented in moderate velocities, which applies both to air and water. It is, that *the resistance is proportional to the square of the velocity.* For example, a velocity of twenty miles an hour causes a resistance four times greater than a velocity of ten miles an hour, for the square of twenty (which is 20 times 20, or 400) is four times the square of ten (which is 10 times 10, or 100). Thus, by increasing the velocity of bodies through the air or water, we must increase the power in a greater proportion, in order to compensate the loss caused by resistance.

Although the above rule is nearly correct for moderate velocities, it deviates considerably from what is observable in the case of great velocities, such as that of a cannon-ball. When the velocity is upwards of 1000 feet per second through the air, the quick passage of the body is believed to cause a partial vacuum behind it, which causes a retardation of its motion.

Resistance to motion in fluids is greatly modified, also, by the form of the moving body. The form that gives least resistance is nearly that of a parabola, or a form somewhat resembling the breast of a duck, the head of a fish, or the rounded bow of a vessel, sharpened to cleave the fluid through which the body passes.

[BOOKS ON MECHANICS, MACHINERY, &c.

One of the most comprehensive works on this subject is Hebert's "*Engineer's and Mechanic's Encyclopædia,*" 2 vols. 8vo, London, with numerous engravings. Haswell's "*Engineer's and Mechanic's Pocket-book,*" is a cheap and useful compendium. Mosley's "*Illustrations of Mechanics,*" edited by Professor Renwick, is excellent on all the branches which it treats. Professor Renwick's "*Application of Mechanics to Practical Purposes,*" is one of the most useful books of its class, and is consulted with great advantage by working mechanics. The "*Treatise on Mechanics,*" translated from Boucharlat and edited by Professor Courtenay, (Harpers New York,) is a regular scientific view of the whole subject. Ewbank's "*Hydraulics and Mechanics*" is interesting, from its giving the history of these sciences, and the progress of the arts dependent on them, among the ancients. As a book of general reference Dr. Ure's "*Dictionary of Arts, Manufactures, and Mines,*" published recently by the Appletons of New York, is excellent. It classifies the subjects in alphabetical order; is very extensive and complete; and brings each subject down to the present state of science. The treatise of Lardner and Kater is excellent authority, but not so recent as Dr Ure's Dictionary, and not a tenth part so extensive.]

HYDROSTATICS—HYDRAULICS—PNEUMATICS.

GENERAL DEFINITIONS.

MATTER exists in three principal forms—solid, liquid, and gaseous or aëriform. These forms respectively, and the various modifications of them, are the immediate result of certain principles of attraction and repulsion operating on the atoms or particles of which matter is composed

The solid, liquid, and aëriform varieties of matter, assume a position on our globe corresponding to their heaviness or density in a given volume. The solid sinks lowest, and composes the chief mass of the earth; above the solid lies the liquid variety, in the form of the ocean, rivers, and lakes; and above all is the atmosphere, consisting of an expanse of aëriform matter, which wraps the whole earth round to an elevation of from forty-five to fifty miles above the highest mountains. In this great ocean of air, loaded less or more with particles of moisture from the liquids beneath, we live, breathe, and move, and plants grow and receive an appropriate nourishment.

Though differing both in substance and appearance, the liquid and aëriform varieties of matter resemble each other in many of their properties and tendencies, and constitute the class of bodies termed *fluids*. Fluids signify bodies which will flow, or whose component particles are easily moved among each other. Some fluids are so thick and viscous, or sticky, that they can scarcely flow, as tar, honey, and some metals in a state of fusion; others flow with ease, as water and distilled spirits; while others are so light and volatile, as to be impalpable to the touch and invisible to the eye, as pure atmospheric air and various gases.

It is common to divide fluids into two kinds—non-elastic fluids and elastic fluids; that is, fluids which cannot be compressed into a smaller bulk, and those which are susceptible of compression. The non-elastic fluids are water and all other varieties of liquid bodies; but recent experiments prove that the term is not strictly applicable to them. It has been found that water may be compressed in a confined vessel, to a small extent, by means of a very great pressure, and it is certain that water at a considerable depth in the ocean is more dense or compressed than at the surface; water, consequently, is an elastic substance; but as it can be compressed only with very great difficulty, the term non-elastic fluid is not altogether inappropriate.

Atmospheric air and all gases are elastic. They can with little difficulty be compressed into a much smaller volume than they ordinarily possess; and when the pressure is removed, they return to their original bulk. Some gases may be compressed to such an extent as to assume the form of liquids and solids; in other words, from the condition of being perfectly invisible to the eye, they can be made to appear as a piece of solid matter, which may be touched and handled.

In treating the subject of fluids, it is convenient to refer in the first place to those which are of the liquid form, and afterwards to those which are elastic or aëriform. Pure water, at an ordinary temperature, furnishes the most suitable example of liquid bodies. Water also gives the name of the department of science which includes the laws of liquids. Thus *Hydrostatics*, from two Greek words signifying *water* and *to stand*, treats of the weight, pressure, and equilibrium of liquids in a state of rest; and *Hydraulics*, from two Greek words signifying *water* and *a pipe*, treats of liquids in motion, and the artificial means of conducting liquids in pipes, or raising them by pumps.

HYDROSTATICS.

In ancient times water was believed to be an element or simple substance in nature. It is now ascertained by experiment that water is not an elementary body, but is a substance composed chiefly of two gases in a state of chemical union, and into these gases it can be resolved by an artificial process. The investigation of this subject belongs to *Chemistry*.

As a liquid, water consists of exceedingly small particles or atoms of matter in mechanical combination.

The exact nature and form of the atoms composing water are not satisfactorily known, in consequence of their exceeding smallness. They may be compared to very small particles of sand, cohering slightly, and easily slipping or sliding over each other. Whatever may be the nature and form of these exquisitely fine atoms, it is certain that they can adhere firmly together so as to assume the form of a solid, as in the case of ice, and be made to separate from each other, and disperse through the thinner fluid of the atmosphere, in the forms of steam, clouds, or mist.

Thus, *imperfect cohesion of atoms or particles* is a property common to all fluids. The atoms composing water, being in closer union than those of air, are observable as a mass, and palpable to the touch. When the hand is dipped into them, and then withdrawn, a certain quantity of the atoms is brought away on the surface of the skin; and this adhesion of the particles of water (caused by attraction of cohesion) is what we in ordinary language call *wetness*. Certain substances, as is well known, absorb water to a great extent; in such cases, the minute particles of the water merely penetrate and fill up the crevices in the substance.

Solid bodies, as a stone, or piece of metal, or wood, have a natural tendency to press only in one direction, that is, downwards, or in the direction of the earth's centre, in obedience to the law of terrestrial attraction.

Water has a similar natural tendency to press downwards, and from the same cause; as, for example, when a jug of water is spilled, the water is seen to fall in a stream to the ground.

Water, however, is governed by a law of pressure, independently of this general law of gravitation. This peculiar or independent law consists of a tendency in the particles of any mass of water to press equally in all directions.

Pressure equally in all directions may be considered as the first or great leading law in reference to water, and generally all fluids, liquid and gaseous.

The pressure equally in all directions is a result of the exceeding smallness of the individual particles, and of the perfect ease with which they glide over or amongst each other.

To exemplify equal pressure, fill a leathern bag with water, and then sew up the mouth of the bag so closely that none of the water can escape. Now, squeeze or press upon the bag so as almost to make it burst. The pressure so applied does not merely act upon the water immediately under the point of pressure, but acts equally upon every particle of water in the mass—the particles at the centre being as much pressed upon as those at the outside; and it will be observed that the water will squirt out with equal impetuosity at whatever part you make a hole in the surface.

In this, as in all similar cases, there is a transmission of pressure throughout the mass. Each particle presses on those next it; and so, by the force communicating from particle to particle, the whole are equally affected.

In the case of water lying at repose in an open vessel, the tendency to press equally in all directions is not observed to act upward, because the gravity of the mass keeps the water down; but on pressing upon the surface of the liquid, we observe that it rises against the compression, or tries to escape in any way it can. To take another example—if we plunge our hand into a vessel of water, we displace so much liquid, and cause it to rise higher up the sides of the vessel. In this case the water is observed to rise without any reluctance; it as readily presses upward as downward.

Although it is a property in fluids to press equally in all directions, the degree of intensity of pressure in any mass of fluid is estimated by the vertical height of the mass, and its area at the base.

Pressure of water in proportion to its vertical height, and its area at the base, is therefore a second leading feature in the laws of water. In other words, the pressure of a column of water does not depend on the width or thickness of the column, but on its height and the extent of its base or lower part.

The whole of any fluid mass may be imagined to consist of a number of columns of an inconsiderable thickness, which stand perpendicularly on the horizontal base of the containing vessel, and press the base of the vessel with their respective weights. The pressure, then, if the height of the fluid be the same throughout, is as the number of columns, and this number is according to the area of the base. Consequently, in vessels whose bases differ as to area, and which contain fluids of the same density, but different heights, the pressure will be in the compound ratio of the bases and heights.

If the columns of which a fluid mass was supposed to consist, were formed of particles lying in perpendicular lines, the pressure of the fluid would be exerted on the bottom of the vessel only; but as they are situated in every irregular position, there must of consequence be a pressure exerted in every direction, which pressure must be equal at equal depths. For if any part of the whole mass were not equally pressed on all sides, it would move towards the direction in which the pressure was least, and would not become quiescent till such equal pressure was obtained. The quiescence of the parts of fluids is therefore a proof that they are equally pressed on all sides.

Several interesting experiments may be made to prove that the pressure of water is in proportion to its height and width of base.

Figure 1 represents a vessel with a broad top EE, tapering to a narrow base CD. The dotted enclosure A B C D represents an ideal column of water the width of the base. The vessel is supposed to be filled with water to the surface EE. Yet the base or bottom sustains no more pressure than that described by the ideal column ABCD; for the other parts of the contained fluid can only press the column ABCD, and also the sloping sides, laterally, and therefore do not contribute to the increase of the weight or pressure on the bottom CD.

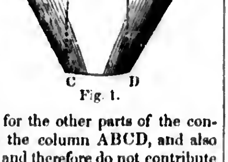

Fig. 1.

If we take a vessel of the same capacity, but with a broad base, as in fig. 2, the pressure on the bottom is very different. In this case, the base EF sustains a pressure equal to the weight of a column whose base is EF, and height equal to AC; for the water in the central column ABCD presses laterally or sidewise, with the same force as it does on the part on which it stands; and thus a uniformity of pressure is established over every part of the bottom.

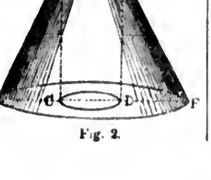

Fig. 2.

From these two cases combined, the reason is evident why fluids contained in the several parts of vessels remain everywhere at the same height; for the lowest part where they communicate may be regarded as the common base, and the fluids which rest thereon are in equilibrio then only, when their heights are equal, however their quantities may vary.

We may prove the truth of these propositions in various ways. Let ABCD, fig. 3, represent a cylindrical vessel, to the inside of which is fitted the cover G, which by means of leather at the edge, will easily slide up and down in the internal cavity, without permitting any water to pass between it and the surface of the cylinder. In the cover is inserted the small tube EF, open at top, and communicating with the inside of the cylinder below the cover at G. The cylinder is filled with water, and the cover put on. Then if the cover be loaded with the weight, suppose of a pound, it will be depressed, the water will rise in the tube to E, and the weight will be sustained. In other words, a very small quantity of water in this narrow tube will press with a force as great as if the vessel were of the dimensions KLCD, instead of ABCD. By filling the tube to F, a force will be gained sufficient to balance additional pound weights on the cover G, and as great as could be conferred by a vessel of equal breadth all the way up to F.

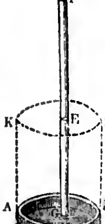

Fig. 3.

Water, in its pressure equally in all directions, presses upwards as well as downwards. This is seen in the above experiments. Take fig. 3 as an example. The water in the vessel ABCD, when the tube is filled, presses, as has been said, with a force equal to that of a column of water of equal breadth all the way up to F. This can only be in consequence of the water in the vessel ABCD pressing violently upwards against the cover G, which violence causes a corresponding reaction on the bottom of the vessel. This reaction, then, is equivalent to vertical height. To use a figure of speech, the water in the vessel is in the condition of a man pressing equally upwards with his shoulders and downwards with his feet at the same time; and the more he is acted upon by weight above, the more powerfully does he exert his pressure in both directions.

An instrument called the hydrostatic bellows has been constructed to exemplify the effect produced by the pressure of a small column of water. As represented in fig. 4, it consists of two circular stout boards connected together with leather, in the form of a pair of strong bellows. A tube A communicates with the interior between the boards. Supposing the instrument to be strong enough, a person standing on the upper board may raise himself by pouring water into the tube, and filling it along with the bellows. It is usual to estimate the pressure by means of weights, W. If the tube hold an ounce of water, and has an area equal to a thousandth part of the area of the top of the bellows, one ounce of water in the tube will balance a thousand ounces placed on the bellows.

Fig. 4.

This remarkable property in liquids, which is called the *hydrostatic paradox*, is analogous in principle to that which in mechanics is called the Law of Virtual Velocities. According to this fundamental rule, a small weight descending a long way, in any given length of time, is equal in effect to a great weight descending a proportionally shorter way in the same space of time. The rule, as applied to liquids, may be stated thus:—A small quantity of water descending in a long column is equal in effect to a proportionately great pressure exerted by a large volume of water in a short column.

The law of pressure in proportion to height of column is shown in the annexed representation, fig. 5, of a vessel with a uniformly level base, and full of water. Dividing the depth into 10 equal sections, to represent feet, as marked from 1 to 10, it is found, that, at the depth of 1, there is a pressure of one foot of water, at 2, two feet, and so on to 10 at the bottom, where there is a pressure of ten vertical feet of water. The average pressure of the whole is at the middle, at 5. These degrees of intensity of pressure have no reference to the horizontal breadth or length of the mass. The same pressure is sustained, whether the vessel be a foot or a mile in breadth.

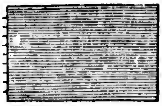

Fig. 5.

As in this example, whatever deficiency of pressure there is upon the perpendicular sides of a vessel of water *above* the middle or point of average pressure, is compensated by a corresponding excess of pressure *beneath* the middle; consequently, the entire pressure diffused over the side is equal to that at the middle or point of average pressure. A perpendicular side of a cubical vessel, according to this statement, sustains a lateral pressure precisely equal to the half of that which is endured by the bottom.

We may calculate the degree of lateral pressure in vessels having perpendicular sides and flat horizontal bottoms, by first finding the number of square feet in the sides below the surface of the liquid; then multiplying that by the number of feet in half the depth of the liquid; by which calculation, the product will express the number of solid feet of the liquid, whose weight is equal to the lateral pressure. We may find the number of square feet in the sides, by multiplying the number of feet in the circumference of the bottom by the number of feet in the depth of the liquid.

Example.—To find the degree of pressure on the perpendicular sides of a vat 24 feet deep from the surface of the liquid, and 40 feet in circumference.—Multiply the 24 by 40, and the product 960 gives the area of the sides; then multiply the 960 by half the height, that is 12, and the product is 11,520 cubic feet of water, or the volume of liquid whose weight is equal to the pressure on the sides. We next find the weight per cubic foot, which is reckoned to be 1000 ounces; then 11,520 multiplied by 1000, gives 11,520,000 ounces, which is the pressure of the water on the sides.

In consequence of the pressure of liquids being as the vertical height and area of the basis, it may happen that the lateral pressure on the sides of a containing vessel is greater than the whole weight of the liquid; this will be the case when the surface of the sides in contact with the liquid exceeds the ratio of double the magnitude of the bottom—at double the magnitude, both lateral and perpendicular pressures are alike, and each is equal to the weight of the liquid.

The circumstance of pressure increasing in proportion to depth, suggests the valuable practical lesson of greatly increasing the breadth of embankments for dams and canals from the top downwards, so as to give much greater strength to the base than the summit; also of increasing the strength of the lower hoops of large vats, to prevent their bursting. It likewise demonstrates the propriety of making dams, ponds, canals, and vessels for liquids generally, as shallow as is consistent with convenience or their required purpose. In each case, it is important to recollect that the degree of pressure on the sides is irrespective of shape or size of the contents, and depends exclusively on the height of the liquid from its upper surface to its base.

That pressure in water is not according to volume, but the height above the point of pressure, is obvious from many facts both in nature and art. Whether we plunge an object a foot deep in the ocean or in a jar of water, the pressure upon it is the same. The mere extent of the volume of liquid is of no consequence. Therefore, a precipitous shore pressed upon by the sea to the height of any given number of feet, suffers no more pressure (supposing the sea to be at rest) than the side of a canal of the same number of feet in length.

If the law of pressure of fluids were otherwise than that now stated, no species of embankment, no strength of shore, could withstand the pressure of the ocean, particularly in a high state of the tide. In consequence of the law of pressure being simply as the vertical height, we are enabled by artificial means to stem the volume of a far-spreading ocean, and to secure the dry land from its invasion. A knowledge of this important law might induce the attempt to secure many thousand acres of land which are now covered by the tide.

If a vessel, as for instance a barrel, be filled with water, and three apertures be made in its side at different heights, as in fig. 6, the liquid will pour out with an impetuosity corresponding to the depth of the aperture from the top. The jet A nearest the top of the barrel, having little pressure above it, will be projected but a short way; the jet B, having a greater pressure, will perhaps go to double the distance; and the jet C, having the greatest pressure of all, will go to a greater distance still. Jets of this kind obey the laws which govern solid projectiles in their flight; they describe a curvilinear motion, the width of curve being proportional to the impressed force.

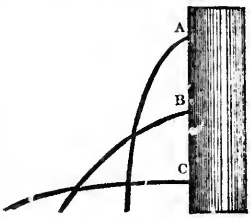

Fig. 6.

Practically, the discharge of liquids from apertures is partly affected by the shape and width of the aperture; for water is retarded by friction, and by its own impetuosity or cross currents in a small channel. It is reckoned that the pressure of water on any body plunged into it, or on the bottom or sides of the containing vessel, is about one pound on the square inch for every two feet in the depth.

Pieces of wood sunk to great depths in the ocean become so saturated with water by the pressure of the superincumbent mass, that they lose their buoyancy, and remain at rest at the bottom. The depth to which divers can descend is limited by the increased pressure they experience in their descent. If a bottle be firmly corked and sealed, and sunk to a great depth in the ocean, the cork will either be forced in or the bottle broken by the pressure. An air-bell rising from a depth, expands as it approaches the surface. At the depth of a thousand fathoms, water is estimated to be about a twentieth part more dense in the bulk than at the surface.

The great effects which may take place by the action of a small but high column of water, are sometimes exemplified in the rending of mountains. In fig. 7, a mountain or high rocky knoll is represented, with a small vertical crevice A reaching from the summit to an internal reservoir of water near the base. If there be no means of outlet to the liquid, and if rain continue to keep the crevice and its terminating reservoir full, the lateral force exerted by the upright column will be very considerable. Supposing the crevice to be an

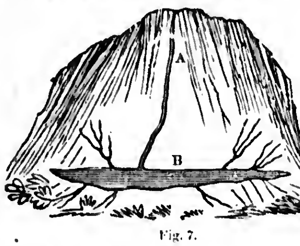

Fig. 7.

inch in diameter, and 200 feet deep, the pressure would be equal to nearly half a ton on every square inch; such a force continually acting on the sides of the mountain (laying out of view the great additional force given by expansion of the liquid in freezing during winter) would probably in time overcome the cohesiveness of the mass, and burst the whole asunder. In this property in water, therefore, we see one of the many provisions of nature for producing changes on the surface of the earth.

Effects of a similar character, but on a less scale, are observable in the bursting of walls behind which earth has been piled, and in which no proper outlets for water have been provided; also in the bursting upwards of drains upon a declivity, when they become choked.

The easy motion of the particles among each other causes them to accommodate themselves to the shape of any vessel. The force of gravity also causes them to seek the lowest level for repose—each particle tries to get as low as it can. The result of this general tendency throughout the mass is a perfect levelness of surface—the top of the water is smooth.

A uniform levelness of surface takes place in every connected mass of water, whatever be its magnitude or its shape. This forms the third leading feature in the laws of water, and is the cause of many of the phenomena in nature.

One of the most familiar examples of the equal height and levelness of surface of water, is that observable in a common teapot. In the representation of a teapot, fig. 8, the surface of the liquid in the pot is seen to be at A, and also at the very same height at B in the spout. A straight dotted line is drawn from the one to the other, to show that both surfaces are of the same level. It is customary to say that the small column of water in the spout balances the large mass of water in the pot, but, in reality, there is no balancing in the case. The water

Fig. 8.

necessarily possesses the same surface level in all its parts; one portion cannot stand higher than another; all portions, great and small, are only distributed parts of a single mass.

The tendency which water has to stand at the same surface level in all parts of its mass, is usually referred to by the phrase "water finding its level."

It is this inherent tendency in water to find its level that produces the various phenomena of the trickling down of rain and moisture into the ground, the flowing of all kinds of streams, from the small brook to the mighty river, and the shooting of rapids and cataracts over precipices. In each case, the water, in obedience to the natural law or tendency which governs it, is only trying to find its level. In pursuit of this object, the water, by the rubbing force which it exercises, wears down all the solid objects which present an obstacle to it in its course. Thus, the substances of which hills and plains are composed, are carried away by streams into the ocean—the ground of continents and islands diminishes in bulk—new land rises in the sea; and so, by the effects of a simple natural cause, great alterations are produced in the external features of the globe.

There are two kinds of levels—the *true level* and the *natural level.** The true level is a perfectly horizontal plane, as for instance an even line, thus ——— or a perfectly even surface of a floor.

The natural level is a surface, every point of which is at the same distance from the centre of the earth. The surface level of water is always the natural level.

The character of a natural level is understood by a reference to the spherical shape of the earth and the pressure of gravitation. The globe is a ball, and any piece of water which lies upon it, lies in the form of a plaster round the ball. Water, therefore, cannot possibly have a true surface level; its level partakes of the sphericity of the ball. Every piece of water, in a state of entire or partial repose, is in this manner convex in its surface.

The degree of convexity of the earth is, as nearly as it can be stated in figures, 7 inches and 9-10ths of an inch, or nearly 8 inches in each mile. The convexity, however, is somewhat less towards the north and south poles, because the earth is a spheroid, or a sphere flattened at the ends.

Fig. 9 represents a segment of the earth's surface, with the appearance of a true and natural level marked

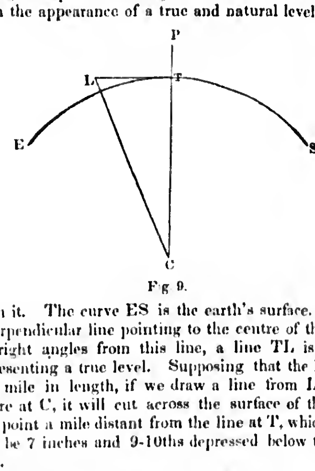

Fig. 9.

upon it. The curve ES is the earth's surface. PC is a perpendicular line pointing to the centre of the earth. At right angles from this line, a line TL is drawn, representing a true level. Supposing that the line TL is a mile in length, if we draw a line from L to the centre at C, it will cut across the surface of the earth at a point a mile distant from the line at T, which point will be 7 inches and 9-10ths depressed below the part at L.

The convexity of the earth's surface is not observable in small quantities of water. The surface of a glass of water is not a true level, but the degree of convexity is so small that it cannot be practically estimated or measured. It is only when a sheet of water is stretched out to an extent of several miles, that the convexity becomes conspicuous. It is very perceptible on the ocean when a ship is seen approaching on the horizon; first the masts and sails of the ship are seen, and lastly the hull. In order to catch the first glimpse of vessels at sea, the point of outlook for them is placed high

* In mathematics the term *apparent level* is used instead of true level, and the term *true level* instead of natural level.

above the water. By this means the person who looks is able to see over a part of the convexity, and give information of the approach of vessels to those placed below.

The convexity of the land is not so conspicuous, in consequence of the many risings and fallings in the surface. It is only in some extensive alluvial plains in different parts of the world that the convexity can be perceived in the same manner as at sea.

In forming roads, railways, and canals, it is necessary to make allowance for the convexity of the earth's surface. The first thing done in such cases is to survey the land by means of an instrument called a *theodolite*. One of the varieties of the theodolite is a small telescope fixed on a stand, which must, when looked through, be placed perfectly horizontal, or in a true level. To find a true level, an instrument is fixed below it, called a *spirit level*, and by that it is regulated.

A spirit level is in universal request in works of art requiring levelness of foundation or surface. It consists of a cylindrical glass tube, as in Fig. 10, containing a quantity of spirits of wine sufficient to fill it, except a small part, in which the air is left. The tube being completely closed or sealed, the small vacancy where the air is left shows an air-bubble at whatever part of the tube is uppermost. The tube being set in a small wooden case with a level bottom, this case is laid upon the block of stone, wood, or other object to be levelled, and when the air-bubble is seen to rest in the middle of the upper side, it signifies that the object on which the instrument lies is a true level. In the accompanying figure, the air-bubble is seen at the middle at *b*; the slightest unevenness would cause the bubble to proceed to *a* at one end, or *c* at the other.

Fig. 10.

A true level being found for the theodolite, the surveyor looks through the glass or telescope towards a pole, the lower end of which rests on the ground, and is held in a perpendicular position by a man at (we shall suppose) the distance of a mile, previously measured. The pole having figures marked upon it, a certain figure on a level with the eye is ascertained; 7 inches and 9-10ths are then reckoned down the pole from the figure, and at that depth we have the natural level from which the surveyor makes his subsequent calculations. If a road were to be made on the plan of preserving a true level, it would proceed in its course at a tangent from the earth's convexity, like the line T L in Fig. 9, and, consequently, would reach a point above that to which it was destined to go. It would be impossible to make the water in a canal pursue a true level; in the attempt to do so, the water would not remain at rest in the channel prepared for it, but would rush towards the lower end.

As most countries are less or more irregular in surface, canals are usually constructed with different levels, so much of the length being on one level, and so much on another, as the case may be. At every change of level there is a lock, or portion enclosed with gateways, to keep the water at the proper level, and to allow the passage of vessels. The locks of a canal, therefore, are like steps of a stair, one at a greater height than another, and by their means vessels may be made to proceed up or down hill.

SPECIFIC GRAVITY.

The more dense in substance that a body is, it is the more heavy or weighty, because it contains the more particles to be operated upon by attraction of gravitation. In reference to the density of bodies, the term *specific gravity* is employed to denote the comparison which is made Thus, the weight of a lump of lead is greater than an equal bulk of cork; therefore its specific gravity is greater; and so on with all other substances, when compared together. For the sake of convenience, pure distilled water, at a temperature of 62 degrees, has been established as a standard by which to compare the specific gravity or relative weight of solid and liquid bodies. Every such body is said to be of either a greater or less specific gravity than water, bulk for bulk.

We have an example of a difference in the specific gravities of liquids, in mercury, water, oil, and spirits. Mercury is considerably more dense or heavy than any of the others; the next in density is water, then oil, and lastly spirits. If we put a quantity of each of these liquids into a glass vessel, one after the other, in the order here mentioned, we shall observe that all keep their respective places without intermixture, the heaviest at the bottom and the lightest at the top. Should they even be jumbled together in the vessel, it will be noticed that they in time rectify the disturbance, each assuming its own position.

Sea or salt water, in consequence of being loaded with foreign matter, is of greater density or specific gravity than pure fresh water of the same temperature. If we therefore pour a quantity of salt water into a glass vessel, and then gently place some fresh water above it, we shall observe the same phenomenon, of each kind of liquid retaining its position, the heaviest to the bottom, and the lightest to the top. After being jumbled together, the two liquids will, as far as possible, return to their former relative position.

If we fill a bottle with water, and dip it with the open mouth downwards into a jar or barrel of spirits, the water, in virtue of its density, will be emptied and sink into the spirits, and the spirits will immediately rush up into the empty bottle, and supply the place of the water.

The force which liquids exert in opposing each other in a state of equilibrium, corresponds to their specific gravities; in other words, a small quantity of a heavy liquid will balance a much greater quantity of a lighter liquid. For example, take a bent glass tube, as in Fig. 11, and pour as much water into it as will extend from the bottom at E to A. This quantity of water will be balanced or kept to its summit level at A by a quantity of mercury measuring from E to B, or by a quantity of oil from E to C, or by a quantity of spirits from E to D. Each of these experiments may be performed one after the other. The pressure of liquids being as the vertical height, and not as breadth, it would make no difference in the result of the experiments, if the limb of the tube for the mercury, oil, or spirits, were increased to a foot, a mile, or any other diameter.

Fig. 11.

Water, at its ordinary temperature of 62 degrees, has a specific gravity of 1000 ounces to the cubic foot. Platinum is 22½ times heavier, or 22½ times the specific gravity of water; gold is 19¼, mercury 13½, copper 8¾, iron 8, common stone about 2½, and brick 2. Alcohol is a little more than 8-10ths of the heaviness or specific gravity of water, or 0.815; and oil of almonds is a little more than 9-10ths, or 0·913. Atmospheric air at the earth's surface is 1-800th part, or 0·00125; in other words, while a cubic foot of water weighs 1000 ounces, a cubic foot of air weighs one ounce and a quarter.

Sea-water generally possesses a specific gravity of 1·035—that is, to 1000 parts of fresh water there are in addition 35 parts of saline substances.* Sea-water being, therefore, 35 parts for every 1000 of water more dense

* This is given only as a general rule The sea is not uniformly salt.

than fresh water, it possesses a proportionally greater power of buoying up bodies. A vessel which will carry 1000 tons on fresh water, will thus carry 1035 tons on the sea.

FLUID SUPPORT.

The immersion of solid bodies in liquids develops some important principles in hydrostatics.

Any body of greater specific gravity than water, bulk for bulk, will sink on being thrown into water; but a body will float if its specific gravity be less than that of water.

The mode of stating the law in reference to the immersion and floating of solid bodies in any kind of fluids, is as follows:—

First.—Any solid body immersed in a fluid displaces exactly its own bulk of fluid, and the force with which the body is buoyed up is equal to the weight of the fluid which is displaced; therefore, the body will sink or swim, according as its own weight is greater or less than the bulk of displaced fluid. This refers to bodies of less density than water.

Second.—Any solid body of a greater density than water, when wholly immersed in that fluid, loses exactly as much of its weight as the weight of an equal bulk of the water—that is, of the water which it displaces.

It is of great importance that these propositions should be fully comprehended, for they explain innumerable phenomena in nature, in reference to the floating or swimming of bodies in water or in the atmosphere.

Water, as has been explained, consists of innumerable small particles, pressing in all directions, or upwards as well as downwards. Let us fix our attention on a supposed single particle in the mass: while the liquid is in a condition of repose, we may imagine the particle to be sustained between contending forces—the force of a column of particles above, and the equally strong force of particles beneath, pushing to get upward or away from this column.

Let us now substitute any solid object for the supposed particle; for example, the quadrangular object A B represented in a vessel of water, Fig. 12. This object, supposed to be of the same density as water, which we see is sunk in a buoyant condition in the water, has displaced a mass of particles, all of which were operated upon in the manner of the supposed single particle. This object, then, by taking the place of the mass of particles, has become subject to the same contending forces, and is consequently floated or sustained to the same extent as they were.

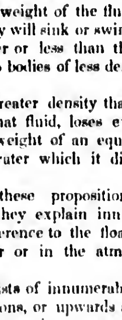

Fig 12

If we suppose that the weight of the object is two pounds, liquid to the amount of two pounds is displaced, and the object is pressed upwards with the force of two pounds. Or, to vary the example, suppose that only the lower half beneath the line C is the solid object, and that the space occupied by the upper half is water, the object is still pressed upwards with a force of two pounds; but being one pound weight in itself, and having a pound of water above it, it remains suspended in equilibrium.

These examples refer to bodies which are of the same density or weight as water, bulk for bulk; we shall now take an example of a body specifically lighter than water, by which it will be observed that the buoyancy is governed by the same principle.

Fig. 13 represents a solid object A B half immersed in a vessel of water. In this, as in all cases in which there is a portion of the object above the water, the weight of that portion is borne by, and therefore conveyed to, the portion which is immersed. Thus, in the example before us, the portion B, though less than a pound weight in itself, by supporting A becomes, we shall say, a pound, and displaces a pound of water; it is therefore buoyed up with the corresponding force of a pound.

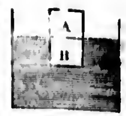

Fig. 13.

Whether a body be large or small in bulk, in proportion to its weight, its displacement of water depends exclusively on its weight, so long as it is not heavier than water. A vessel of cork, wood, or any substance lighter than water, weighing a thousand tons, displaces exactly the same weight of water, or is buoyed up with the same degree of force.

From these circumstances, it appears that the entire weight of any *floating* body may be calculated by measuring the quantity of water which it displaces.

On immersing a stone or any other solid object in water, it is found to be buoyed up in proportion as its specific gravity is less than that of water. If its specific gravity be greater than water, it will sink to the bottom, and if less it will swim. As the water of the ocean becomes of greater specific gravity the greater the depth, it may happen that an object which sinks at the top of the water, will remain suspended in equilibrium when it descends to a point at which the specific gravity of the water is equal to its own.

Whatever be the weight of any solid object when weighed in air, its apparent weight is lessened when weighed in water. Thus a stone may be moved with comparative ease in water, which cannot be lifted without considerable difficulty on land. The apparent diminution of weight in these cases is caused by the support afforded by the liquid. Attraction of gravitation, which is the cause of what we call weight, is counteracted more in water than in air, because the water has a tendency to buoy up the object. The weight of any object in water is thereby lessened to the extent of the weight of a bulk of liquid equal to the size of the object. If the object displace a pound of water, it will weigh a pound lighter in water than in air.

The circumstance of any solid object displacing its own bulk of liquid, and losing exactly as much of its weight as the weight of that bulk of liquid which it displaces, has led to the use of the hydrostatic or water balance, for ascertaining the intrinsic value of gold and other precious metals. For example, by knowing in the first place how much water a pound of pure gold displaces, and then weighing in water, as in Fig. 14, an object said to be a pound of gold, we should observe whether it displaced the proper quantity of water; if it displaced more than was proper, then we should be certain that it contained alloy or some inferior substance, being too bulky for a pound of gold. Such weights are used by goldsmiths.

Fig. 14.

Thus, if a piece of gold weigh 19¼ ounces in air, it would weigh only 18¼ ounces in water; the ounce of weight thus counteracted being just the weight of the water that the gold displaces. Therefore the weight of the gold would be to that of the water as 19¼ ounces to 1 ounce; that is, the specific gravity of gold is 19¼, if water is taken for the standard.

We may cause an object, such as light hollow ball or bladder, to displace much more water than what is equal to its own weight; but in doing so, we must press the ball into the water, and that degree of pressure compensates the deficiency of weight in the ball. Thus, extraneous pressure on a floating body, and weight in the body itself, are the same thing as respects buoyancy.

The human body in a state of health, with the lungs full of air, is specifically lighter than water, and more so in the sea than in fresh water. Persons, therefore, on going or falling into water, cannot possibly sink, unless they struggle so as to prevent the liquid from buoying them up. The body will float with a bulk of about half the head above the surface; and thus a person who cannot swim may live and breathe, until chilled or otherwise paralyzed, by simply stretching himself on his back, and lying with his face above the water. By throwing the arms out of the water, the body does not displace so much liquid; its weight is increased, and it naturally sinks. Ignorance of these facts in hydrostatics, and want of resolution, cause many deaths by drowning.

There are various kinds of apparatus for preventing drowning, called life-preservers. The most common are those which consist of pieces of cork or other very light material attached to the upper part of the body. But air-tight bags are preferable, as they may be said scarcely to encumber the body when empty, and, as danger approaches, they can be inflated with ease by being blown into. Life-boats have large quantities of cork in their structure, and also air-tight vessels made of thin metallic plates; so that, even when the boat is filled with water, a considerable portion of it still floats above the general surface. The bodies of some animals, as sea-fowl, and many other species of birds, are considerably lighter than water. The feathers with which they are covered add very much to their buoyancy. Quadrupeds swim much easier than men, because the natural motion of their legs in walking or running is that which best fits them for swimming. Fishes are enabled to change their specific gravity by means of an air-bag with which they are provided. When the air-bag is distended, they rise to the surface; and when it is contracted, they descend to the bottom.

The buoyant property of liquids is independent of their depth or expanse, for if there be only enough of water to surround an object plunged into it, the object will float as effectually as if it had been immersed in a large mass of water. Thus a few pounds of water may float an object which is a ton in weight. We account for these phenomena by the law of pressure in liquids being as vertical height, not as width of column, and by a body being buoyed up with a force exactly in proportion to the weight of water which it displaces.

These important truths in hydrostatics teach the practical lesson, that if canals be made only as deep or wide as will afford water to surround the vessels placed upon them, they will be sufficiently large for all purposes of buoyancy and navigation. A ship floats no better on the face of a sheet of water miles in width, than it would do on a mill-pond, provided there be enough of water in the pond to keep it off the bottom.

Every solid body possesses a *centre of gravity*, which is the point upon or about which the body balances itself, and remains in a state of rest, or equilibrium, in any position.

The equilibrium of floating bodies is regulated in the same manner. The floating body has a centre of gravity, about which the whole mass will balance itself in the liquid, the heaviest side will sink lowest, and the more light will be uppermost.

In reference to floating bodies, there is a point called the *centre of buoyancy*; this is the centre of gravity of the liquid which is displaced. If the floating body be of the same specific gravity as water, then the centre of buoyancy will be at the same point in the floating body as it would have been in the water; but there is seldom this uniformity, at least not in vessels used for purposes of navigation. It is necessary that all such vessels should be of a less specific gravity than water, in order that a part of their weight may be composed of cargo, stores, passengers, &c., and that they may be sufficiently buoyant.

Heavy materials, called ballast, are usually placed in the bottom of the holds of vessels to insure a low centre of gravity. A ship of the largest capacity and burden, with its centre of gravity properly regulated, rests in the water with a stateliness and stability which cannot be destroyed except by some extraordinary violence.

HYDROMETERS.

If a substance be weighed in two fluids, the weights which it loses in each are as the specific gravities of those fluids. Thus, a cubic inch of lead loses 253 grains when weighed in water, and only 209 grains when weighed in rectified spirit; therefore, a cubic inch of rectified spirit weighs 209 grains, an equal bulk of water weighing 253; and so the specific gravity of water is about a fourth greater than that of the spirit.

The instrument called a *hydrometer* is constructed upon this principle. Its name is derived from two Greek words, signifying *measure of water*; but it is of course used for ascertaining the density of all kinds of liquids. There are various kinds of hydrometers. One of them consists of a glass or copper ball with a stem, on which is marked a scale of equal parts or degrees. When immersed in any fluid, the stem sinks to a certain depth, which is indicated by the graduated scale. The length to which it sinks in the standard of comparison being known, we can thus easily ascertain how much it is specifically heavier or lighter than the fluid.

Much in the same manner is constructed another hydrometer of great delicacy and exactness. It consists of a ball of glass about three inches diameter, with another joined to it, and opening into it, of one inch diameter, *b c*, fig. 15, and a brass neck *d*, into which is screwed a wire *a e*, divided into inches and tenths of an inch, about ten inches long and one-fortieth of an inch in diameter. The whole weight of the instrument is 4000 grains when loaded with small weights, such as shot, in the lower ball *c*. When plunged into water in the jar, this instrument is found to sink an inch if a single grain be laid upon the top *a*; hence a tenth of a grain sinks it a tenth of an inch. So great is the delicacy of this hydrometer, that the difference in specific gravity of one part in 40,000 can be detected. Its total weight of 4000 grains is convenient for comparing water; but the quantity of shot in the lower ball can be varied so as to adapt the instrument to measure the specific gravities of fluids lighter or heavier than the standard of comparison.

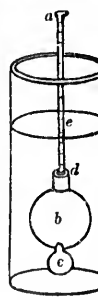

Fig. 15.

There is another very simple hydrometer, which consists of a number of glass beads of different weights, but whose proportions are known, and the beads marked accordingly. These are dropped into the fluid under examination, until one is found which neither sinks to the bottom nor swims upon the surface, but remains at rest wherever it is placed in the liquid; and this bead being numbered, indicates the specific gravity.

In making calculations of the strength and specific gravity of spirits, by the above or any other means, attention must be paid to the degree of temperature of the liquid. Heat expands the liquor, and renders it specifically lighter; all spirits are therefore more bulky, in proportion to their weight, in summer than in winter, and also *apparently* stronger, not really so.

HYDRAULICS.

Having detailed the laws and properties of water in a state of rest or equilibrium, we have now to mention some of the more important results of these laws, and also the effects which are produced upon liquids by the application of forces, whether natural or artificial.

WATER A MECHANICAL AGENT.

Water, as already explained in the Laws of Matter and Motion, may be made a useful agent of power, merely by allowing it to act with the force of its own gravity, as in turning a mill; and in this manner it is extensively employed in all civilized countries possessing brooks which are sufficiently rapid in their descent.

But water may be rendered otherwise useful as an agent of force in the arts. Although subtile in substance, and eluding the grasp of those who desire to handle and hold it, it can, without alteration of temperature, be made to act as a *mechanical power*, as conveniently and usefully as if it were a solid substance, like iron, stone, or wood. The lever, the screw, and inclined plane, or any of the ordinary mechanical powers, are not more remarkable as instruments of force than water, a single gallon of which may be made to perform what cannot be accomplished (except at enormous cost and labour) by the strongest metal.

To render water serviceable as an instrument of force, it must be confined, and an attempt then made to compress it into less than its natural bulk. In making this attempt, the impressed force is freely communicated through the mass, and in the endeavour to avoid compression, the liquid will repel whatever movable object is presented to it. The force with which water may be squirted from a boy's syringe, gives but a feeble idea of the power of liquids when subjected in a state of confinement to the impression of external force.

The mechanical force of water is exemplified by the hydraulic press. This is an engine employed by paper-makers, printers, and manufacturers of various kinds of goods, for the purpose of giving a high degree of pressure or smooth glazed finish to their respective articles. It has generally superseded the screw press, on account of its much greater power, with a less degree of trouble and risk of injury to the mechanism.

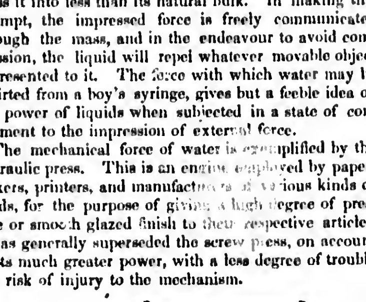

Fig. 16.

Fig. 16 represents the outline of a hydraulic press. A B is the frame, consisting of four upright pillars supporting a cross top of great strength, and against which the pressure takes place in an upward direction. C, the material to be pressed, is forced upward by D, a round iron piston. This piston is very nicely fitted into an iron case, E, which has a cavity F, for receiving the water: the neck of the case grasps the piston so tightly that no water can escape. A small pipe G conveys water into the hollow cavity from a forcing-pump H, which stands in a trough of water T. All that part of the apparatus below the base of the pillars is sunk out of sight in the ground. The pump apparatus is here represented as exceedingly simple, but in real machines it is very complex and of great power.

The pump, on being wrought, forces the water into the cavity. There the water, in endeavouring to escape, operates upon the movable piston, which it causes slowly to rise with its burden. The pressure thus exerted by the liquid almost exceeds belief; unless the case for the water be of enormous strength, it will be rent in an instant as if made of the weakest material. When the weight has been raised to the required height, a stopcock is turned upon the pipe, and the apparatus remains at rest. The opening of the cock allows the water to gush out, and the weight accordingly sinks.

The mode of calculating the power of the hydraulic press is analogous to that for calculating lever powers. Thus, the proportion is estimated between the small bore of the pump and the large bore of the cavity or barrel for the piston. Suppose that the pump has only one thousandth of the area of the barrel, and if a man, by means of its lever handle, press its rod down with a force of five hundred pounds, the piston of the barrel will rise with a force of one thousand times five hundred pounds, or more than two hundred tons. A boy working the pump by a long handle, and taking a sufficiency of time, will raise a pressure of thousands of tons.

In the hydraulic press, a force-pump is employed for the sake of convenience; the same end could be attained by a small column of water of a great elevation, on the principle of pressure in liquids being as vertical height.

AQUEDUCTS—FOUNTAINS.

The tendency in a liquid to find its level, has permitted the construction of apparatus, consisting of pipes and cisterns, for supplying towns with water. No species of hydraulic machine has been of such great use to mankind as this apparatus.

In ancient times, the fact of water rising to an uniform level in every part of its volume, was either not perfectly understood, or there was a deficiency of materials wherewith to construct the apparatus required for carrying water a great distance.

From whatever cause, towns were in these times supplied with water by means of open canals, either cut in the level ground, or supported on the top of arches built for the purpose. These structures, with their elevated channels, were called aqueducts. In Italy, and some other countries in the south of Europe, the remains of stupendous aqueducts, miles in length, still exist.

By a knowledge of the laws of fluids, and by possessing an abundance of lead and iron, we are enabled in the present day to construct apparatus for supplying towns with water in a manner the most effectual and simple; causing a cheap iron or leaden tube, sunk in the ground, to perform the office of the most expensive and magnificent aqueduct.

The method of supplying towns with water consists in leading a pipe of sufficient diameter from a lake, river, or fountain of fresh and pure water, to the place where the supply is required. The iron pipes used for this purpose are composed of a number of short pieces soldered together, and extending to any length, or in any direction. From these main pipes smaller tubes of lead are led into the houses requiring the supply of water; and by means of these minor tubes, the water may be carried to any point which is not of a higher level than the original fountain affording the supply.

Fig. 17.

Fig. 17 is a representation of the mode of supplying towns with water in this convenient manner. A pipe is observed to proceed from a lake on the top of a hill down into a valley, and thence to supply a house situated on the opposite rising ground. From the pipe, in its passage across the valley, a small tube is carried to supply an ornamental fountain or jet d'eau. The water spouts from this jet d'eau with a force corresponding to the height of the lake above.

In towns not commanding a supply of water from a sufficient height, the water is forced by an apparatus of pumps to an elevated reservoir, and from that the pipes are laid. When the water is impure, or loaded with muddy particles, it is usual to purify it by filtration at the reservoir; it is made to filter or ooze through a mass of fine sand, in which the particles of mud are [illegible].

Springs in the ground are natural hydraulic operations, and are accounted for on principles connected with the laws of fluids. One kind of springs is caused by capillary attraction, or natural attractive force, by which liquids rise in small tubes, porous substances, or between flat bodies closely laid towards each other. This species of power is a remarkable variety of the mutual attraction of matter, and is as unaccountable as the attraction of gravitation, or the attraction exercised by the lodestone.

Springs from capillary attraction are believed to be less common and of smaller importance than springs which originate from the obvious cause of water finding its level. The water which falls in the form of rain sinks into the ground in high situations, and finds an outlet at a lower level, though perhaps at a considerable distance.

Some springs are also accounted for by a reference to atmospheric action, but these will form a subject of notice under the head Pneumatics.

FRICTION BETWEEN FLUIDS AND SOLIDS.

The flowing of water through pipes, or in natural channels, is liable to be materially affected by friction. Water flows smoothly, and with least retardation from friction, when the channel is perfectly smooth and straight. Every little inequality which is presented to the liquid, helps to retard it, and so likewise does every bend or angle in its path. A smooth leaden pipe will thus convey more water than a wooden pipe of the same capacity. Practically, an allowance is made in the magnitude of pipes for the loss of speed by friction. Where the length of the tube is considerable, and there are several bendings, it is not unusual to allow a third of the capacity for retardation.

By increasing the capacity of pipes, a prodigious gain is secured in the transmission of water. The loss from friction on a small tube of an inch diameter of bore is so great, that one of twice the capacity will deliver five times as much water.

The rate at which water flows from an orifice in a reservoir, or containing vessel, is affected by the situation and the shape of the orifice.

The most favourable situation for the orifice is at the bottom of the vessel; but the velocity of the emission is not in the ratio of the height of the liquid, or of a perpendicular column of particles; for as the water presses in all directions alike, there is from all parts of the vessel a general rush as it were to the outlet, thus putting the whole mass in motion.

Although the rush of water at the outlet is not as the ratio of the depth, it depends upon the depth. Thus, if a vessel ten feet high be penetrated at the side on a level with the bottom, and the water stand at two feet and a half within, it will issue outwards with a certain degree of velo[illegible] If the height of the water be quadrupled, that [illegible] vessel be filled, the velocity will be doubled. In o[illegible]in a threefold velocity, a ninefold depth is [illegible]r a fourfold velocity, sixteen times the d[illegible]red, and so on. In fact, in whatever propor[illegible]city of efflux is increased, the quantity of [illegible]ed in a given time must be also increased in [illegible] proportion; hence the quantity of water discharged conjointly with its degree of velocity will be increased in proportion to the pressure. There is here a striking coincidence between the descent of water and the relation which exists between the height from which a body falls, and the velocity acquired at the end of the fall.

It has been ascertained that water rushes with most advantage from an orifice, when the orifice is in the form of a short round tube inserted into the vessel, and of a length equal to twice its diameter.

It has also been found, that if the pipe, instead of being flush or level with the bottom of the reservoir, entered into it to some distance, it had the effect of making the flow of water even less than that which issued through the simple hole without any pipe. The singular fact of a pipe and hole of the same diameter discharging different quantities of water under different circumstances, whilst the head or pressure remains the same, must be accounted for by cross or opposing currents being created by the rush which all fluids make to the orifice. Currents will thus form from the top and sides of the containing vessel, and by their inertia they will cross each other, and thus impede the descent of the perpendicular column, causing the water which issues to run in a screw-like form; this, however, is in a great measure obviated by the application of a short tube from the aperture. That the projection of the tube too far into the interior of the vessel should make the flow less than if there were no pipe at all, may be thus explained:—The columns which descend from near the outside of the vessel, by turning up again to reach the discharging orifice, come into more direct opposition to the motion of the central descending columns, whilst they are at the same time themselves compelled to turn suddenly in opposition to their own inertia, before they can enter the pipe. Thus, the discharge is more effectually impeded than if it were proceeding from a mere opening in the bottom of the vessel. The tube for the discharge of water should not only be short and round, but also trumpet-mouthed or funnel-shaped, both internally and externally, that being the form which admits the flow of liquid with the least possible retardation.

The effects of friction between liquids and solids are nowhere so conspicuous as in the flowing of rivers. The natural tendency in the water to descend at a certain speed, is limited by the roughness of the bottom, bends in the course of the stream, and small projections on the

banks. From these causes, the water in a river flows with different velocities at different parts in any vertical section across the current. It flows at a slower rate of speed at and near the bottom than at the surface, and also slower at the sides than at the middle.

The resistance which a body moving in liquid meets with, when it comes in contact with a solid, is as the square of the velocity of the moving body; in other words, the resistance is not twice but four times with a double rate of speed. This is easily explained:—

A vessel moving at the rate of one mile per hour displaces a certain quantity of water, and with a certain velocity; if it move twice as fast, it of course displaces twice as many particles in the same time, and requires to be moved by twice the force on that account; but it also displaces every particle with a double velocity, and requires another doubling of the power on this account; the power thus twice doubled, becomes a power of four. When the body is moved with a speed of three or four, a force of nine or sixteen is wanted, and so on. Thus, the resistance increases as the square of the speed.

This important law suggests practical hints of considerable importance. For instance, in steam navigation, if an engine of fifty horse power impel a vessel at the rate of seven miles an hour, it would require two of the same power to drive her ten miles an hour, and three such to drive her twelve miles an hour. Hence the enormous expense of fuel attending the gaining of a high degree of velocity.

ACTION ON THE WATER IN RIVERS.

In cases where it is desirable to preserve the banks of rivers from injury, either from the regular action of the current or from floods, the water ought to be allowed a free open channel, with banks of a very gradual descent. The utmost violence of water in a state of motion may be rendered comparatively harmless, by allowing the flood or torrent to expend itself on a sloping or shelving shore. Inattention to this simple fact in hydraulics frequently causes much destruction to property on the banks of rivers.

A very small fixed obstacle, such as a stone or pebble, may partially impede and turn aside a brook of a slow current. The water, by striking on a stone at one side, is bent aside to the opposite bank, a little farther down; there it strikes upon the bank, and is returned to the side it formerly struck. Thus, proceeding in currents from side to side, the banks become worn down at particular places, and in time a new and serpentine course is given to the stream. In the case of rivers flowing with considerable velocity, impediments of this kind are usually overcome, and the stream pursues its straight onward course, dashing down all obstacles to its progress. Thus, rivers are generally winding in their course in flat countries, and straight in mountainous regions.

It sometimes happens that the water at the surface of a river may be moving in one direction, while the water at the bottom is flowing in an opposite direction. This is an exceedingly interesting phenomenon, which is observed to occur in certain rivers communicating with the sea, and is caused by the action of the tides and the difference of specific gravity in salt and fresh water. When the tide is flowing inwards, the salt water rushes up the channel of the river, but not in such a manner as to stem the current of fresh water, which, being lighter, floats on the top of the salt water, and pursues its downward course to the ocean. In those instances in which there is no great disturbance of the two liquids, the fresh water, by its specific lightness, floats on the surface of the sea to a distance of many miles from the land.

WAVES.

Waves are the risings and fallings of the water, caused by some power, such as the blowing of the wind. The power, whatever it happen to be, communicates a force to the mass of liquid, and a series of undulations is the consequence.

These undulations, or waves, exhibit the transmission of the communicated force. The force does not advance or alter the lateral position of the water at any given point; it only alters the water in its vertical position, or in relation to its depth. When, therefore, waves advance, the water does not advance with them: the water but rises and falls, and assumes the figure of undulations on its surface. When the undulations approach the shore the water then acquires a progressive motion, where it is shallow, and by friction on the bottom or impulsion against the shore, the communicated force is exhausted. The shaking of a carpet affords an exact representation of the action of waves or undulations.

Waves are comparatively superficial; they seldom, even in the greatest storms, rise to a height of more than twelve feet above the level of calm water, and make an equal descent beneath, making altogether an appearance of twenty-four feet; at eight or ten feet below the hollow or trough of the waves the water is tranquil. Waves "mountains high" is only a figure of speech.

ALTERATION OF TEMPERATURE.

By altering the temperature of liquid bodies, they become liable to peculiar laws, and exhibit peculiar phenomena.

At a temperature of 40 degrees of Fahrenheit's thermometer, water is at the point of greatest density. When the temperature is reduced below this point, the liquid gradually increases in volume till it reaches 32, when it freezes. When the temperature is raised above 40, the volume increases till it reaches the boiling-point, at which it has expanded to the extent of 1-22d additional to its bulk.

In consequence of this expansibility in heating, hot or warm water is specifically lighter than cold water; therefore, in heating any mass of water in a vessel over a fire, the lighter or warm particles rise to the top, while the cold and heavy particles sink to the bottom, to be heated and to rise in their turn. In this manner the process of heating proceeds, until all the particles are of a uniform temperature, which is at the boiling-point, when the liquid gradually flies off in steam.

If water be heated by the action of the fire, or the sun's rays on its upper surface, the mass is longer in attaining the vaporific point than when heated below, because water is a bad conductor of heat, and therefore the heat penetrates with difficulty through the upper stratum of warmed liquid to reach that which is beneath; and if the mass be very large, as, for instance, the ocean, no intensity of heat applied above can warm it throughout, or to any considerable depth.

Certain currents or sets of the ocean are known to be produced by the effort to attain an equability of temperature throughout. The power of the sun's rays at and near the equator heats the sea in that part of its volume, to the depth of two or three hundred feet. This upper stratum of heated water flows in currents towards the north and south poles, and there to a certain extent tempers the severity of the cold. The waters of the northern and southern tracts of ocean, displaced by these currents, necessarily sink below them, and push on towards the equator, to supply the deficiency caused by the departure of the waters above. Thus, in the economy of nature we see a process in constant action precisely the same in principle as that upon which the artificial hot-water apparatus has been established.

Having now discussed Hydrostatics and Hydraulics, we come to the kindred subject of Pneumatics, for which, as will be observed, we have reserved a notice of certain hydraulic machines involving pneumatical agency

PNEUMATICS.

GENERAL DEFINITIONS.

Pneumatics, from the Greek word *pneuma*, breath or air, is the name of the department of science which relates to the weight, pressure, or motion of air, or of any aëriform or gaseous fluids.

It was anciently supposed that the air of the atmosphere was an element or simple substance in nature. It is now satisfactorily established that air is not an elementary body, but is composed of certain gases in intimate union, and these gases can be separated from each other by a process in art.

Air, in its common condition, is a thin transparent fluid, so subtile that it cannot be handled, and when at rest it cannot be felt.

That it is a body, however, is quite obvious, because we feel its impression or force when agitated as wind, or when we wave our hand quickly through it. In the quick motion of the hand, we feel that it is partially opposed by something; and in inhaling breath into the lungs, we feel that we are drawing something through the mouth—that *something* is air.

Air, like every other substance, whether solid or fluid, possesses a certain gravity or weight. The weight of air certainly, bulk for bulk, is much less than that of water; still the weight may be accurately computed. A bottle full of air weighs heavier in a balance than a bottle of the same capacity from which the air has been extracted.

A cubic foot of water, as has been mentioned, weighs 1000 ounces. A cubic foot of air weighs only 523 grains, being a little more than one ounce; water, therefore, is about 840 times heavier than the air of our atmosphere. Inasmuch as water is a standard for comparing the gravities of liquids, air is a standard in the same respect for all aërial substances.

The specific gravity of air being denominated 1000, oxygen gas is 1111; nitrogen gas 972; hydrogen gas 69; and carbonic acid gas 1529. The lightest of these kinds of gas, therefore, is hydrogen, and the heaviest carbonic acid. Hence, if indefinite quantities of these aëriform bodies were placed in a vessel, or in an apartment, we should find, that, after certain portions had gone into intimate union, according to the laws by which they combine, the surplus portions of each would assume relative positions according to their respective weights—the heaviest to the bottom, and the lightest to the top. Such an experiment would resemble that previously noticed, of the mixture of mercury, oil, water, and spirits.

Air and all kinds of gases are rendered lighter by the application of heat, for then the particles in the mass are repelled from each other, and occupy a greater space; this process of lightening or thinning is called rarefaction. Rarefied air, being specifically lightest, mounts above that of a common density. The warmest air is always at the top of a room, and the coldest at the bottom.

Air is distinguished from water not only by its extreme comparative lightness, but by the property of clasticity; it is a compressible and elastic fluid.

When any quantity of air is compressed into a smaller space than it naturally occupies, it will return to its natural bulk on the pressure being withdrawn.

A small bladder of air may be squeezed between the hands so as to be considerably reduced in size; and on opening the hands again, and withdrawing the pressure, it will instantly resume its former bulk. If a metallic tube or barrel be fitted with a movable plug or piston, which is made to work in it perfectly air-tight, the air which occupies the space between the top and the bottom of this barrel when the piston enters, can be compressed to a hundredth part, or even less, of its usual bulk. If the force, however, by which the piston is pushed down, be withdrawn, the air, by its elasticity, will force it up again with a power equal to that by which its descent was resisted.

In proportion as any given volume of air is diminished by pressure, its elastic force is increased; in other words, the elastic force or elasticity of air is proportional to its density.

THE ATMOSPHERE.

The air, as formerly expressed, is a great ocean wrapped round the earth to a depth of from forty-five to fifty miles above the highest mountains, and forms a menstruum which is essential to the existence of all animals and plants.

This ocean of air penetrates into all unoccupied places, in the same manner as water flows into all crevices and holes beneath the level of its surface; and it also finds a place in the bodies of animals, plants, and liquid substances; hardly any thing, indeed, that we see in nature or art, is free from air, unless force has been employed to extract it.

The height of the atmosphere, though usually estimated at forty-five or fifty miles, is in reality unknown. The highest point above the level of the sea, which has ever been reached by any human being, is 21,000 feet, which has been attained in a balloon.

It is only conjectured, from the refraction of the sun's rays and other circumstances, that the height of the atmosphere is about fifty miles. At and near the level of the ocean it is most dense, in the same manner as water at the bottom of the sea is more dense than it is at the surface, on account of the incumbent pressure. As we ascend mountains, or in any other way penetrate upwards into the atmosphere, the air becomes gradually less dense, and so thin is it at the height of three miles on the summit of Mont Blanc, that breathing is there performed with some difficulty. Beyond this limited height, the density of the air continues to diminish, and at the elevation of about fifty miles, it is believed to terminate.

The extreme height of the atmosphere is not observable from the situation in which we are placed on the earth. Our eye, on being cast upwards, perceives only a vast expanded vault, tinted with a deep but delicate blue colour; and this in common language is called the sky. The blueness so apparent to our sense of sight is the action of the rays of light upon the thin fluid of the upper atmosphere, and the brightness is in proportion to the absence of clouds and other watery vapours. In proportion as the spectator rises above the surface of the earth, and has less air above him, and that very rare, the blue tint gradually disappears; and if he could attain a height at which there is no air, say at above fifty miles in height, the sky would appear perfectly dark or black. Travellers who have ascended to great heights on lofty mountains, describe the appearance of the sky from these elevated stations as dark or of a blackish hue.

The atmosphere possesses the capacity of absorbing and sustaining moisture, but only to a limited extent. When saturated to a certain degree, it is relieved by the falling of the moisture in the form of rain. It is calculated that the whole atmosphere round the globe could not retain at one time more moisture than would produce about six or seven inches of rain.

By an elevation of temperature, the capacity of the atmosphere to absorb and sustain moisture is increased, and by a lowering of temperature, decreased. Cold breezes, by lowering the temperature of the air, cause the aëriform moisture to assume the appearance of clouds, and then to fall as rain.

LAWS OF AIR.

First—The pressure of the air is equal in all directions: *Second*—Its degree of pressure depends on the vertical height or depth, and at any place is proportional to its density: *Third*—Its surface is level in all parts of its volume: *Fourth*—It affords support according to its density and to the weight of the fluid displaced.

That air presses equally in all directions may be rendered evident by filling a bladder with that fluid, and then pressing upon it so as almost to make it burst. The pressure is freely communicated through the mass, as in the case of the bag of water, and it will be observed that the confined air will rush out with equal impetuosity at whatever part you make a hole in the surface.

The level of surface of air is less perfect than the uniform level of water, on account of the greater elasticity of the substance. In a series of strata of air of different densities, one above the other, a small portion of each mingles with those which immediately adjoin it—the particles of one commingle to a certain extent with those of another. There is thus, as respects aërial bodies, a modification of the law of uniform levelness of surface in all parts of the volume of fluid.

PRESSURE OF AIR.

The pressure depending on the vertical height or depth of air, is an important property in the atmosphere, and on it depends the explanation of numerous phenomena.

Air being a substance possessing gravity, it must of necessity press downwards in the direction of the centre of the earth, and therefore the degree of pressure on any given point will be equal to the weight of the column of air above the point, and proportional to the density of the air at that point.

The idea of the atmosphere possessing the property of gravity or pressure, is of comparatively modern date. No such notion was entertained by the ancients, in consequence of living animals being observed to move with perfect ease in all directions, and because there was no other appearance in nature calculated to suggest it to their minds.

It was however remarked, that, when the air was sucked out of a small glass tube, the lower end of which was immersed in water, the water rushed up into the tube and occupied the situation of the displaced air. In consequence of this and similar phenomena, it was alleged as a doctrine in physics, that "nature abhors a vacuum."

A vacuum is a place destitute of air or any other kind of matter; and the notion was, that whenever by any chance such an empty space was found, nature interposed with all imaginable haste to fill it. With this very rude idea, pumps were formed to raise water, the rising of the water in these instruments being ascribed simply to nature's abhorrence of a vacuum. At length it was discovered that water could not be drawn up by a pump above a height of about thirty-two feet, and that a vacuum above that elevation remained unfilled; whereupon the terms of the doctrine were changed, and it was said that nature abhorred a vacuum only to a height of thirty-two feet, but no farther.

This explanation was seemingly unphilosophical, and men's minds being carefully turned to the subject, various experiments were performed, and the important truth became manifest, that the atmosphere possessed gravity or pressure; also, that that pressure was the sole cause of the rushing of liquids into tubes exhausted of air—the height of the ascending liquids being in every case limited by the degree of pressure of the incumbent atmosphere. Thus the discovery of a simple truth in science at once abolished the fantastic doctrine of nature's abhorrence of vacuum, and all the laboured sophistry with which it was supported.* Nature has no dislike to a vacuum; a vacuum will occur in all situations from which solids or fluids are accidentally or artificially excluded.

The degree of pressure imposed by the atmosphere on any given spot on the earth's surface, as already noticed, is equal to the weight of the column of air above that spot, and is also proportional to the density of the air at the place. The atmosphere is deepest or of greatest vertical height at the level of the ocean, and there it exerts the greatest pressure. The pressure of the air at the level of the sea is usually reckoned to be about 15 pounds on every square inch.*

The pressure of 15 lbs. to the square inch refers to every shape of surface at or near the sea's level. The pressure is sideways, upwards, oblique, and in every other direction, as well as downward, because fluids press equally in all directions. Thus, in every crevice, nook, or vessel, in which air happens to be, the pressure is equally intense. The human being, for example, sustains the pressure of 15 lbs. to the square inch all over his person, and this is a load under which he could not possibly move,† unless the pressure was also exerted in the interior of his body, or through his whole system of muscles, viscera, and bones, by which means the external pressure is counteracted, and he feels no pressure whatever.

If, however, the air by any means be withdrawn from the interior of any object, that object becomes immediately susceptible of the external atmospheric pressure. There are many familiar examples of this pressure around us. One of the most common consists in causing a thimble to adhere to the hand by sucking the air from beneath it: the adhesion is the result of the pressure of the atmosphere on the exhausted space on the hand. Another consists in lifting a stone by means of a sucker, formed of a string and a wetted piece of leather, as in the accompanying figure. The wetted leather is in this case pressed down upon the stone, and the string is then pulled: if air were admitted under the end of the string, the sucker would come off; but none being admitted, the atmosphere presses on the sucker, a rigid adhesion of the sucker to the stone is produced, and the stone, if not too heavy, is lifted.

Fig. 18.

The surgical process of cupping is upon the same principle. A glass cup is held with its mouth near the part to be operated on, and the air being consumed within it by a lighted taper, it is instantly applied, and adheres with great force. The part having been previously lanced, the blood, rushing to fill the vacuum, enters the cup in copious small streams. The feeling endured in cupping is that of considerable weight.

The feet of flies and some other insects are formed on the principle of the sucker, by which means they are enabled to walk and run with security on the ceiling of an apartment, back downwards, or on an upright and smooth pane of glass. At each step in advance, they procure a hold by the formation of a vacuum or air-tight space beneath their feet. The rapidity with which these vacuums or air-tightnesses are formed and destroyed, is an exceedingly interesting phenomenon in the economy of the animal, and cannot be rivalled by the utmost efforts of human skill. On a very moderate computation, a fly, in travelling six feet in the space of a minute, creates and destroys as many as 10,000 vacuums. When deprived

* This great discovery in physical science was made by Torricelli, an eminent Italian mathematician, about the year 1644. It was suggested by an ineffectual attempt to raise water from a deep well near Florence, by means of a pump of a greater height than thirty-two feet.

* The actual pressure varies from 14 lbs. to 15 lbs. according to circumstances. By various authorities it is stated at 14⅞ lbs. For convenience, we state it throughout in the text at 15 lbs.

† The body of a man has a surface of 2000 square inches, and therefore the pressure upon him is equal to 30,000 lbs.

of the outer extremities of its legs, on which the apparatus for adhesion is situated, a fly can walk without any apparent difficulty on a horizontal surface, such as a table, but is quite incapable of adhering to the roof, or of climbing any upright surface.

Limpets, snails, and some other crustaceous animals, adhere to rocks and stones, by causing a vacuum within their shells, which they accomplish by shrinking into a smaller bulk; by this simple contrivance, nature has effectually provided for their safe adhesion to their appropriate places of residence.

THE AIR-PUMP.

Air may be artificially withdrawn from a containing vessel by means of an apparatus called the air-pump. This apparatus is usually small, for standing on a table, and consists chiefly of a glass jar called a receiver, placed mouth downwards over a flat surface, and with a small brass pump to draw the air from it. The annexed cut, fig. 19, represents an outline section of an air-pump, the working of which may be described. R is the glass receiver standing on a flat and smooth plate SS, and fitting so exactly that no air can penetrate between the edges of the receiver and the plate. In the plate SS, there is a channel A B issuing into the barrel of a pump. P is the piston of the pump, with its rod C above, which is moved upwards and downwards by a handle and winch. The rod C works in a tight collar D. At the bottom of the pump there is a valve V, by which the air escapes, and is prevented from again entering. On depressing the piston, a portion of the contained air is expelled by the valve, and on raising the piston again to its position at the top, another column of air is admitted from the receiver into the pump, which is expelled in its turn. Thus, by a process of expulsion, the air in the receiver becomes at every stroke downwards more rare, till at length a vacuum sufficient for all practical purposes is established. The valve V, which opens outwards, is kept forcibly shut at every rising of the piston by external pressure of the atmosphere.

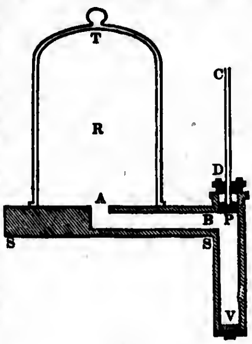

Fig. 19.

By means of the air-pump, a number of interesting experiments in pneumatics may be performed. For example, if a bladder half full of air, and tightly tied at the neck, be placed under the receiver, and a vacuum then produced, the air in the bladder will expand by the removal of the external pressure, and seem as if ready to burst. Dried raisins, during a similar operation, will expand, and have all the pulpness of new fruit; and an egg, by the expansion of its confined air, will explode. Any small animals, such as mice, placed below the receiver and deprived of air, will immediately die, both from want of breath and the expansion of their bodies.

The atmosphere serves to retard the falling of bodies of a light and porous nature; and, therefore, in the exhausted receiver of an air-pump, all such bodies descend with the same velocity as bodies of a heavy compact nature. A piece of coin and a feather let fall at the same instant of time, from a hook within the top of an exhausted receiver, will strike the bottom at the same moment.

That atmospheric air is useful for the transmission of sound, in the absence of other media, is also exemplified by the air-pump. If we place a small bell in a receiver, in such a manner as to admit of being rung easily from the outside without admitting air into the inside, whilst the receiver is full of air the sound of the bell will be distinctly heard; but after the receiver has been exhausted, and although the bell be struck with the same force, the sound will be inaudible, or nearly so. If a small portion of air be admitted, it will be faintly heard, and it will gradually increase according to the quantity of air which is allowed to enter the receiver. Thus, we are indebted to the air as a medium for conveying to us the sound of each other's voices, and all the melodious notes which constitute music.

The act of inspiring and expiring air resembles the alternating action of an air-pump. The air, on being drawn in through the appropriate tubes, fills the lungs, and the chest is expanded; having performed its office, the air is expelled in an impure condition, leaving a partial vacuum within, until another inspiration causes another expansion.

A machine called a condensing pump or syringe, is formed for the purpose of showing experiments with air more dense than that of the common atmosphere. The apparatus, which is represented in fig. 20, consists of a close glass jar or receiver fixed in a frame. A wire and hook serve to communicate with the interior during the performance of experiments. The syringe *i* is wrought by the piston with the handle *k*. From the bottom of the syringe there is a tube communicating with the interior of the receiver. When the piston is raised, a valve beneath opening inwards, admits air into the cylinder of the syringe, and when it is depressed, this quantity of air is forced into the receiver; by the alternate raising and depressing of the piston, an immense quantity of air is forced into the receiver.

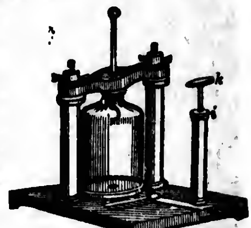

Fig. 20.

The elastic force of air so condensed is very great, and is employed for the projection of balls from an instrument called an air-gun. A certain quantity of compressed air is confined in a chamber at the inner end of the barrel, and when allowed to escape by touching a valve, a bullet is projected with a force resembling that of gunpowder.

The explosive force of gunpowder itself is nothing else than the sudden disengagement of air from the particles of the powder.

PRESSURE OF AIR ON SOLIDS AND LIQUIDS.

The pressure of the atmosphere affects all liquids as well as solid bodies. The load of the incumbent air is as sensibly exerted *within* any given mass of water as on the surface. Thus atmospheric pressure keeps water and other liquids at the density they are usually seen to possess.

If a glass be filled with water, and placed under the receiver of an air-pump, the abstraction of the air, by the removal of the atmospheric pressure, will cause the water to expand or become less dense, and it will overflow the vessel in which it is contained.

Water in its ordinary condition contains a certain quantity of particles of air mixed up with it. When the atmospheric pressure is lightened, these particles of air expand, and being of a less specific gravity than water, they mount to the top of the liquid in the form of small globules, and so fly off. The same effect is produced by expanding water by means of heat; the globules of air rise to the surface, and escape or remain attached to the inside of the vessel. Crystal bottles of water may be observed to be covered inside with small air-bells when the weather becomes suddenly light or warm. Water which has been boiled is comparatively free of air, and has an insipid flavour.

Certain gases are generated in some liquors, such as in porter, beer, and champagne wine, and unless the bottles in which they are contained be of sufficient strength to endure the expansive tendency, they will burst. On drawing the cork from a bottle of one of these liquors, the confined gas or air is suffered to expand, and the contents gush forth, a mixture of froth, and liquid. If the liquid remain in an open glass for a short time, a large portion of the long-confined gases escapes into the atmosphere, and the liquor seems flat or dead. A portion of confined air, however, still remains, in consequence of the atmospheric pressure. If we take a glass of ginger-beer which seems quite dead, and place it under the exhausted receiver of an air-pump, it will again froth and appear brisk.

Some mineral waters on springing from the ground sparkle like beer. These most likely rise from great depths, where the incumbent pressure is considerable, and on attaining the surface of the earth they expand, and give forth the air pent up in their mass.

If a bladder full of air be carried from a low situation to a great height, the contained air will expand, and the bladder will burst, the same as if placed under the exhausted receiver of an air-pump.

If a bladder be filled with air at a great height, where the fluid is rare, and brought to a low situation, the contained air will be compressed by the more dense fluid without, and the bladder will appear as if only half or partially filled.

The fluids in the animal and vegetable system are similarly affected by atmospheric pressure. Our bodies, for instance, would expand, and our blood-vessels probably be ruptured, if placed for a short time in a vacuum. On the same principle, any change in the density of the atmosphere has an effect on the animal frame.

The atmospheric pressure, in ordinary conditions of the air, and at the level of the sea, as already stated, is equal to 15 lbs. to the square inch. If by any means, such as digging into the earth, we should go below the sea's level, the weight will be found to increase. In deep coal mines, for instance, the pressure of the atmosphere is something more than 15 lbs. to the square inch.

The pressure diminishes in a similar degree as we ascend into the atmosphere. At every step upwards from the shore the burden of the superincumbent mass lightens. At the height of three miles, one-half of the weight is lost; or, in other words, at that height the air is only half the density of air at the sea's level.

The breathing apparatus of animals is suited to an atmospheric density and pressure such as is found at the sea's level, or at a moderate elevation above it. By ascending in the atmosphere, as in climbing hills, we are deprived of the quantity of air to which we have been accustomed; and when we reach a height of three miles, we in reality inhale only one-half of the weight of air into the lungs that we use at the sea's level. Consequently, those who ascend to great elevations experience difficulty in breathing, and feel an expansion in their blood-vessels and muscles by the removal of a portion of the ordinary pressure.* All the joints in our bodies, particularly those of the knee and shoulder, are in a great measure held together by the external pressure of the atmosphere; and thus a principle in pneumatics compensates for a loading of muscular ligaments.

A consideration of the effects of atmospheric pressure, and its variability at different elevations, also the alterations in pressure caused by the expansion or lightening of the air by heat, and its increased density by cold and moisture, tends to explain the remarkable influence which change of climate has upon the human constitution. Thus, the inhabitants of countries possessing a light dry atmosphere are usually more lively than those of countries with a heavy moist climate.

PRESSURE ON MERCURY—THE BAROMETER.

The pressure of the atmospheric column at any given point, may be weighed with considerable exactness, by balancing it against an opposite column of mercury, water, or other liquid.

The pressure of 15 lbs. to the square inch at the ocean's level is found by experiment to be equal to the weight of a column of mercury of 30 inches in height, a column of water 33 feet in height, or a column of oil 37 feet in height. In other words, the burden of the whole of our atmosphere is equivalent to an ocean of mercury covering the earth to a height of 30 inches, an ocean of water to a height of 33 feet, or an ocean of oil to a height of 37 feet.

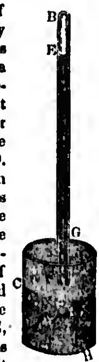

Fig. 21.

The fact of such being the degree of atmospheric pressure admits of easy proof, by means of a glass tube upwards of thirty-two inches in length, and a cup half filled with mercury, as represented in fig. 21. The tube is close at its upper end at B, but open at its lower extremity, which is immersed in the mercury below the surface level C P D. The tube having in the first place been filled with pure mercury, a finger is placed on its open end to prevent the egress of the liquid, and thus held, the lower end of the tube is turned downwards, and plunged into the vessel of mercury, when the finger is removed from the orifice. The mercury in the tube will now be observed to fall to E, or the height of about thirty inches above the surface C P D, and there it will remain.

The question now arises, Why the mercury in the tube does not run out altogether into the cup, instead of standing to the height of thirty inches in the tube? The explanation of the phenomenon is, that from E to B in the tube is a vacuum, and therefore the mercury at its upper extremity is entirely free of atmospheric pressure—there is no superincumbent weight to push it out. The column of mercury E P presses with nothing but its own weight on the mercury of the cup. This weight of thirty inches of mercury is counterbalanced by the pressure of air on the surface of the mercury in the cup; and thus it is evident that the weight of the atmosphere is equivalent to the weight of thirty inches of mercury. If by any means we remove the atmospheric pressure from the mercury in the cup, the mercury in the tube will immediately sink into the cup.

The circumstance of the column of mercury in the tube being narrow, and the surface of the mercury in the cup being broad, makes no difference in the experi-

* It is known that travellers, and even their practised guides, often fall down suddenly as if struck by lightning, when approaching lofty summits, on account chiefly of the thinness of the air which they are breathing, and some minutes elapse before they recover. In the elevated plains of South America, the inhabitants have larger chests than the inhabitants of the lower regions—another admirable instance of the animal frame adapting itself to the circumstances in which it is placed.—*Arnott's Physics.*

ment, because the pressure of elastic fluids is as their density, not as width of volume. The same result would occur if the surface of the mercury presented to the atmospheric pressure were only the width of the tube.

The height at which mercury stands in a tube of this kind, always bears reference to the incumbent weight of the atmosphere on the open and lower extremity of the column. If we increase the external pressure by artificial means, or by descending below the sea's level, the mercury rises; if we decrease it by artificial means, or by ascending into the atmosphere, or if the atmosphere is rarefied by heat, the mercury falls.

This very obvious connection between the rising and falling of mercury in a tube, and the atmosphere, has suggested the construction of an instrument called the *barometer* (a word from the Greek, signifying *weight* and *measure*), by which the effects of atmospheric pressure may be accurately known.

The barometer in common use consists of a narrow glass tube upwards of thirty inches in length, and bent upwards at its lower extremity, as represented in fig. 22. The mercury is introduced into the tube with great care, so that a perfect vacuum exists at the upper extremity. The surface of the mercury in the bent part is open to the action of the atmosphere, and buoys up a small plummet or float, F, to which a thread is attached; the thread proceeds upwards to a small pulley, G, over which it goes, and terminates in a small ball, W. The friction of the thread on the pulley turns a small index, H, which points to figures on the surrounding dial. Commonly, the whole apparatus, except the dial-plate, is concealed in an ornamental frame.

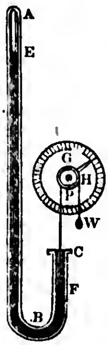

Fig. 22.

Barometers of this description are adjusted in such a manner that the smallest rising or falling of the mercury from atmospheric action affects the index on the dial, and shows the degree of pressure.

In common circumstances, the mercury ranges from 29 to 30 inches. It seldom sinks so low as 28, or rises to 31. When it falls, an indication is given of diminished pressure, and as diminished pressure causes the air to expand, and consequently to be sensibly cooled, moisture is liable to be precipitated in the form of rain. Hence a fall in the mercury of the barometer is considered a prognostic of rain or wet weather, and a rise the reverse. The dial of the barometer is marked accordingly.

The barometer, besides being a weather-glass, is used as an instrument for measuring the heights of mountains, or heights attained in balloons, above the level of the sea.

As the entire atmosphere sustains thirty inches of mercury in the tube, it follows that at every step as we ascend, the pressure will become less, and a less body of mercury be sustained. It is found that at the height of five hundred feet the mercury has sunk half an inch. But the fall does not proceed in this ratio as we go upwards, because a half of the whole atmosphere is within about three miles, and the other half expanded to an altitude of about fifty miles. Hence, on gaining a height of three miles, the mercury is found to have sunk to fifteen inches, or one half; and on gaining a height of four miles, to twelve inches.

Barometers for measuring heights are constructed with a determined scale, marked along the tube of mercury, and by consulting it as we ascend, we learn the height of any spot that we may reach. Perfect exactness, however, is not to be expected in this mode of measurement, because the atmospheric pressure is liable to variation from temperature, and the mercury is liable to contraction or expansion from the same cause. To guard against error, a thermometer, as well as a barometer, is consulted in ascending heights, and the indications of both instruments, according to a scale established by experiment, determine the degree of elevation. Thus, for a diminution of one degree of temperature between 0 and 32 degrees, the mercury in the barometer falls 0·0034 of an inch, and between 32 degrees and 52 degrees it rises 0.0033 of an inch

PRESSURE ON WATER—PUMPS.

The effect of atmospheric pressure on water is observable in various contrivances in the arts.

Fill a glass to the brim with water, and lay a piece of paper over the whole surface of the liquid: then turn the glass carefully upside down, holding on the paper by the hand; the water will now remain in the glass, being upheld by the pressure of the atmosphere against the paper.

Glass fountains of water for bird-cages, ink-holders, and reservoirs of oil for lamps, are constructed on the principle of the liquid being upheld by atmospheric pressure.

The apparatus for lifting water from wells, forming the common sucking-pump, acts on the principle of removing the atmospheric pressure from a column of the liquid, thus causing a vacuum in the pump, and allowing the atmospheric pressure on the surface of the liquid in the well to force up and balance the column of liquid.

Fig. 23 represents the outline of a common sucking-pump; it consists of a cylinder, furnished with a piston A made to fit air-tight. In this piston there is a valve opening upwards, not seen in the cut. When the piston is raised, the air is rarefied more and more at each stroke in that portion of the cylinder through which it has moved upwards, and the pressure of the air upon the surface of the water on the outside of the tube forces the fluid into it. The valve B is at the same time opened upwards, and the water after several strokes rushes in above it. When the upward stroke of the piston is complete, it is again depressed—the water passes through the valve in the piston, and on the next stroke, it is discharged at the spout. It is evident, that, when the piston is sunk downwards, the water cannot be again forced out of the pump, because the valve at the bottom is pressed down, and prevents its escape.

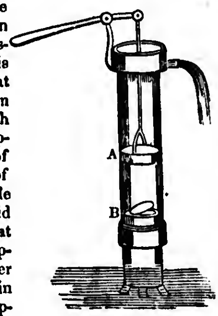

Fig. 23.

Water may in this manner be lifted by a pump to any height, but in each case the lower or fixed valve in the pump must be less than 34 feet from the surface of the water. It is, however, disadvantageous to lift water from great depths by this means. In such cases it is usual to employ a succession of pumps, one above another.

It is customary to call pumps hydraulic machines; properly speaking, they are both hydraulic and pneumatic machines, for water is raised by them in a great measure through the agency of atmospheric pressure.

The form of pump used for forcing water to a height above the ground, as in the case of fire-engines or portable forcing-pumps for gardens, is different from the common suction-pump. The object in the forcing pump is to lift water to a certain height by the formation of a vacuum, and then to inject it with violence into the air.

The action of the forcing-pump apparatus is represented in fig. 24. The piston A sucks the water by its upward motion; but on depressing it, the valve B is closed, and the water is consequently forced through the pipe C.

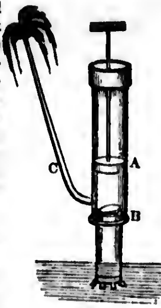

Fig. 24.

In the case of supplying water to the boiler of a steam-engine, it is necessary to employ a forcing-pump, in order to overcome the pressure of steam within the boiler. The force with which the water is injected overcomes the tendency which the steam has to rush out.

Cold or moderately warm water can only be lifted by a pump. If the water be above a certain temperature, about 150 degrees at the utmost, the sucker cannot form a perfect vacuum, because, in the attempt to do so, the water yields a steam or vapour which fills the space; in other words, by removing the atmospheric pressure by the piston, the water begins to vaporize as if about to boil. When a pump is made to operate upon hot water, it labours in vain to raise the liquid. This circumstance limits the heat of water injected into the boilers of steam-engines; or if the water is injected at a high temperature, it must receive its heat between the pump and the boiler. This is sometimes done, by causing the tube from the pump to pass through a vessel of waste steam.

SYPHONS.

Atmospheric pressure is very conspicuous in the case of the syphon.

A syphon is a tube bent in a particular manner, and is used for drawing off liquors from casks, or water from reservoirs. One kind of syphon is represented in fig. 25, and consists of a tube bent into two equal limbs, each open at the extremity. If such a syphon be filled with water and inverted, so as to turn the two orifices downwards, the liquid will not run out, but remain suspended in the tube, because the pressure of the column of water within is not so great as the pressure of the air without, and thus its escape outwards is prevented. If one end be put into a vessel of water, the vessel will be emptied down to a level with the orifice. It is evident that, when one end of the syphon is inserted in water, the pressure of the atmosphere upon the surface of the water impels the liquid through the tube, and it could be forced upwards to an elevation of above thirty feet, or the height to which water rises in a vacuum. The diagram represents an instrument of this kind furnished with two cups, firmly attached to the ends, which, by retaining a portion of the liquid, keeps the syphon always full and ready for use.

Fig. 25.

Syphons are more commonly made with a long and short limb, as in fig. 26. On inserting the short limb into a vessel of liquid, and drawing the air out of the tube at the mouth A, the liquid will rush out in a stream, and continue flowing till the vessel is emptied. The pressure upwards into the tube at A is the excess of the atmospheric pressure above the vertical pressure of the column of fluid A B; and the similar pressure at C is the excess of the atmospheric pressure above the vertical pressure of the column of fluid B C; but the latter excess is evidently the greater, and hence the liquid in the vessel is necessarily forced upwards through the tube from C to B; and thus the vessel is drained of its contents. By placing a stopcock on the tube above A, the stream can be checked, and permitted to flow at pleasure. There are instances of towns being supplied with water by means of large syphons of this kind. In these cases the syphon is brought over a rising ground from a lake or fountain at some distance. Certain kinds of springs are accounted for on the principle of the syphon; they act from the combined effects of a vacuum and atmospheric pressure.

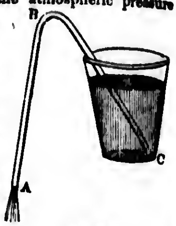

Fig. 26.

APPLICATION OF HEAT TO WATER.

The pressure of the atmosphere affects the boiling of water. At the common pressure of about 15 lbs. to the square inch, water will boil, or attain the vaporific point, at 212 degrees Fahrenheit. If we remove the atmospheric pressure by an air-pump, as is done in the boiling of sugar, we can produce the phenomenon of boiling at a much lower temperature. At the summit of Mont Blanc, where the atmospheric pressure is light, water is found to boil at 187 degrees.

Steam produced from boiling water is a transparent, colourless, and invisible substance, like air. If we could look into the boiler of a steam-engine, we should see nothing but the water in a state of ebullition. The white cloudy-looking matter which is emitted in the form of vapour, is moisture produced by the partial condensation of the steam in the atmosphere—taking the form of vapour is a step towards becoming liquid again.

A cubic inch of water produces exactly a cubic foot, or 1728 cubic inches, of steam, at 212 degrees of temperature; in other words, when water is transformed into steam, it occupies 1728 times its former bulk. In this expanded condition steam is of a less specific gravity than air. Its density is expressed by 0·625, that of air being 1.

The elastic force of steam in the process of heating—that is, the force with which it seeks to expand—differs at different temperatures; at first the force is inconsiderable, but it rapidly increases as the temperature is raised. At a temperature of 212 degrees, the elastic force is 15 lbs. on the square inch of the containing vessel, or equal to the external pressure of the atmosphere; at 250 degrees, it is 30 lbs.; at 272 degrees, it is 45 lbs.; at 290 degrees, it is 66 lbs.

BUOYANT PROPERTY OF AERIFORM FLUIDS.

The atmosphere, as has been stated, possesses the property of buoying up bodies which, bulk for bulk, are lighter than itself. The law governing buoyancy in liquids is precisely the same as that governing buoyancy in aëriform fluids, and may here be repeated in reference to air.

1st. Any solid body immersed in a fluid displaces exactly its own bulk of fluid, and the force with which the body is buoyed up is equal to the weigh of the fluid which is displaced. This refers to bodies of less density than air. 2d. Any solid body of a greater density than air, when wholly immersed in that fluid, loses exactly as much of its weight as the weight of an equal bulk of air—that is, of the air which it displaces.

The support afforded to bodies in the atmospheric fluid by its resistance is very evident from many appearances in nature, as the support of vapours or clouds, the rising of smoke and fine particles of dust, and the flying of birds; in art, it is exemplified by the flying of a boy's paper kite, the rising of soap-bubbles, and its buoyant property by the floating of balloons.

The flight of birds is not accomplished altogether by the buoyant property in the air. These animals support themselves by striking their wings against the fluid through which they are passing; and this friction, along with the property of buoyancy in the atmosphere, sustains them at any height to which they are pleased to ascend. Birds do not generally fly above half a mile in height, and seldom above a few hundred yards. At considerable elevations the air is so specifically light as to be unsuitable for their easy support. Those which rise to the higher regions of the atmosphere, as for instance the eagle, are provided with large wings, which enable them to support themselves in the comparatively thin fluid in which they move.

The light heated air which escapes from a fire, ascends, and is buoyed up by the more dense air beneath. Hydrogen, or any other gas of a less specific gravity than air, in the same manner ascends and floats in the atmosphere at the height at which it finds air of its own specific gravity. On the same principle, if heated air or any light gas be enclosed in a large silk bag, it will ascend in the atmosphere till it reach a region of air which is incapable of supporting it. Thus, a soap-bubble enclosing warm air readily ascends to the ceiling of an apartment. If the bubble be made with cold water, it will sink instead of rising.

A balloon is a bag made of fine varnished silk, and of such a magnitude that the difference betwixt the weight of its contents and that of the displaced air is sufficient to support the weight of the silk and the other parts of the apparatus. Balloons were originally made to rise by being filled with heated air from a fire hung beneath them; but this dangerous and inconvenient practice was in course of time superseded by the use of hydrogen gas, one of the lightest airs which can be prepared. Hydrogen gas has latterly been succeeded by carbureted hydrogen, which, though not so light, is more easily obtained, being the gas with which towns are now generally lighted. Employing a moderately pure and light gas, the contents of a balloon may be estimated to weigh only an eighth of the weight of the atmosphere, bulk for bulk; and hence, after adding another eighth for weight of apparatus, it will ascend with a force of six-eighths; in other words, if the gas and apparatus weigh two pounds, the balloon will lift from the ground a weight of other six pounds. The force with which a balloon will ascend is therefore to be calculated by measuring its capacity in cubic feet, and comparing the result with an equal bulk of atmospheric air: the difference of weight is the buoyant force of the balloon.

Of aërostation, or the art of moving through the air in balloons, great expectations were originally entertained; but the experience of half a century has proved that it is of no practical value. Its only use is the exhibition of an interesting principle in pneumatics. A balloon constructed in the best known manner, and moving upwards with a powerful force, is subject to the following drawbacks:—as the balloon ascends, its contents expand in consequence of the increasing rarefaction of the atmosphere; if, therefore, it has been entirely filled when on the ground, a portion of the gas must be allowed to escape as it rises, otherwise it will burst. Discharges of ballast are also required in consequence of the absorption of moisture from clouds; and there being no means of recovering the lost ballast, the balloon, on the return of heat, rapidly rises in the air, its contents expanding in the ascent, and rendering further liberations of gas necessary to prevent explosion. These alternations continuing to operate more or less frequently, it is evident that they must soon put an end to the buoyant power, however great originally, and, along with the contending effects of winds, forcibly terminate the excursion through the air.

[WORKS ON HYDROSTATICS, HYDRAULICS, AND PNEUMATICS.

The writers we shall refer to, independently of those who treat on every branch of natural philosophy in conjunction, are as follows:

"Hydrostatical and Pneumatical Lectures, by Roger Cotes, A. M." This work was published after the death of the author, by Dr. Smith; it possesses great merit, and will, so long as science lasts, be esteemed very highly by its votaries. The early death of Mr. Cotes, at the age of thirty-three, was deplored by mathematicians as a public calamity. Sir Isaac Newton asserted that, had his life been spared, he would have proved one of the greatest men that ever lived. "If Mr. Cotes had lived," said this illustrious philosopher, "we should have known something."

"The Principles of Hydrostatics, for the use of the Students in the University of Cambridge, by the Rev. Dr. Vince," includes the fundamental principles of Pneumatics and Acoustics; and, independently of an account of the instruments illustrative of Hydrostatics, he has given full descriptions of the air-pump and condenser; the thermometer, hygrometer, and pyrometer. There is also a section devoted to the subjects of winds, vapours, and the formation of springs.

Ewbank's "*Mechanics and Hydraulics*" is most thorough and satisfactory on the history of Hydraulics, with the application of the science to the common arts of life. It is very richly embellished with engravings illustrating hydraulic machinery and implements both ancient and modern.

Adams's "Lectures on Natural Philosophy" contains a great number of experiments in pneumatics, with numerous engravings illustrating the apparatus employed in the experiments.

The apparatus employed in Pneumatics is manufactured in great perfection by Mason, of Philadelphia, and Claxton, of Boston.—*Am. Ed.*]

OPTICS—LIGHT—ACOUSTICS.

OPTICS—LIGHT.

The term *Optics* is derived from a Greek word which signifies *seeing*, and applies to that branch of natural philosophy which treats of the phenomena of *light* and *vision*. Of the precise character of light, there are various theories, but none which admits of actual demonstration or proof. By some it has been described as consisting of very minute particles, which are thrown off from what are called luminous bodies in all directions, and with immense velocity; while others consider it as the effect of an undulation or vibration produced by luminous bodies in the thin and elastic medium which is interposed between them and the seat of our vision; this vibration producing an effect upon our organs, which we recognise as light, in a manner analogous to the impression of sound on the ear, caused by vibrations of the atmosphere. This theory is called the *undulatory* theory of light; and the former theory, in which light is supposed to consist of *material* particles, is called the theory of *emission*. Whatever may be the cause or absolute nature of light, we know it is a remarkable property of luminous bodies, that it enables us to see the luminous objects themselves, as well as others, and that its absence produces darkness.

All visible bodies may be divided into two classes—*self-luminous* and *non-luminous*. Under the first head are comprised all those bodies which possess in themselves the property of exciting the sensation of light or vision, such as the heavenly luminaries, terrestrial flames of all kinds, phosphorescent bodies, and those bodies which shine by being heated or by friction. Under the second class we recognise such bodies as have not of themselves the power of throwing off particles or undulations of light, but which possess the property of reflecting the light which is cast upon them from self-luminous bodies. A non-luminous body may thus, by reflection, receive light from another non-luminous body, and communicate it to a third, and so on. All reflected light, however, is inferior in point of brilliancy to that which comes direct from a self-luminous body.

Anciently, it was believed that light was propagated from the sun, and other luminous bodies, instantaneously; but the observations of modern inquirers have shown that this was an erroneous hypothesis, and that light, like sound, requires a certain time to pass from one part of space to another, though the velocity of its motion is truly astonishing, as has been manifested in various ways. Astronomers have proved, by observing the eclipses of Jupiter's satellites, when that planet is nearest and when it is farthest from the earth, that light moves from the sun to the earth, a distance of 95,000,000 of miles, in seven and a half minutes, or about 200,000 miles during a single vibration of the pendulum. So prodigiously great is this velocity, that, as far as any common observation is concerned, light may be said to be perfectly instantaneous in its universal action.

Light proceeds in a straight direction from the luminous body which produces it, towards the part or situation against which it is permitted to act. In consequence of this directness, a shadow or darkened spot is observable behind any opaque object presented to the light. During night, we are in the earth's shadow, and this shadow reaches so far beyond us into space, that when the moon plunges into it in her course, she undergoes an eclipse. The direct shining of the sun, or any other luminous body, is in the form of *rays*, or thin ethereal lines, each acting independently of the other; no such separation of parts, however, is observable, in common circumstances, in consequence of the diffusive properties of our atmosphere. Seeing is simply the reception of the direct or reflected ray from an object by our eye. Until the rays of the sun reach the spot on which we are placed, we are neither conscious of light nor of the presence of the sun as an object. In the same manner, a candle being lighted and exposed in the open country in a dark night, all who are able to see it are within the influence of its rays; but beyond a given distance these rays are too weak to produce vision, and all who are in this remote situation cannot see the smallest appearance of the candle. It will therefore be understood, that the seeing of any luminous object is equivalent to being within the influence of rays of sufficient intensity proceeding from it. The number of rays which proceed from even a common candle is so vast as to be beyond our imagination to conceive; for if such a light is visible within a sphere of four miles, it follows, that if the whole of that space were surrounded with eyes, each eye would receive the impression of a ray of light.

In proportion as light advances from its seat of production, it diminishes in intensity. The ratio of diminution is agreeable to that which governs physical forces, that is, the intensity of the light will diminish as the square of the distance increases, or at the rate of 1, 4, 16, &c. But in proportion as we lose in intensity we gain in volume; the light is the weaker the farther it is from the candle, but it is filling a wider space.

Preliminary to any further exposition of the nature and action of light, we offer the following definitions of terms. Any parcel of rays, passing from a point, is called a *pencil* of rays. By an optical *medium* is meant any pellucid or transparent body, as, for example, air, water, or glass, which suffers light to pass through it. *Parallel rays* are such as move always at the same distance from each other. If rays continually recede from each other, they are said to *diverge*; if they continually approach each other, they are said to *converge*. The point at which converging rays meet is called the *focus*; the point towards which they tend, but which they are prevented from coming to by some obstacle, is called the *imaginary focus*. When rays, after passing through one medium, on entering another medium of different density, are bent out of their former course, and made to change their direction, they are said to be *refracted*; when they strike against a surface, and are sent back again from the surface, they are said to be *reflected*. A *lens* is a glass ground into such a form as to collect or disperse the rays of light which pass through it. These are of different shapes, and thence receive different names. The following figures individually represent sections of the variously shaped lenses and other glasses used in optics.

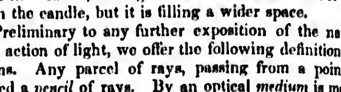

Fig. 1.

A is a triangular stalk of pure glass, of which we have here a cross sectional or end view, and which is called a *prism*. Each side of the prism is smooth. B is a section of a piece of plane glass, with sides parallel to each other. C is a sphere or ball of glass, and consequently is convex on all parts of its surface. D is a piece of glass convex or bulging on its two sides, and is called a *double convex lens.* It is this kind of lens which is used for magnifying objects, in spectacles, telescopes, and other instruments. E is a *plano-convex lens*, flat on one side ano convex on the other. F is a *double concave lens*, a glass hollowed on each side. G is a *plano-concave lens*, or planed on one side and concave on the other. H is a *meniscus*, or lens convex on one side and concave on the other, both surfaces meeting, and of which we have an example in watch-glasses. I is an example of the *concavo-convex* lens, in which the surfaces disagree, or do not meet when continued. In all these lenses, an imaginary line, represented by M G N, and passing through the centres of the surfaces, is called the *axis*. Thus, the line said to pass through the centre of any lens, in a direction perpendicular to its surface, is called its axis.

In treatises on optics, it is customary to divide the subject into two sections, under the heads Dioptrics and Catoptrics. The term *dioptrics* is compounded of two Greek words signifying to *see through*, and refers to the transmission of rays of light through transparent bodies, as well as the laws by which they are produced. *Catoptrics* is a term also from the Greek, and signifies to *see from* or *against*; it refers to the reflection of light from surfaces, and the formation of images by means of mirrors and other objects.

REFRACTION OF LIGHT.

Refraction, as already mentioned, is the bending of rays of light from the course they formerly pursued. If the rays, after passing through a medium, enter another of a different density, perpendicular to its surface, they are not refracted, but proceed through this medium in their original direction. For instance, if the sun's rays were to strike upon the surface of a river at right angles, or perpendicularly, to its surface, they would go straight to the bottom, and the line they observed in the air would be continued in the water. But if they enter obliquely to the surface of a medium either denser or more rare than what they moved in before, they are made to change their direction in passing through that medium; in other words, they are refracted.

The mode of the refraction depends on the comparative density or rarity of the respective media. If the medium which the rays enter be denser, they move through it in a direction nearer to the perpendicular drawn to its surface. On the contrary, when light passes out of a denser into a rarer medium, it moves in a direction farther from the perpendicular. This refraction is greater or less, that is, the rays are more or less bent, or turned aside from their course, as the second medium through which they pass is more or less dense than the first. To prove this in a satisfactory way, take an upright empty vessel into a darkened room, which admits but a single beam of light obliquely through a hole in a window-shutter. Let the empty vessel stand on the floor, a few feet in advance of the window which admits the light, and let it be so arranged that, as the beam of light descends towards the floor, it just passes over the top of the side of the vessel next the window, and strikes the bottom on the side farthest from the window. Let the spot where it falls be marked. Now, on filling the vessel with water, the ray, instead of striking the original spot, will fall considerably nearer the side towards the window. And if we add a quantity of salt to the vessel of water, so as to form a dense solution, the point where the ray strikes the bottom will move still nearer to the window. In like manner, if we draw off the salt water, and supply its place with alcohol, the beam of light will be still more highly refracted; and oil will refract yet more than alcohol

The property of refraction may also be observable in the following experiment. Let the annexed oblong figure represent a vessel half filled with water, and R the ray of light which may be expected to pass through

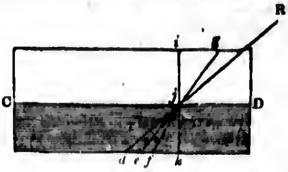

Fig. 2.

it to the bottom at *d*. The direction of the ray is perfectly straight until it enters the water at *j*, when, instead of proceeding in a straight line to *d*, it is bent from its course and compelled to strike the bottom of the vessel at *e*. If oil instead of water had been used, the ray would have been still more bent, and have reached the bottom at *f*. If the ray had been sent directly downwards, as from *i* to the surface of the water at *j*, it would not have been refracted, but have proceeded straight to the bottom at *k*.

The following simple experiment is well known:—Take an empty basin and place it on a table, then lay a shilling at the bottom of the basin, in such a position that the eye of the observer will not see it. Now, fill the basin with water, and the shilling, though lying unmoved, will come completely into sight. The explanation of this phenomenon is, that the ray of light producing vision in the eye is bent on emerging from the water, and has all the effect of conveying our sight round a corner.

The refractive power of water is also observable when we thrust a straight stick or instrument into it, on aiming at any object. We see that the stick seems to be bent, and fails in reaching the point which we desired it should. On this account, the aim by a person not directly over a fish must be made at a point apparently below it, otherwise the weapon will miss by flying too high. Persons who spear salmon in rivers require to calculate upon this refractive power in taking their aim.

With regard to the refractive power of transparent substances or media, the general rule, with certain limitations, is, that it is in proportion to the densities of the bodies. It increases, for instance, from the most perfect vacuum which can be formed, through air, fresh water, salt water, glass, and so on. But those substances which contain the most inflammable matter, have the greatest refractive power. It was from the great refractive powers of the diamond and water, that Newton, with admirable sagacity, predicted that they contained inflammable principles. This fact future discoveries in chemistry verified. Tables of the refractive powers of substances most interesting in optics will be found in Brewster's Optics. From these it would appear that substances which contain fluoric acid have the least refractive power, as inflammable ones have the greatest. With regard to the cause of refraction, on the theory of emission, the refracting medium would attract the particles of light, and increase their velocity during their transmission, and would alter the direction of their motion, thus causing refraction but the intensity of the attractive force would require to be different for light of different colours; and on the undulatory theory, the ether within the refracting medium would be condensed by the attraction of its particles on the ether, and the velocity of transmission of the wave of light through this condensed ether would be less than in free space, and, from this cause, the direction of the motion would be altered, or refraction would take place· and from the different lengths of the waves of different colours, the velocity of their transmission would be dif ferent, thus causing different degrees of refrangibility according to the difference of colour.

The refraction of rays of light is observable in the case of common window-glass. The two sides of a pane not being perfectly parallel to each other, bodies seen through it appear as if distorted; and as the obliquities in the glass are very various, the distortions are equally grotesque and numerous. Some windows are purposely ground on the surface, to produce universal and minute refraction; and thus so great a confusion is introduced among the rays, that objects are not distinguishable through the glass. When the obliquities on the surface of one side of a piece of glass stand distinct from each other, so as to admit of refraction in a clear and distinguishable manner, then each obliquity affords a separate view of an object on the opposite side, and thus an object seems to be multiplied as many times as there are obliquities.

The refraction of light is observable on a great scale in relation to our atmosphere. The rays of the sun, on reaching the confines of the atmospheric fluid which envelops the earth, enter a medium of greater density than that which they have previously been pursuing, and consequently are refracted or bent. One obvious effect of this is, that we never see the sun in the actual position which he occupies. He is always, less or more, in relation to our eyes, what the shilling is said to be in the above experiment with the basin of water. This is peculiarly the case in the morning, when his earliest rays reach our eyes; entering a denser medium, these rays bend round to meet our vision, and we actually see the body of the sun a few minutes before he has risen above the horizon—like the shilling in the basin, we see him round a corner. In proportion as the sun approaches the zenith, the refraction diminishes; and as he recedes towards setting, it increases. So considerable is it in the hazy atmosphere of the evening, that we retain a sight of the sun's disk after it has sunk. The same phenomena occur in relation to the other heavenly luminaries.

From these explanations it will appear that the directness of our vision is at all times liable to be disturbed by atmospheric conditions. So long as the atmosphere betwixt our person and the object we are looking at is of the same density, we may be said to see in a straight line to the object. But if by any cause a portion of that atmosphere is rendered less or more dense, the line of vision is at once refracted or bent from its course. A thorough comprehension of this simple truth in science has banished a mass of superstition. It has been found that, by means of powerful refraction, objects at a great distance, and round the back of a hill, or considerably beneath the horizon, are brought into sight. In some countries, this phenomenon is called the *mirage*. The following is one of the most interesting and best authenticated cases of mirage. In a voyage performed by Captain Scoresby in 1822, he was able to recognise his father's ship, when below the horizon, from the inverted image of it which appeared in the air. "It was," says he, "so well defined, that I could distinguish by a telescope every sail, the general rig of the ship, and its particular character; insomuch that I confidently pronounced it to be my father's ship the *Fame*, which it afterwards proved to be; though, on comparing notes with my father, I found that our relative position at the time gave our distance from one another very nearly thirty miles, being about seventeen miles beyond the horizon, and some leagues beyond the limit of direct vision. I was so struck by the peculiarity of the circumstance, that I mentioned it to the officer of the watch, stating my full conviction that the *Fame* was then cruising in the neighbouring inlet."

A curious phenomenon of this kind was seen by Dr. Vince, on the 6th of August, 1806, at 7 P.M. To an observer at Ramsgate, the tops of the four turrets of Dover Castle are usually seen over a hill between Ramsgate and Dover. Dr. Vince, however, when at Ramsgate, saw the whole of Dover Castle, as if it had been brought over and placed on the Ramsgate side of the hill. The image of the castle was so strong and well defined, that the hill itself did not appear through the image.

In the sandy plains of Egypt, the mirage is seen to great advantage. These plains are often interrupted by small eminences, upon which the inhabitants have built their villages, in order to escape the inundations of the Nile. In the morning and evening, objects are seen in their natural form and position; but when the surface of the sandy ground is heated by the sun, the land seems terminated at a particular distance by a general inundation: the villages which are beyond it appear like so many islands in a great lake, and between each village an inverted image of it is seen.

That the phenomena of the mirage are produced by variations in the refractive power of the atmosphere, can be proved by experiment. If the variation of the refractive power of the air takes place in a horizontal line perpendicular to the line of vision—that is, from right to left—then we have the lateral mirage: that is, an image of a ship may be seen on the right or left hand of the real ship, or on both, if the variation of refractive power is the same on each side of the line of vision. If there should happen at the same time both a vertical and a lateral variation of refractive power in the air, and if the variation should be such as to expand or elongate the object in both directions, then the object would be magnified as if observed through a telescope, and might be seen and recognised at a distance at which it would not otherwise have been visible. If the refractive power, on the contrary, varied so as to contract the object in both directions, the image of it would be diminished as if seen through a concave lens.

In order to represent artificially the effects of the mirage, Dr. Wollaston suggested the viewing of an object through a stratum of spirit of wine lying above water in a crystal jar, or a stratum of water lying above one of syrup. These substances, by their gradual incorporation, produce a refractive power diminishing from the spirit of wine to the water, or from the syrup to the water; so that, by looking through the mixed or intermediate stratum at a word or object held behind the bottle which contains the fluids, an inverted image will be seen. The same effect, it has been shown, may be produced by looking along the side of a red-hot poker at a word or object ten or twelve feet distant. At a distance less than three-eighths of an inch from the line of the poker, an inverted image is seen, and within and without that an erect image.

The method employed by Sir David Brewster to illustrate these phenomena, consists in holding a heated iron above a mass of water bounded by parallel plates of glass; as the heat descends slowly through the fluid, we have a regular variation of density, which gradually diminishes from the bottom to the surface. If we now withdraw the heated iron, and put a cold body in its place, or even allow the air to act alone, the superficial stratum of water will give out its heat, so as to produce a decrease of density from the surface to a certain depth below it. Through the medium thus constituted, the phenomena of the mirage may be seen in the finest manner.

Double Refraction of Light.—In the preceding part of this section, we have considered a single ray of light, reflected or transmitted through the substance of a transparent body, as leaving it in the same way in which it came into contact with it, namely, in a single pencil or ray. But there are a great many bodies which have the power of breaking the pencil of light incident upon their surfaces into two separate parts or pencils, more or less inclined to one another, according to the nature and state of the body, and according to the direction of the inciden pencil. This is called double refraction, and the bodies which produce it are called doubly refracting bodies or crystals. They are very numerous, and include all salts and crystallized minerals not having the primitive forms of the cube, the regular octohedron, and the rhomboidal dodecahedron. Of all known bodies, the Iceland spar, or rhomboidal carbonate of lime, shows the fact with the greatest certainty; and as it is a mineral easily procured, it has been generally used in experiments upon this subject. Its crystals are of a rhomboidal form, having six acute solid angles, and two obtuse. Double refraction of light is employed to advantage in some kinds of light-houses; and those who wish to investigate its nature and properties may be referred to advanced treatises on the subject.

With respect to the *polarization of light*—which is the separation of a ray of light into two rays, having different properties from each other, among which properties is that of producing colour in a variety of ways, although the original ray may be common or white light—we must also refer to works of higher scope than the present.

COLOUR BY REFRACTION.

One of the most remarkable phenomena attending refraction is, that the rays of light which seem to us to be white, may be separated into rays of various colours. It will be obvious that light has the effect of representing colours, where no colour substantially exists, by noticing the glancing and varied hues on irregular surfaces of glass, ice, or other crystallized substances.

The proper method of analyzing the rays of light, and discovering into what colours they may be resolved, is to procure a prism, and perform the following experiment in a darkened chamber:—In the window-shutter E of a

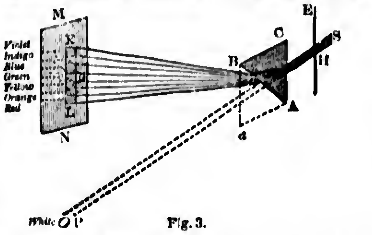

Fig. 3.

darkened room, make a small hole H, through which admit a beam of the sun's light S, which, when nothing is interposed, will proceed in a straight line to P, and form a luminous white spot. If we now interpose a prism B A C, whose refracting angle is B *a* C, so that the beam of light may fall on its surface C A, and emerge at the same angle from its second surface B A in the direction *g* G, and if we receive the refracted beam on the opposite wall, or on a white screen M N, "we should expect," says Sir David Brewster, "from the principles already laid down, that the white beam which previously fell upon P would suffer only a change in its direction, and fall somewhere upon M N, forming there a round white spot exactly similar to that at P. But this is not the case. Instead of a white spot, there will be formed upon the screen M N an oblong image K L of the sun, containing seven colours, viz.: red, orange, yellow, green, blue, indigo, and violet, the whole beam of light diverging from its emergence out of the prism at *g*, and being bounded by the lines *g* K, *g* L. This lengthened image of the sun is called the solar spectrum, or the prismatic spectrum. If the aperture H is small, and the distance *g* G considerable, the colours of the spectrum will be very bright. The lowest portion of it at L is a brilliant red. This red shades off by imperceptible gradations into orange, the orange into yellow, the yellow into green, the green into blue, the blue into a pure indigo, and the indigo into a violet. No lines are seen across the spectrum thus produced; and it is extremely difficult for the sharpest eye to point out the boundary of the different colours. Sir Isaac Newton, however, by many trials, found the lengths of the colours to be as follow, in the kind of glass of which his prism was made:—Red, 45; orange, 27; yellow, 40; green, 60; blue, 60; indigo, 48; violet, 80—Total length, 360."

These colours are not equally brilliant. At the lower end L of the spectrum, the red is comparatively faint, but grows brighter as it approaches the orange. The light increases gradually to the middle of the yellow, where it is brightest; and from this it gradually declines to the upper or violet end K of the spectrum, where it is extremely faint.

From the phenomena which we have now described, Sir Isaac Newton concluded that the beam of white light is compounded of light of seven different colours, and that for each of these different kinds of light, the glass of which his prism was made had different indices, that is, measures of refraction; the index of refraction for the red light being the least, and that of the violet the greatest.

By means of a second prism placed behind a hole in the screen M N, opposite the centre of each coloured space, Sir Isaac Newton refracted the light a second time. In this case it was not drawn out into an oblong image as before, and was not refracted into any other colour than that which formerly belonged to each particular ray. Hence this great philosopher concluded that the light of each particular colour possessed the same index of refraction; and he termed such light homogeneous, that is, of the same kind, or simple; white light being regarded as heterogeneous, that is, of different kinds, or compound.

By various experiments, Sir Isaac proved that all the colours, when again combined, formed or recomposed white light. Indeed, the doctrine may be illustrated by mixing together in proper proportions seven colours as like those of the spectrum as can possibly be got. By their union a grayish white is formed, for powders of the exact tint as those of the spectrum cannot be obtained. It may also be proved in this manner:—Let a circle of paper be divided into sections of the same size, and coloured like the spaces in the spectrum, and placed upon a humming-top, which is made to revolve rapidly; the effect of all the colours when combined is to produce a grayish white.

"All transparent substances, in bending light," observes Dr. Arnott, "produce more or less of the separation of colour; but it is an important fact, that the quality of merely bending a beam, or of *refraction*, and that of dividing it into coloured beams, or of *dispersion*, are distinct qualities, and not having the same proportion to each other in different substances. Newton, from not discovering this, concluded that a perfect telescope of refraction could never be made; he supposed that the bent light would always become coloured, and so render the object indistinct. We now know, however, that, by combining two or more media, we may obtain bending of light without dispersion—thus, by opposing a glass which bends five degrees and disperses one degree, to another glass which bends three degrees and disperses one, the opposing dispersions will just counterbalance or neutralize each other, while the two degrees of excess of bending will remain to be applied to use."

It having been found, by the experiments of Newton and others, that none of the seven colours of the solar spectrum could be broken by the prism into new colours, the theory was in some measure established that there were *seven* primitive colours. In time, however, practical men discovered that there were only *three* simple or homogeneous colours, and that all others resulted from them. These three primitive colours were *red*, *blue*, and *yellow*. That this was the true doctrine of colours, has been completely set at rest by the experiments of Mr. D. R. Hay (Edinburgh), author of a treatise on the Laws of Harmonious Colouring. We extract the following account of Mr. Hay's experiments from the work in question, and the principle of which seems afterwards to have been adopted by Sir D. Brewster:—

"Although this theory (that of there being only three primitive colours) was not set up in opposition to that of the natural philosophers, but seemed only to be established in a practical point of view, neither was it supported by any scientific experiments; yet it appeared to me more consistent with the general simplicity of nature, and I could not believe that she required seven homogeneous parts to produce what art could do by three. For instance, an artist can make all the colours, and indeed a correct representation of the prismatic spectrum (so far as the purity of the materials will allow), with three colours only; while, according to the theory of Sir Isaac Newton, seven simple or homogeneous colours were employed to produce the real one.

"The following discovery, made by Buffon, and illustrated by succeeding philosophers, helped to strengthen me in the conviction, that the scientific theory might, like that of the practical artist, be reducible to three simple or homogeneous parts. If we look steadily for a considerable time upon a spot of any given colour, placed on a white or black ground, it will appear surrounded by a border of another colour. And this colour will uniformly be found to be that which makes up the triad; for if the spot be red, the border will be green, which is composed of blue and yellow; if blue, the border will be orange, composed of yellow and red; and if yellow, the border will be purple—making in all cases a tri-unity of the three colours called by artists homogeneous.

"With a view to throw such light upon the subject as my limited opportunities would permit, I went over the experiments by which Sir Isaac Newton established his theory, and the same results occurred: I could not separate any one colour of the solar spectrum into two. The imperceptible manner in which the colours were blended together upon the spectrum, however, and the circumstance of the colours which practical people call compound, being always placed at the adjunct of the two of which they say it is composed, with my previous conviction, induced me to continue my experiments: and although I could not, by analysis, prove that there were only three colours, I succeeded in proving it to my own satisfaction, synthetically, in the following manner:—

"After having tried every colour in succession, and finding that none of them could be separated into two, I next made a hole in the first screen in the centre of the blue of the spectrum, and another in that of the red. I had thereby a spot of each of these colours upon a second screen. I then, by means of another prism, directed the blue spot to the same part of the second screen on which the red appeared, where they united and produced a violet as pure and intense as that upon the spectrum. I did the same with the blue and yellow, and produced the prismatic green; as also with the red and yellow, and orange was the result. I tried, in the same manner, to mix a simple with what I thought a compound colour, but they did not unite; for no sooner was the red spot thrown upon the green than it disappeared.

"I tried the same experiment with two spectra, the one behind, and of course a little above the other, and passed a spot of each colour successively over the spectrum which was farthest from the window, and the same result occurred. It therefore appeared to me that these three colours had an affinity to one another that did not exist in the others, and that they could not be the same in every respect, except colour and refrangibility, as had hitherto been taught.

"These opinions, the result of my experiments, I published in 1828, as being a necessary part of a treatise of this nature; and I did so with great diffidence, well knowing that I was soaring far above my own element in making an attempt to throw light upon such a subject. I had, however, the gratification to learn that these facts were afterwards proved in a communication read to the Royal Society of Edinburgh by Sir David Brewster, on the 21st of March, 1831, in which he also showed that white light consists of the three primary colours, red, yellow, and blue; and that the other colours shown by the prism are composed of these.

"The three homogeneous colours, yellow, red, and blue, have been proved by Field, in the most satisfactory manner, to be in numerical proportional power as follows—yellow three, red five, and blue eight.

"When these three colours are reflected from any opaque body in these proportions, white is produced. They are then in an active state, but each is neutralized by the relative effect that the others have upon it. When they are absorbed in the same proportions, they are in a passive state, and black is the result. When transmitted through any transparent body, the effect is the same; but in the first case they are material or inherent, and in the second impalpable or transient. Colour, therefore, depends entirely on the reflective or refractive power of bodies, as the transmission or reflection of sound does upon their vibratory powers."

To persons practically engaged in colours, we have much pleasure in recommending Mr. Hay's work, as containing a variety of useful information.

THE RAINBOW.

Every one knows that the rainbow is that brilliant and many-coloured arch which is occasionally seen spanning the sky opposite to the sun. In France and elsewhere, it is called the arc of the sky; and whilst to poets and other admirers of nature it is an object almost worshipped for its beauty, to the philosopher it is no less interesting and attractive. Rainbows are only visible when rain is falling between the spectator and that part of the sky which is opposite to the sun which is in its centre, as if at the end of a straight line drawn from the sun through the eye of the spectator towards the opposite horizon; and being always under the horizon, the bow is less than a semicircle. It consists of two bows or arches, the one inner or primary, the other outer or secondary; and within the primary rainbow, and in contact with it, and without the secondary one, there have been seen supernumerary bows.

The primary or inner rainbow, which is commonly seen alone, is part of a circle, whose radius is 41°. It consists of seven differently-coloured bows, namely, violet, which is the innermost, indigo, blue, green, yellow, orange, and red, which is the outermost. These colours have the same proportional breadth as the spaces in the prismatic spectrum. This bow is therefore only an infinite number of prismatic spectra, arranged in the circumference of a circle; and it would be easy, by a circular arrangement of prisms, or by covering up all the central part of a large lens, to produce a small arch of exactly the same colours. All that we require, therefore, to form a rainbow, is a great number of transparent bodies capable of forming a great number of prismatic spectra from the light of the sun.

Sir David Brewster thus explains the cause of the arc of the sky:—As the rainbow is never seen unless when rain is actually falling between the spectator and the sky opposite to the sun, we are led to believe that the transparent bodies required are drops of rain, which we know to be small spheres. If we look into a globe of glass or water held above the head, and opposite to the sun, we shall actually see a prismatic spectrum reflected from the farther side of the globe. In this spectrum, the violet rays will be innermost, and the spectrum vertical. If we hold the globe horizontal, on a level with the eye, so as to see the sun's light reflected in a horizontal plane, we shall see a horizontal spectrum, with the violet rays innermost. In like manner, if we hold a globe in a position intermediate between these two, so as to see the sun's light reflected in a plane inclined 45° to the horizon, we shall perceive a spectrum inclined 45° to the horizon, with the violet innermost. Now, since in a shower of rain there are drops in all positions relative to the eye, the eye will receive spectra inclined at all angles to the horizon, so that when combined, they will form the large circular spectrum which constitutes the rainbow.

To explain this more clearly, let A B, fig. 4, be drops of rain exposed to the sun's rays, incident upon them in the direction T A, T B, out of the whole beam of light which falls upon the drop; those rays which pass through or near the axis of the drop will be refracted to a focus behind it; but those which fall on the upper side of the drop will be refracted, the red rays least, and

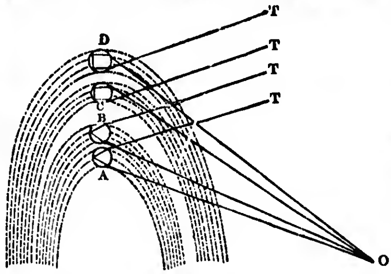

Fig. 4.

the violet most, and will fall upon the back of the drop with such sufficient obliquity that many of them will be reflected, as shown in the figure. These rays will be again refracted, and will meet the eye at O, which will perceive a spectrum or prismatic image of the sun, with the red space uppermost, and the violet undermost. If the sun, the eye, and the drops A B, are all in the same vertical plane, the spectrum produced by A B will form the colours at the very summit of the bow, as in the figure. Let us now suppose a drop to be near the horizon, so that the eye, the drop, and the sun are in a plane inclined to the horizon, a ray of the sun's light will be reflected in the same manner as at A B, with this difference only, that the plane of reflection will be inclined to the horizon, and will form part of the bow distant from the summit. Hence it is manifest that the drops of rain immediately above the line joining the eye, and the upper part of the rainbow, and in the plane passing through the eye and the sun, will form the upper part of the bow; and the drops to the right and left hand of the observer, and without the line joining the eye and the lowest part of the bow, will form the lowest part of the bow on each hand. Not a single drop, therefore, between the eye and the space within the bow, is concerned in its production; so that, if a shower were to fall regularly from a cloud, the rainbow would appear before a single drop of rain had reached the ground.

If we compute the inclination of the red ray and the violet ray to the incident rays T A, T B, we shall find it to be 42° 2′ for the red, and 40° 17′ for the violet, so that the breadth of the rainbow will be the difference of those numbers, or 1° 45′, or nearly three times and a half the sun's diameter. These results coincide so accurately with observation, as to leave no doubt that the primary rainbow is produced by two refractions and one intermediate reflection of the rays that fall on the upper sides of the drops of rain.

It is obvious that some of the rays will suffer a second reflection at the points where they are represented as quitting the drop; but these reflected rays will go up into the sky, and cannot possibly reach the eye at O. But though this is the case with rays that enter the upper side of the drop, as at A B, or the side farthest from the eye, yet those which enter it on the under side, or the side nearest the eye, may after two reflections reach the eye, as shown in the drops D C, where the rays T T enter the drops below. The red and violet rays will be refracted in different directions, and, after being twice reflected, will be finally refracted to the eye at O; the violet forming the upper part, and the red the under part of the spectrum. If we now compute the inclination of these rays to the incident rays T T, we shall find them to be 50° 58′ for the red ray, and 54° 10′ for the violet ray; the difference of which, or 3° 12′, will be the breadth of the bow, and the distance between the bows will be 8° 15′. Hence it is clear that a secondary bow will be formed without the primary bow, and with its colours reversed, in consequence of their being produced by two reflections and two refractions. The breadth of the secondary bow is nearly twice as great as that of the primary one, and its colours must be much fainter, because it consists of light that has suffered two reflections in place of one.

Many peculiar kinds of rainbows have been observed, such as lunar ones, in which, however, the colours are faint and barely perceptible. Supernumerary rainbows are sometimes seen. "On the 5th of July, 1828," says Sir D. Brewster, "I observed three supernumerary bows within the primary bow, each consisting of green and red arches, and in contact with the violet arch of the primary bow. On the outside of the outer or secondary bow, I saw distinctly a red arch, and beyond it a very faint green one, consisting of a supernumerary bow, analogous to those within the primary rainbow."

Red rainbows, distorted rainbows, and inverted rainbows on the grass have been observed. The latter are formed by the drops of rain suspended on the spiders' webs in the fields. It is only necessary to mention that the iris, so frequently seen overarching the cataract, is produced by the refraction of light in passing through the misty vapour generated by the fall of the column of water.

REFLECTION OF LIGHT.

Light, as has been mentioned, is diffused around us by the refractive power of the atmosphere, and therefore objects are quite visible though the rays of the sun do not strike directly upon them; in plainer terms, the atmosphere may be compared to the thick piece of glass called a *bull's eye* fixed in the deck of a ship, by which rays of light are collected and dispersed into all corners of the apartment beneath. The atmosphere being thus a vehicle of light, it may be supposed that, if we were to ascend to a great height above the level of the earth, or beyond the sphere of the atmosphere, we should be almost in darkness, although we were in reality nearer the sun. There is reason to believe that such would be the case; for travellers who have ascended to the summit of Mont-Blanc, or about 15,000 feet above the level of the sea, mention, that at that height the sky appears to be of an exceedingly dark blue colour, or almost black, and the light so faint that the stars are visible. We may understand from this that the rays of the sun travel through immense regions of darkness before they reach our atmosphere.

and are diffused into that universal soft light which we observe around us.

But, besides being diffused by a pure atmospheric medium, light is greatly increased in brilliancy by *reflection*. If all the objects on the surface of our planet were to be black, which is a negation of all colour, the sun's light would be absorbed, or at least return no part of the rays which fell upon them; and we should, even while the sun shone, possess much less light than we now enjoy. Nature has avoided this calamity, and, by producing all varieties of colours in objects, the sun's rays which fall upon them are less or more reflected, or sent back into the general mass of light. We now, then, understand, that every object we see reflects rays of light, and that these rays travel from the object to our eye, as soon as we bend our vision upon it: inasmuch, however, as a thousand or more individuals may see the same object at the same instant of time, it is evident that the rays proceed at all points, and fall upon eyes at every variety of angle.

If the object be clear or polished in its surface, it will possess the power of representing the image of any object within reach of its rays. Thus, the surface of a smooth lake will represent the image of the sky above, or the neighbouring hills, or of any object floating on its surface. This natural property in clear surfaces has suggested the formation of mirrors or looking-glasses. A mirror, or *speculum*, as it is scientifically called, is any instrument of a regular form, employed for the purpose of reflecting light or forming images of objects. Mirrors usually consist of metal or glass, having a highly polished surface. Those which are constructed of glass are coated upon the back with quicksilver, or rather with tin-foil mixed with a little mercury, for the purpose of reflecting more light; were this not the case, so little light would be thrown back, on account of glass transmitting it to a considerable extent, that a very indistinct image would be formed. The word speculum is generally confined to metallic mirrors, and they are either plane, concave, or convex. The plane ones are perfectly flat like a looking-glass; and a common watch-glass conveys a very good idea of the other two species of mirrors. Coat the hollow surface with mercury, and place it before a candle, it forms a convex mirror; coat it upon the other side, and employ it as before, it becomes a concave mirror.

If a plane mirror AB be placed exactly in a horizontal position, a ray of light c darting downwards in an exactly perpendicular direction, and striking it at *d*, will be thrown back in the exact path which it traversed in its descent, without any deviation. If, however, it descends in an oblique manner, as is shown at *e*, a point midway between the perpendicular *c* and the horizontal AB, it will not return, as in the former instance, to the place whence it came, but will be reflected from the mirror at an angle exactly equal to that at which it descended upon *d*. The ray *e d* is called the *incident ray*, and the ray *d b* is termed the reflected ray. In the figure *e d c* is called the *angle of incidence*, and *b d c the angle of reflection:* and they are both, as we have observed, exactly equal to each other. This being the fact, we have afforded us a method of universal application, by which, when once the angle of incidence, or that at which the ray falls upon a body, is found, that of reflection is easily obtained. This holds true whatever shape the mirror may be of, plane, concave, or convex, and whatever number of rays may fall upon it.

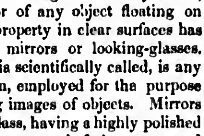

Fig. 5.

Let us apply the principle here mentioned to the simple phenomenon of seeing ourselves in a plane looking-glass. When we stand directly in front of a mirror, we see our image represented in it; and as we move, so does the image appear to move also, but with a peculiarity in its motion: if, for example, we walk towards the mirror, the image is seen to approach in a similar manner, but the approach is with double the velocity, because the two motions are equal and contrary. Suppose, however, while we stand at the glass, another person walks up behind us, his image will appear to us to move at the same rate as he walks, though to him the velocity will seem double, because, with regard to us, there will be but one motion, and with regard to him there will be two equal and contrary motions.

In this case of standing directly in front of the mirror, the image is necessarily before us, for the rays proceeding from our eye to the mirror are sent back from the surface without any angle of incidence. The case is otherwise when we stand so far at a side that we cannot see ourselves in the glass, though we can see the image of another person equally far off on the opposite side. Two persons so situated will see each other though they cannot see themselves, because the rays from the first person striking on the glass form an angle of reflection, and dart off in the direction of the second person, while the rays from the second person are similarly reflected towards the first. Such is a practical exemplification of the angle of reflection in mirrors.

The principle of reflection may be more minutely explained as follows:—We suppose RR to be the surface of a plane mirror, the arrow MN any object placed in front of it, and E the eye of an observer placed at *i k*. Of the rays which shoot in a rectilinear direction from the points MN of the object, and are reflected from the mirror, those which enter the eye are few in number, and must be reflected from portions DF and GH of the mirror, so situated with reference to the eye and the object, that the angles of incidence of the rays which fall on these portions must be equal to the angles of the reflection of those which enter the eye between *i* and *k*. For instance, the ray MD is reflected in the direction D *i*, and the ray MF in the direction F *k*. In the same manner, the rays NG and NH will be reflected severally in the directions G *i* and H *k*. If the rays *i* D and *k* F be continued backwards, they will meet at a point *m*, whence they will appear to have come to the eye. For the same reason, the rays G *i* and H *k*, if continued in the same manner, will seem to meet at the point *n* as their focus, and *m n* will be the virtual image of the object MN. It is called *virtual*, because it is not formed by the actual union of rays in a focus, and cannot be received upon paper. The virtual image *m n* is as far behind the mirror as the object MN is before it; consequently, if we join *m n*, it will be of the same dimensions as MN, and have the same position behind the mirror as the object has before it. If we join the points M *m* and N *n*, the lines M *m* and N *n* will be perpendicular to the mirror RR, and consequently parallel. In every position of the eye, the image is seen in the same spot; its absolute size is always the same, and its apparent size is also the same when seen at equal distances from the eye. If the object MN is an individual surveying himself in the mirror, he will see his perfect image as if at *m n*.

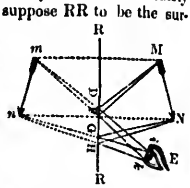

Fig. 6.

The manner in which rays are reflected from a concave mirror, next deserves our attention. It will have been frequently observed by the reader, that when he looked at himself in the hollow of a polished metal spoon, his face and bust appeared to be inverted, or upside down. We explain this by referring to the accom panying diagram, fig 7. MN is an object placed at some distance from a concave mirror AB, whose centre is C,

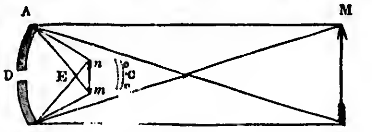

Fig. 7.

and whose principal focus is E. The rays from M fall diverging upon the mirror, and are reflected to a focus at *m* (a little without the principal focus), where they form an image of the extremity M. In the same way, a representation of the extremity N will be painted at *n*, so that a complete but inverted image of NM will thus be formed; and it is evident that it will be very bright, though small, because a great number of rays are concentrated, and concur in forming each point of the image. The size of the image thus formed corresponds to the distance of the object from the mirror. If the latter be large, and the former very bright, a series of beautiful experiments may be made by varying the distance of the object, and observing the variations in the size and place of the image. As the object recedes from the mirror, the picture approaches E, and gradually decreases in size.

If we consider *m n* as a small object, a magnified representation of it will be formed at MN, which, when viewed by a convex lens, such as will be afterwards described, constitutes a *reflecting microscope*. If we place a small concave mirror *o p* behind it, so as to enlarge the image, and reflect the rays through an opening D in the large mirror AB, then this second image may be magnified still more by means of a lens, in which case it constitutes a Gregorian reflecting telescope, so called from the inventor James Gregory. If instead of a concave we employ a convex mirror *o p*, and place it between E and *n m*, so as to reflect the rays which would otherwise have met at *n m*, then an enlarged image would in this case also be painted at D, where it can be magnified as in the former instance.

An image formed by a concave mirror is always highly magnified when the object is near the focus, but as it passes that point and approaches the mirror, the image gradually decreases in size, and becomes equal to the object when the latter touches the mirror. Indeed, when the object is placed between the principal focus and the mirror, the image is a virtual one apparently formed behind the mirror, or would be so formed behind it if the substance of the mirror permitted. Concave mirrors, from their property of converging rays into a focus, may be used as burning-glasses; practically, mirrors of this shape are used to gather the rays from lamps, and reflect them, with increased brilliancy, into the darkness. The lamps of coaches, light-houses, &c., are fitted up with these reflectors.

With respect to convex mirrors, they always form images of a diminished size, because the rays which form them become convergent in their passage to the eye of the spectator; in other words, the rays from the object proceed to a virtual or imaginary focus behind the mirror, and thence the image, in a miniature form, seems to be reflected to the eye. In this, as in all cases of reflection from concave mirrors, the size of the image represented is exactly what it might be expected to be if we could see through the glass, and observe the dimensions at the virtual focus.

It is perhaps not generally known, that images may be formed upon a piece of paper, by placing a small hole between the object and the paper, and excluding all extraneous light. This will be best understood by the following diagram:—

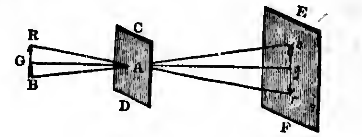

Fig. 8.

Let CD be a window-shutter having a small aperture A, and EF a piece of paper placed in a dark chamber. Then, if an illuminated object, RGB, is placed on the outside of the shutter, we shall observe an inverted image of this object painted on the paper at *r g b*. In order to understand how this takes place, let us suppose the object RGB to have three distinct colours—*red* at R, *green* at G, and *blue* at B; then it is plain that the *red* light from R will pass in straight lines through the aperture A, and fall upon the paper EF at *r*. In like manner, the *green* from G, and the *blue* light from B, will severally fall upon the paper at *g* and *b*, and an inverted image *r g b* of the object RGB will be painted upon it. Every coloured point in the object RGB having a coloured point corresponding to it, and opposite to it, on the paper EF, the image *b g r* will be an accurate picture of the object RGB, provided the aperture A is very small. If it be increased in size, indistinctness in the image will ensue; for, with a large aperture, two adjacent points of the object will throw their light on the same point of the paper, and thus create confusion in the picture. It is perfectly clear, that if the paper EF be moved to a farther distance from the hole A, the size of the image will be increased; and if it be brought nearer to it, it will be diminished.

LENSES.

Lenses, as already mentioned, are of different forms, and consequently possess different refractive powers. A lens may be composed of any transparent substance, as glass, diamond, a globule of water, &c.; in the arts, a lens is made of glass, as pure and colourless as possible. The design in forming lenses is to procure a medium through which the rays of light from any object may pass, and converge to a corresponding point beyond. The manner in which the rays proceed through the glass, and then centre in a focal point, will depend on the form of the lens, its capacity for refraction, and the distance of the object.

If we take a piece of glass, flat on one side and cut into different faces on the other, and then look through it from the flat side at any object—for instance, a pea, we shall see as many peas as there are faces receiving the rays from the single pea. We may exemplify this

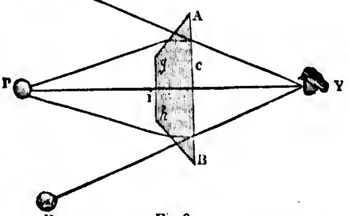

Fig. 9.

principle of multiplication by the preceding figure, in which AB is a lens flat on one side, and cut into three faces on the other, $g\,h$. Y is the eye of the spectator, and P the pea to be looked at. The eye receives a pencil of rays direct through the lens at *i*, and sees the object without refraction. A pencil also proceeds from P to the face *g* A, and another pencil proceeds from *c* to the face *h* B, and in both cases the rays are bent and refracted to the eye. This eye, however, does not recognise the path of either of these oblique rays, but perceives the image of a pea at D and at E; and thus three peas seem to be seen in place of only one.

In smoothly ground lenses, in which there are no distinct faces to multiply the images of an object, the rays bend, as we have said, so as to meet in a corresponding point beyond them. A lens may consist of a perfect globe of glass, or globe filled with pure water, in which case the refractive power will be considerable; a double convex lens, which is the more common kind, may be viewed as a portion cut out of the side of a sphere, as seen in the annexed figure. Here, as in all such cases of convexity, the focus of the parallel rays passing through the lens is at *f*, which is the centre of the sphere of which the farther or anterior side is a portion, or a point at half the diameter of the sphere from it. (Half the diameter is technically called the *radius.*) Should we take a plano-convex lens, the focal point would be considerably different. In fig. 11 we have an example of this kind of lens, which evidently possesses only half the refractive power of the double convex glass. Here the parallel rays, falling on the convex side of the lens, are seen to converge at the distance of the whole diameter of the sphere. Thus, the focal point at which the rays of light fall, is always regulated by the degree of curvature of the lens. We shall illustrate this by various diagrams, to which we ask the reader's careful attention, for the subject is somewhat difficult, and cannot be comprehended by a superficial glance.

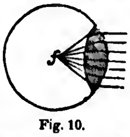

Fig. 10.

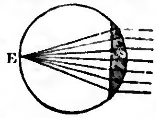

Fig. 11.

We take a double convex lens, represented by A B C, the axis of which is the line G′ C D′. The ray D′ G′,

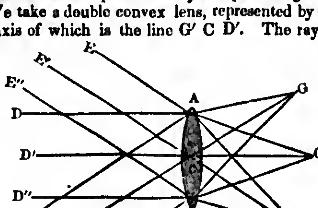

Fig. 12.

being straight through the centre, suffers no refraction; but the rays D A and D″ B are refracted, so as to meet at the focal point G′. We now observe that the parallel rays E A, E′ C, and E″ B, and also F A, F′ C, and F″ B, falling obliquely on the lens, will in a similar manner be refracted, and have their foci at G and G″, at the same distance from the lens. Those lines which pass through the centre, as E′ C G″ and F′ C G, do not alter their direction, not being refracted. Thus, in whatever way parallel rays pass through a lens, we have a focal point beyond it, be it straight forward or in an oblique direction.

The distance at which the rays meet beyond the lens is exemplified in the next diagram (fig. 13), given by Dr Arnott in his treatise on Physics, and whose definition of the focal point we beg leave to offer:—"Rays falling from *a* on a comparatively flat or weak lens at L, might meet only at *d*, or even farther off; while, with a stronger or more convex lens, they might meet at *c* or at *b*. A lens weaker still might only destroy the divergence of the rays, without being able to give them any convergence, or to bend them enough to bring them to a point at all, and then they would proceed all parallel to each other, as seen at *e* and *f*; and if the lens were yet weaker, it might only destroy a part of the divergence, causing the rays from *a* to go to *g* and *h*, after passing through, instead of to, *i* and *k*, in their original direction.

"In an analagous manner, light coming to the lens in the contrary direction from *b c d*, &c., might, according to the strength of the lens, be all made to come to a focus at *a* or at *l*, or in some more distant point; or the rays might become parallel, as *m* and *n*, and therefore never come to a focus, or they might remain divergent.

"It may be observed in the annexed figure, that the farther an object is from the lens, the less divergent are the rays darting from it towards the lens, or the more nearly do they approach to being parallel. If the distance of the radiant point be very great, they really are so nearly parallel that a very nice test is required to detect the non-accordance. Rays, for instance, coming to the earth from the sun, do not diverge the millionth of an inch in a thousand miles. Hence, when we wish to make experiments with parallel rays, we take those of the sun.

"Any two points so situated on the opposite sides of a lens, as that when either becomes the radiant point of light, the other is the focus of such light, are called *conjugate foci*. An object and its image formed by a lens, must always be in *conjugate foci;* and when the one is nearer the lens, the other will be in a certain proportion more distant.

"What is called the *principal* focus of a lens, and by the distance of which from the glass we compare or classify lenses among themselves, is the point at which the sun's rays, that is parallel rays, are made to meet; and thus, by holding the glass in the sun, and noting at what distance behind it the little luminous spot or image of the sun is formed, we can at once ascertain the focus of a glass, as at *a* for the rays *e* and *f*."

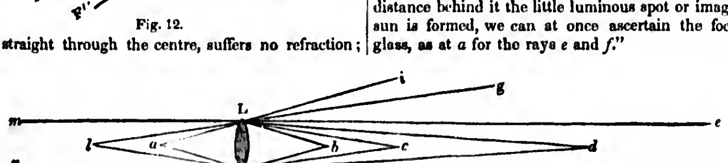

Fig. 13.

From the preceding explanations, it will be understood that when an object is placed at any distance from a lens, an image of it will be formed in the corresponding conjugate focus; but to see this image distinctly, the eye must generally be placed at least six inches behind it, that is, farther from the lens. When, however, the object is placed in the principal focus, the rays are refracted parallel, and the image in this case is distinct when seen at any distance. But the most remarkable quality of a double convex lens remains to be noticed; we allude to its magnifying power. This quality is entirely a result of the refractive powers of the glass: embraced within the sphere of the rays from the lens, the object is apparently expanded in size, and seen brought nearer to the eye. This may be elucidated, for small objects seem near, by a reference to the diagram, fig. 14.

Let E be the eye, and *m n* the diameter of its pupil, R W a small object placed at the least distance of distinct vision (about six inches from the eye for small objects); and let R W be its apparent size when seen by the unaided eye. If a convex lens A B is now interposed between the eye and the object, so that the object R W

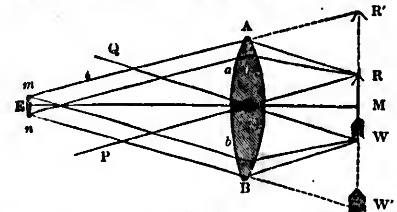

Fig. 14.

shall be in the principal focus of the lens, an enlarged image R′ W′ of the arrow will then be seen, its extremities R′ W′ lying in the directions E A, E B. The directions of these rays are determined thus:—From R and W draw the central rays R C P, W C Q, through the centre C of the lens; then the rays of the conical pencil, proceeding from the point R to every point of the nearer surface of the lens, are refracted in such a manner by the lens, that they all emerge in directions parallel to the central ray R C P; but of the whole refracted pencil only a small portion enters the eye, namely the pencil A *m n a*, limited by the size of the pupil *m n*; and the head A of the arrow, whence this pencil proceeds, appears to lie in the direction of the pencil E A R′ at R′. It is shown exactly in the same manner, that the point W will appear in the direction E B W′ at W′. The enlarged image of the small arrow R W is therefore R′ W′. The proportion in which the image is enlarged will be easily ascertained thus:—The triangles E R′ W′, C R W, are similar, and therefore the ratio of R′ W′ to R W, is that of E R′ to C R, or of E M to C M; that is, as the least distance E M of distinct vision, to the focal length C M of the lens. If, therefore, the least distance of distinct vision be divided by the focal length of the lens, the quotient will be its magnifying power. If E M be reckoned 6 inches for small objects, and if the focal length C M be 2 inches; then, since 6, divided by 2, gives 3 for a quotient, the magnifying power is 3 times. If C M were one quarter of an inch, then 6, divided by ¼, gives 24 for a quotient, and the magnifying power would in this case be 24 times.

A more simple explanation may be attempted as follows:—Turn to fig. 9, representing the lens with three faces on one side and flat on the other. There it is observed that the vision travels in the direction of the ray from the object, as it passes through the glass, and therefore sees an appearance of three objects. Now, in the above case of a magnifying lens, the vision in the same manner travels from the eye at E in the direction of the angle of refraction; it goes on to R′ and W′, and thus the actual object being drawn out, as it were, to meet these points of vision, or seemingly expanded by the bent rays, we of necessity see an apparently larger object. If the glass were cut in faces, instead of being smooth, the object would not appear drawn out, but would be multiplied in as many points as there are faces.

The inversion of the image by a lens may be illustrated by the diagram, fig. 15. A B C is an arrow, with the point uppermost, placed beyond the focus at F, of a double convex glass *d e f*. In virtue of the refractive power of the lens, the rays which proceed from A meet at Z, and form an image of the arrow-point inverted; while the rays from C meet at X, and form a similarly inverted image of the feather part of the arrow. The rays proceeding from B unite at *b*. Here, only rays from A, B, and C, are represented for the sake of clearness, but in point of fact rays from all parts of the object proceed through the lens, and hence an entire image is formed in an inverted position. Should the object A B C

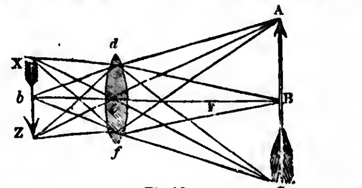

Fig. 15.

be brought nearer the lens, the image will be removed to a greater distance, because then the rays are rendered more divergent, and cannot so soon be collected into corresponding points beyond. To procure a distinct image, the object must be removed farther than the focal point F from the glass. In this exemplification, the object seems to be diminished; but if we make the small arrow the object, the larger one will be the image of it magnified.

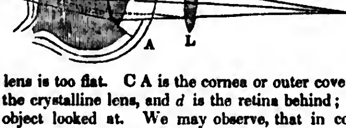
In order to explain the power of lenses in magnifying distant objects, and bringing them near us, let us suppose an object placed at one hundred feet distance from the eye of a spectator. Let us place a convex glass of twenty-five feet focal distance half way between the object and the eye; then, as has been previously observed, an inverted image of the object, and of the same size, will be formed fifty feet behind the lens. If this picture is looked at six or eight inches behind it, it will be very distinctly seen, and nearly as well as if the object itself had been brought to within six or eight inches of the eye of the spectator. If, however, instead of a lens of twenty-five feet focal length, a lens of a shorter focus is made use of, and so situated with respect to the eye and the object that its conjugate foci are at the distance of twenty and eighty feet from the lens—that is, the object is twenty feet before the lens, and its image eighty feet behind it—then the size of the image will be four times that of the object. If the eye, therefore, looks at this magnified image six inches behind it, it will be seen with great distinctness. In this case the image is magnified four times directly by the lens, and 200 times by being brought 200 times nearer the eye; so that its apparent magnitude is 800 times larger than before. At distances less than the preceding, the rule for finding the magnifying power of a lens, when the eye views the image which it forms at six inches' distance, is, according to Sir David Brewster, as follows:—"From the distance between the image and object in feet, subtract the focal distance of the lens in feet, and divide the remainder by the same focal distance. By this quotient divide twice the distance of the object in feet, and the new quotient will be the magnifying power, or the number of times that the apparent magnitude of the object is increased. When the focal length of the lens is quite inconsiderable, compared with the distance of the object, as it is in most cases, the rule becomes this: Divide the focal length of the lens by the distance at which the eye looks at the image; or, as the eye will generally look at it at the distance of six inches, in order to see it most distinctly, divide the focal length by six inches, or, what is the same thing, double the focal length in feet, and the result will be the magnifying power."

THE EYE—VISION.

Having, in our Account of the Human Body, described the anatomical construction of the eye, we shall here confine ourselves to the actual process of vision. As mentioned in the article referred to, the eye, in front, consists of the *iris* or variously coloured ring, which has the property of contracting or expanding to regulate the admission of light through the little dark spot in the centre called the *pupil*. Immediately behind the iris and pupil, there is a transparent substance, resembling in shape a double convex glass, which is thence called the *crystalline lens*. The use of this lens is to collect and refract the rays of light, so that they may converge to a point beyond; in other words, cause them to fall on the back part of the eye, called the *retina*. Such are the main instruments of vision; and the sense of seeing is produced by certain nerves which convey intelligence of the image on the retina to the brain. If these nerves be injured, the image will still be pictured on the retina, but the mind will possess no power of recognising their presence.

It will be understood from these explanations, that the main instrument of vision is the crystalline lens, which collects the rays and brings them to a focus on the retina. If the lens be perfectly transparent, and of the proper convexity, the light is enabled to act with due effect on the retina, and the representation of the object looked at will be correctly pictured to the mind. But if the transparent coating of the eye be dull, or the lens be either too flat or too convex, every object will appear dim.

Two kinds of defective vision are more common than any other, and they are known by the name of *long-sightedness* and *short-sightedness*. Long-sightedness, or the power of seeing objects best at a considerable distance, is caused by too great a flatness in the crystalline lens and outer coating of the eye; and the deficiency of vision in old persons is usually from a similar cause. To remedy this defect, as far as possible, artificial lenses of glass are employed. These lenses are called *spectacles*, and may be supposed to act in the manner we have now to describe. Fig. 16 represents an eye in which the crystal-



line lens is too flat. C A is the cornea or outer covering, *b* is the crystalline lens, and *d* is the retina behind; B is the object looked at. We may observe, that in consequence of the flatness of the lens *b*, the rays proceeding from the object are not sufficiently refracted, but proceed to a focus as far back as R; in other words, the focus would be at R, if the retina would permit; but as the retina is in the way, the rays, from not being focalized upon it, cause imperfection in the vision. To remedy this, we interpose an artificial convex lens, or glass of a pair of spectacles, L L, and by its aid the rays, represented by dotted lines in the figure, are brought to a focus on the retina at *d*. Thus, by selecting spectacles of a proper focalizing power in relation to the eyes, one kind of imperfect vision is very happily remedied.

Short-sightedness arises from a cause the reverse of that just alluded to, being produced by too great a degree

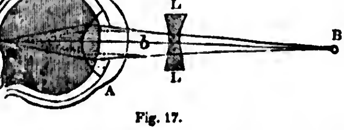


Fig. 17.

of convexity in the crystalline lens and cornea. In this case, the rays come to a focus too soon within the eye, and do not reach the retina, unless the object is brought quite close to the organs of vision. We offer a representation of this condition in Fig. 17. In consequence of the projecting globularity of the cornea C A, and the too great refracting power of the crystalline lens, the rays from the object B fall short of the retina at R. To remedy this, we interpose a double concave lens, L L, by which the rays are rendered more divergent before they reach the eye, and are brought to a focus, where they should be, on the retina.

We have said above, that in short-sighted persons the rays do not reach the retina unless the object is held close to the eyes. The effect produced by this is similar to that of employing concave spectacles; because the nearer we hold an object to our sight, the angle of the rays from it is the wider; the rays are more expanded before they enter the eye—that is, more divergent. This may be illustrated by Fig. 18. The extreme rays from a

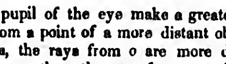

Fig. 18.

point to the pupil of the eye make a greater angle at o than those from a point of a more distant object *a* make at *a*; that is, the rays from o are more divergent on entering the eye than the rays from *a*, and thus nearness of an object is equivalent to seeing it at a greater distance through a concave lens. So when the object a is farther distant than o, the rays from *a* have a less divergence, which is equivalent to viewing it at a nearer distance with a convex lens. These remarks, however, refer merely to the distinctness of the vision, and not to the apparent size of the object.

The apparent magnitude of the same object when

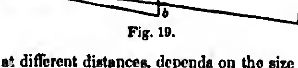

Fig. 19.

viewed at different distances, depends on the size of what is called the *visual angle*—that is, the angle formed at the eye by the rays from the extremities of the object. We may exemplify this by Fig. 19. An eye is looking at an object *a b*, and another object *c d*, at double the distance. It is evident that the rays from *a b* are more expanded, or cause a larger angle in the eye, than the rays from *c d*. Various familiar phenomena are explained from the law of the visual angle under which an object is seen; the apparent size being less always in proportion as the distance of an object is greater. Hence the principles of perspective in drawing, by which objects are made to appear at a great distance in the background of a picture, although in reality they are as far forward as the objects in front.—(See DRAWING AND PERSPECTIVE.)

Another important circumstance connected with vision requires to be noticed. In consequence of the refractive power of the crystalline lens, the rays from an object fall upon the retina in such a manner that the image is there pictured upside down; and this inversion of the real appearance of things requires to be corrected by an act of the mind under the influence of experience. We beg leave to offer Dr. Arnott's explanations on this somewhat puzzling point:—"Because the images formed on the retina are always inverted as respect the true position of the objects producing them—just as happens in a simple camera-obscura—persons have wondered that things should appear upright, or in their true situations. The explanation is not difficult. It is known that a man with wry neck judges as correctly of the position of the objects around him as any other person, never deeming them to be inclined or crooked, because their images are inclined in relation to the natural perpendicular of his retina; and that a bedridden person, obliged to keep his head upon his pillow, soon acquires the faculty of the person with wry neck; and that boys who at play bend themselves down to look backwards through their legs, although a little puzzled at first, because the usual position of the images on the retina is reversed, soon see as well in that way as in any other. It appears, therefore, that while the mind studies the form, colour, &c., of external objects in their images projected on the retina, it judges of their position, not by the accidental position of the images on the retina, but by the direction in which the light comes from the object towards the eye, no more deeming an object to be placed low because its image is low in the eye, than a man in a room into which a sunbeam enters by a hole in the window-shutter, deems the sun low because its image is on the floor. A candle carried past a key-hole, throws its light on the opposite wall, so as to cause the luminous spot there to move in a direction the opposite of that in which the candle is carried; but a child is very young indeed who has not learned to judge at once of the true motion of the candle by the contrary apparent motion of the image. A boatman, who, being accustomed to his oar, can direct its point against any object with great certainty, has long ceased to reflect that to move the point of his oar in some one direction, his hand must move in the contrary direction. Now, the seeing things upright, by images which are inverted, is a phenomenon akin to those which we have here reviewed."

The same able writer on physics proceeds to a definition of another peculiarity in visual arrangements, namely, why, from having two eyes, the object does not appear to us to be double:—"In answer to this, we shall only state the simple facts of the case. As in two chess-boards there are corresponding squares, so in the two eyes there must be corresponding points, and when on these points a similar impression is made at the same time, the sensation or vision is single; but if the impression be made on points which do not correspond, owing to some disturbance of the natural position of the eyes, the vision becomes double. Healthy eyes are so wonderfully associated, that, from earliest infancy, they constantly move in perfect unison. By slightly pressing a finger on the ball of either eye, so as to prevent it following the motion of the other, there is immediately produced the double vision: and tumours about the eye often have the same effect. Persons who squint have always double vision, but they acquire the power of attending to the sensation in one eye at a time. Animals which have the eyes placed on opposite sides of the head, so that the two can never be directed to the same point, must have in a more remarkable degree the faculty of thus attending to one eye at a time.

"The corresponding points in the two eyes are equidistant and in similar directions from the centres of the retinæ, which centres are called the points of distinct vision, and at them the imaginary lines named the axis of the eyes terminate; but it is worthy of remark that these points, in being both to the right or both to the left of the centres, must be one of them on the inside of the centre, as regards the nose, and the other on the outside—that is to say, a point of the left eye between the centre and nose has its corresponding point in the right eye between the centre and the cheek—and from this fact arise consequences meriting attention. When the two eyes are directed to any object, their axis meet at it, and the centres of the two retinæ are opposite to it, and all the other points of the eyes have perfect mutual correspondence as regards that object, giving the sensation of single vision; but the images formed at the same time, of an object nearer to or farther from the eye than the first supposed, cannot fall on *corresponding* points, for an object nearer than where the axes meet would have both its images on the outsides of the centres, and an object more distant would have both its images on the insides of the centres, and in either case the vision would be double. Thus, if a person hold up one thumb before his nose, and the other in the same direction, but farther off, by then looking at the nearest, the more distant will appear double, and by looking at the more distant, the nearest will appear double. The reason for applying the term 'point of distinct vision', to the centre of the retina, is felt at once by looking at a printed page, and observing that only the one letter to which the axis of the eye is directed, is distinctly seen; and, consequently, that although the whole page be depicted on the retina at once, the eye, in reading, has to direct its centre successively to every part."

The retina of the eye possesses such exquisite sensibility, that it retains the impression of the image of any bright object presented to it, for the space of the sixth of a second after the object has been withdrawn, or after the eye has been shut. Thus, the burning end of a rapidly whirled stick will appear to form hoops of fire; and a fiery meteor or sky-rocket shooting rapidly through the air, will appear as a long line of light. The mind is in these and similar instances deceived, as the eye in reality sees only a point of fire at precisely the same time. The retina, for the same reason, retains for a time an impression of any vivid colour. When we look at the sun, the retina is so strongly affected as to be incapable for a time of seeing other objects distinctly. The most remarkable circumstance connected with these phenomena is, that when the eye is shut after such impressions, a spot of colour, *different* from the colour looked at, is apparently seen. A spot of this nature is in optics called a *spectrum;* and works of an extended character on the science embrace lengthened definitions of the various spectra with which the eye will be affected. We need here only refer to the experience of our readers on this interesting point, and mention generally, that no satisfactory explanation has ever been given of the reason why the colours in the spectra differ from those which were actually seen.

OPTICAL INSTRUMENTS.

Telescopes.—Telescopes, sometimes called spying-glasses, are instruments in the form of tubes, fitted up with lenses of different kinds and powers, and used for examining distant objects. The word telescope is from the Greek, and signifies *afar off*, and *to see*. A telescope of a simple construction, consists of a convex lens placed at one end of a tube, which is termed the *object-glass;* and by it the light reflected by the objects in front is collected and formed into images near the other end of the tube, where they are inspected by another lens, of shorter focal length, called the *eye-glass*. This lens is fixed in a smaller tube, which slides backwards and forwards, so as to admit of the focal distance being adjusted to different eyes, &c. In telescopes with only two lenses, such as those used for astronomical purposes, with a convex eye-glass, the image is inverted—a circumstance of no importance in viewing the heavenly bodies. In Fig. 20 we have a representation of the manner in which a simple telescope with two glasses acts.

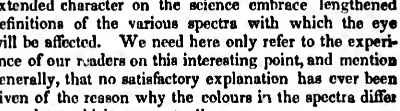

Fig. 20.

A E B is a double convex lens, forming the object-glass, and C D is a double concave lens forming the eye-glass. It may be observed, that from the object at M, a pencil of rays go on diverging till they reach the convex lens A E B, where they are so refracted that they would converge and meet in the point *m*, did not the lens C D refract them parallel. The pencil of rays from N, in the same manner, are converged to a point *n*. As the rays are rendered parallel on merging from the glass C D, they convey a clear image to the eye at E. The telescope made by Galileo was of this simple construction.

The magnifying power of such a telescope being limited, it became necessary to contrive an instrument in which the deficiency would be remedied. This has been accomplished by the construction of a telescope with a convex eye-glass, called the *astronomical* telescope. But this telescope inverts the image—a deficiency which is removed by constructing the instrument with four double convex lenses, as represented in Fig. 21. The rays from the object M N, are refracted

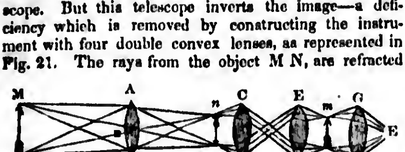

Fig. 21.

by the glass A E B, and we have an inverted image *n*. The rays now pass through C D and E F, by which transit they bring the image upright at *m*, and by the glass G H they are made to enter the eye at E. This, and other instruments in which refracting lenses are employed, are called *refracting telescopes*, and they magnify or bring near in proportion as the focal distance of the object-glass is greater than the focal distance of the eye-glass.

Refracting telescopes require to be of considerable length where much power is required, and on that account reflecting telescopes are for many purposes preferred. The reflecting telescope was invented by Sir Isaac Newton, but has been much improved since his time. A view of the improved instrument is given in Fig. 22. The peculiarity of this instrument is, that the image of the object is reflected from a concave mirror within the tube, and this image is again reflected from a small mirror to the eye. Referring to the figure, T is

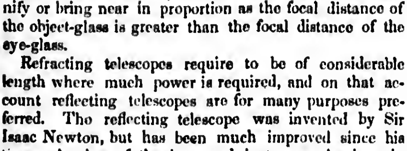

Fig. 22.

the tube, and A B the object to be represented. At the end opposite from the object, there is a small tube *t t*. At the main end of the wide tube, there is a concave mirror D F, with a hole in the middle at P. The principal focus of this mirror is at I K; here the image *m* is inverted, and the rays, crossing each other at *n*, go on to the small reflector L. From this they are reflected in parallel lines through the hole P. At P they enter the plano-convex lens R, which causes them to converge at *a b*; but here the image requires to be magnified, which is done by means of the plano-convex lens S; in other words, the object is seen under the angle *c f d*. In order to accommodate focal distances, the small mirror L can be removed to a greater distance or brought nearer, by the rods and screws communicating from X.

Microscope is a term compounded of two Greek words, signifying *to see what is small*, and denotes that instrument employed to examine minute objects. Those microscopes of greatest power, and termed compound, approach to the telescope in their form. The difference lies in this, that whilst in the telescope the object-glass forms the image of a distant object just as much smaller than itself as the distance of the image from the glass is less, in the microscope, conversely, a small object, placed near the focus of the object-glass, produces a more distant image, as much larger than itself as the image is more distant. In both cases an appropriate eye-glass is employed. The object-glass of a microscope is in general very small, that of a telescope large. An object-glass of a microscope having one-eighth of an inch of focal distance, and so placed as that the image of the object is formed at six inches, the image will be of a diameter forty-eight times as great as the object; and when viewed through an eye-glass of half an inch focus, it will appear magnified twelve times more, or will appear 30,000 times larger than the object. A single or one-lens microscope, magnifies chiefly by allowing the eye to see the object nearer than it could do without the glass.

A *Camera-Obscura* or *Dark Chamber* is formed by placing a convex lens in an aperture made in the window-shutter of a darkened room. A glass of proper size and focal distance is chosen, and a screen or the wall of the chamber is properly prepared to receive the light, and by this means there is painted on it an accurate picture of all the objects seen from the window, every thing bearing an exact resemblance to the reality. Nothing can surpass the beautiful effects produced by this delightful instrument.

The *Camera Lucida* is an instrument now frequently used in drawing landscapes, delineating objects of natural history, and copying and reducing drawings. The best form of the instrument consists of a piece of thick parallel glass, at one end of which there is a metallic mirror having a highly polished face. The rays from the object are made first to pass through the glass, when they are reflected back upon one of its sides by the mirror, and from the glass they are again reflected to the eye.

The Magic Lantern.—When a small object is placed close to a lens, and the image reflected upon the wall of a dark chamber, at say, one hundred times farther from the lens than the object is, there will be a greatly magnified representation of the object. It will only be seen, however, under ordinary illumination; and it is therefore necessary to have a very strong light, concentrated by a suitable mirror or glass, and directed upon the object. When artificial light is employed, as of a lamp, the instrument then becomes a magic lantern. It consists of an argand burner placed in a dark lantern, on one side of which is a concave mirror, the vertex being opposite the centre of the flame, which is placed in its focus.

A representation of a magic lantern is offered in fig 23. The lantern is made of tin japanned; and to

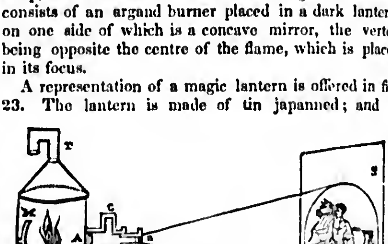

Fig. 23.

carry off the smoke from the flame, it is provided with a tube T at the top. L is the light, and M N a concave mirror to give strength to the light, and send the rays through the tube A B in front. At A in this tube is a hemispherical illuminating lens, and there is a convex lens at B. In the middle of the tube there is a wide part, C D, open at the sides, for the reception of *slides*. These slides are slips of glass on which pictures are

...ainted, and the principle of the apparatus consists in forming a representation of the picture, in a magnified size, on a distant white wall or screen S. The slide being placed in one of the conjugate foci of the lens B, the image is consequently enlarged. By bringing the ... nearer the screen, we diminish the representation, because we cause the rays to strike the screen at a point where they are less divergent. It is an improvement in exhibiting the representations from the magic lantern, to cause the images to fall on a piece of distended and wetted muslin, behind which the spectators are placed. Lately, the mode of representing scenes has been further improved by using two lanterns, placed at equal distances; in this case, while the view in one is being withdrawn, the view in another is coming on, and the eye is charmed with seeing, for example, a scene in winter dissolve and assume the appearance of a similar scene in summer. Such is the principle of the *dissolving views*, exhibited at the Polytechnic Institution in London, in 1841.

ACOUSTICS.

The term Acoustics is derived from two Greek words, which signify *I hear* and *an art*, and is applied to that branch of natural philosophy which treats of the nature of *sound*, and the laws of its production and propagation.

Atmospheric vibration is allowed to be the cause of sound. For instance, a bell is struck by its clapper, the body of the bell consequently vibrates, as we may sensibly assure ourselves by applying our nail lightly to the edge: in its agitation, it beats or makes impulses on the air, which, yielding under the stroke or pressure, is compressed or condensed to a certain distance around. The compressed air instantly expands, and in doing so, repeats the pressure on the air next in contact with it; and thus each one of the original strokes of the vibrating metal sends out a series of *shells* of compressed air, somewhat like the waves dispersed over a lake from the dropping of a stone into its placid bosom, and like them always lessening in bulk and force. These *shells* are from two inches to thirty feet in thickness. The air, thus agitated, finally reaches the ear, where it gives a similar impulse to a very fine nervous membrane, and the mind then receives the idea or impression which we call a *sound*.

With regard to the velocity with which the impulse of sound advances, it appears, from the most accurate experiments on the discharge of pieces of ordnance, and marking the interval between the flash and the report, at a distance carefully measured, that, when the atmosphere is at the temperature indicated by 62° of Fahrenheit's thermometer, sound travels at the rate of 1125 feet per second, which is nearly equal to the velocity of a cannon-ball the moment it issues from the piece.* The ball is very speedily retarded by the resistance of the air, but sound advances with undiminished velocity, though unequal intensity. It will travel a mile in little more than four seconds and a half, or twelve and three-fourth miles per minute. On this depends an easy method of determining in many cases our distance from objects, and which may often prove useful, particularly in thunder-storms. We have only to observe in seconds the interval between the flash and the report, and allow four seconds and a half to every mile, or 1125 feet to every second. It is remarkable, also, that all kinds of sounds, strong or weak, acute or grave, advance with the same velocity; and this arises from the circumstance, that all the oscillatory movements in the air, however minute or however extended, are performed each in the very same interval of time. For every degree of Fahrenheit above 62°, the velocity of sound is increased one foot and about a seventh (strictly 1 14-100th foot), and for every degree below 62°, it is lessened in the same measure; so that, when the temperature is at the freezing point, the rate is only 1090 feet per second.

That water is a vehicle of sound as well as the air, is proved by various circumstances, particularly by the fact, that a bell rung under water can be heard above and if the head of the auditor be also under water, it will be still more distinctly heard. The sound which the sonorous body produces, however, is graver than that which it gives forth in the air. That the atmosphere is necessary for the transmission of sound is evident from the fact, that a bell rung in the exhausted receiver of an air pump can scarcely be heard. Smooth bodies form favourable channels of sound, as, for example, the surface of ice, snow, water, or the hard ground. Savages, it is well known, are in the habit of putting their ear to the ground in order to discover the approach of enemies or beasts of prey. Tubes convey sounds with great accuracy and to great distances, and this property has been applied to various useful purposes. The most valuable of these purposes is that of examining the chests of persons supposed to possess pulmonary affections. This is done by means of the *stethoscope*, an instrument invented by Dr. Laennec of Paris, and which resembles a small trumpet. The wide end of the instrument is applied to the body, and the other is held to the ear of the physician, who then has a very clear perception of the sounds caused by the action of the lungs, and can judge whether they be healthy or the reverse. A person of skill can exactly describe the condition of the lungs from the nature of the sounds which thus reach his ear.

In a public exhibition in London, there has long been shown an apparatus consisting of a four-footed stand and several trumpet-mouthed tubes, from any one of which a spectator will receive a ready answer to a question. The answer is said to come from "the invisible girl," and the true explanation of the puzzle is, that a secret tube in the legs of the apparatus communicates the sounds to a girl placed in a neighbouring apartment.

In consequence of sound requiring a certain length of time to travel, it is impossible for two sounds at any distance from each other, to be heard at the same moment by persons who are not at equal distances from both. "If two persons, A and B," says an American writer, "are standing at the distance of one mile from each other, and each fires a gun at the same moment, A will not hear B's gun until several seconds after he hears his own, because the sound will require that time to pass through the distance between them. And the same will be the case with B. One might at first suppose that if A should wait and fire at the moment he hears the report from B, the two sounds would then be heard together. A would hear them together, but the time that must elapse after B had fired, before the sound from A would come to *him*, would be greater than if they fired at the same moment. For he must wait till the sound of his own gun had gone to A, and then until the sound of A's discharge should return to him. It is thus evidently impossible for two persons, standing at a distance from each other, to produce a sound which shall be heard by both at the same time.

It is on account of this principle, that in long ranks of soldiers, where two bands of music are placed at a considerable interval from each other, it is impossible for the two bands to keep time with each other. They may indeed play together, but each soldier will hear the nearest sounds quickest, and thus they will seem to be

* The velocity here assigned to sound, is that given by Sir John Herschel, as the mean of the best experiments.

out of time. It is often noticed too, that if from an eminence we look upon a long column which is marching to a band of music in front, the various ranks do not step exactly together. Those in the rear are in each step a little later than those before them. This produces a sort of undulation in the whole column, which is difficult to describe, but which all who have noticed it will understand. Each rank steps, not when the sound is *made*, but when, in its progress down the column at the rate of 1125 feet per second, it reaches their ears. Those who are near the music hear it as soon as it is produced, while the others must wait till sufficient time shall have elapsed for it to have passed through the air to them.

"Should a commander stand at the distance of a fifth of a mile from his army, and command them to fire, they might all obey at the moment when the word of command reaches them; but the officer will hear the report of the guns from those at the side nearest him first, then those a little farther off, and so on to the most remote. Thus, though all might obey with equal alacrity, the sounds will not and cannot appear simultaneous, for the reports of the distant guns must be delayed long enough for the command to pass from the officer to the men, and then for the sound to return. All attempts, therefore, to make their firing appear exactly simultaneous from a long line must be in vain."

An *echo*, or duplication of sound, is one of the most interesting phenomena in acoustics. The cause of it is precisely analogous to the reaction of a wave of water. When a wave of water strikes the precipitous bank of a river, it is thrown back in a diagonal direction to the side whence it came, and there again strikes on the bank. In the same manner, the pulses or waves of sound are reflected or thrown back from flat surfaces which interrupt them, and, thus returning, produce what we call an echo. It is evident that the smoother the surface which reflects the sound, the more perfect will be the reverberation. An irregular surface, by throwing back the wave of sound at irregular intervals, will so confound and distract it, that no distinct or audible echo will be reflected. On the contrary, a regular concave surface will reflect sound in such a manner, that at a certain point the reflections from each part of the concave surface will be concentrated into a focus capable of producing a very powerful effect. The velocity with which an echo returns to the spot where the sound originates, depends, of course, upon the distance of the reflecting surface; and since sound travels at the rate of 1125 feet in a second, a rock situated at half that distance will return an echo in exactly one second. The number of syllables which we pronounce in a second will in such a case be repeated distinctly, while the end of a long sentence would blend with the commencement of the echo.

An echo may be double, triple, or even quadruple, according to the nature and number of the projecting surfaces from and to which the sound is allowed to play. Distinctly marked echoes of this combined and planned order may sometimes be heard in the vaults of cathedrals, in which case the waves of sound are driven from side to side of a deeply groined arch, and reverberate in protracted peals. One of the most interesting echoes of this kind in nature, is that which occurs on the banks of the Rhine at Lurley. If the weather be favourable, the report of a musket, fired on one side, is repeated from crag to crag, on opposite sides of the river alternately, as represented in fig. 24. P is considered as the primary point of radiation for the sound, and crossing the river it strikes at 1, then is sent off to 2, and so on to 3 and subsequent points, stopping or faintly dying away opposite E.

There are some remarkable echoes in ecclesiastical structures arising from peculiarities in the construction.

Fig. 24.

In erecting the baptistry of the church of Pisa, the architect, Giovanni Pisano, disposed the concavity of the cupola in such a manner, that any noise from below is followed with a very loud and long double echo. Two persons whispering, and standing opposite to each other, with their faces near the wall, can converse together without being overheard by the company between. This arises from the elliptical form of the cupola, each person being placed in the focus of the ellipse. In the cathedral church of Gloucester, there is, or was lately, a whispering gallery above the eastern extremity of the choir, which extends from one end of the church to the other. If two persons, placed at considerably distant points, speak to one another in the lowest voice, it is distinctly heard. A similar effect is produced in the vestibule of the Observatory of Paris, and in the cupola of St. Paul's, in London. A tourist has mentioned, that in Italy, on the way to Naples, and two days' journey from Rome, he saw in an inn a square vault, where a whisper could easily be heard at the opposite corner, but not at all on the side corner that was near to you. This property was common to each corner of the room. He saw another on the way from Paris to Lyons, in the porch of a common inn, which had a round vault. When any person held his mouth to the side of the wall, several persons could hear his whisper on the opposite side.

The whispering gallery in St. Paul's, London, is a great curiosity. It is 140 yards in circumference, and is just below the dome, which is 430 feet in circumference. A stone seat runs round the gallery along the front of the wall. On the side directly opposite the door by which visitors enter, several yards of the seat are covered with matting, on which the visitor being seated, the man who shows the gallery whispers with the mouth near the wall, at the distance of 140 feet from the visitor, who hears his words in a loud voice, seemingly at his ear. The mere shutting of the door produces a sound like a peal of thunder rolling among the mountains. The effect is not so perfect if the visitor sits down half way between the door and matted seat, and much less if he stands near the man who speaks, but on the other side of the door.

It is of great importance that buildings designed for large auditories should be constructed in such a manner that the voice of the speaker will neither echo from the walls nor be lost to the hearers. The best known form of apartment for the proper distribution of sound, is that in which the length is from a third to a half more than the breadth, the height somewhat greater than the breadth, and having a roof bevelled off all round the sides. This species of ceiling, called technically a coved or *coach roof*, from its being lower at the sides than centre, is in all cases best suited for conveying sounds clearly to the ears of auditors.

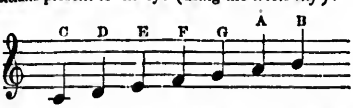
MUSICAL SOUNDS.

There is a peculiar character in sounds, depending on the character of the sounding body. A blow with a hammer, or the report of a pistol, produces only a noise. But if a body be of such a thinness and tightness as to produce a succession of impulses of a sufficient degree of quickness, a *tone* is the result, namely, a sound composed of a great number of noises, all so close upon each other, that they bring but one result to the ear. Wires and strings of metal and catgut, slips of metal, fine membranes, and columns of the air itself enclosed in tubes, are the most familiar means of producing sounds of this kind. Such sounds are said to be musical.

The study of musical sounds, as a branch of natural philosophy, is calculated, perhaps, to give as much pleasure to a man of science as music itself can convey to those who are gifted with what are called good ears. The natural character of these sounds, and their relations to each other, are very remarkable; while the relation of the whole to the human mind must be regarded as one of the most interesting proofs of creative design which the entire circle of nature presents.

The principal sounds of music may be said to be only seven in number. There are other five, which may be produced by the voice with some little difficulty; but the voice, in an untutored condition, gives forth only seven. The notes are of different degrees of shrillness, one rising above another in succession. A person who knows nothing of music beyond having heard another sing or play, and having seen the key-board of a piano-forte, will be ready to say that there are more notes than seven; but there are only seven that are, strictly speaking, various. The voice or an instrument may run up into other notes; but all of these are repetitions of the first seven, and identical respectively with them, in all respects except shrillness. In ordinary piano-fortes, there are at least six repetitions of the seven notes, so that the uppermost keys are more peepy than the voice of a child, while the lowest rumble like a drum.

The seven notes are named Do, Re, Mi, Fa, Sol, La, Si, or by the first seven letters of the alphabet in a peculiar arrangement, namely, C, D, E, F, G, A, B. They are thus represented in the well-known language which musicians present to the eye (using the *treble clef*):



Let an ordinary piece of catgut or violin-string be extended between two points on a board, and screwed up. It may be made, according to its length and degree of tension, to vibrate, when struck, exactly two hundred and forty times in a second. The note which it thus produces is C, or Do; and a man, on trial, will find that this is the note with which he is most apt to begin a song, when he attempts to sing. The note in his voice will be perfectly in unison with the note produced by the string; that is to say, they will melt into and agree with each other, and the effect will be pleasant. This is because the membrane at the top of the singer's windpipe (the instrument of his voice) vibrates exactly the same number of times in a second, producing that note, as the string does. The equality in the number of vibrations is what makes the notes the same, and the effect harmonious and agreeable.

We shall suppose the string to be forty-five inches long that produces the note C of 240 vibrations in a second. Being extended between two pegs near the surface of a board, the experimenter may place his finger upon it right in the centre, and twang or strike either half, when he will find a much shriller note produced, being, in reality, the first C, or Do, of a new series of the seven notes. In this case, the vibrations are exactly double, namely, 480 in a second, these being always the more rapid the shorter the string or the greater its tightness. The second or upper C is called the *octave* of the first, being the eighth note above it.

We shall now suppose that the string is shortened only so far as to leave thirty inches, or two-thirds of its length, free for twanging. This shorter string will sound the note G, or Sol. In this case, as the length of string is two-thirds, so are the vibrations three-halves, or one and a half times those in the former instance, namely, 360. All the other notes are produced by different proportions of string and numbers of vibrations, as shown in the adjoining scale:—

- C or Do (oct.), 22½ in. 480 vib.
- B or Si, 24 in. 450 vibrations.
- A or La, 27 in. 400 vibrations.
- G or Sol, 30 in. 360 vibrations.
- F or Fa, 33¾ in. 320 vibrations.
- E or Mi, 36 in. 300 vibrations.
- D or Re, 40 in. 270 vibrations.
- C or Do, 45 in. 240 vibrations.

What is remarkable here is the curious mathematical proportions on which the various notes depend. Taking the first C as one, and its octave as one-half, we have various lengths of string for the intermediate notes, in the following proportions: namely—for D eight-ninths, for E four-fifths, for F three-fourths, for G two-thirds, for A three-fifths, and for B eight-fifteenths; all of which proportions are exactly reversed with regard to the numbers of vibrations, these being in succession nine-eighths, four-fifths, &c. The proportions, as clearly appears to the eye from the above scale, are not regular: the string is first shortened five inches, then four, then two and a quarter, next three and three-quarters, and so on. Nevertheless, these are the musical notes which the voice naturally gives forth, and which the mind recognises as beautiful. The string twanged at lengths of what would appear more regular proportion, would give forth musical sounds, but not the seven notes of music—not those peculiar sounds which all nations recognise as such, and which nature has manifestly appointed to serve in that character.

Irregular as the proportions appear, there are some of the seven notes which are more proportioned to each other than the rest. They are said to be more *in harmony* with each other; and the effect, when they are struck together, is pleasing. It is to be observed in the first place, that a note always harmonizes well with its *octave*, or the eighth or repeating note above it. This is supposed to be because the vibrations of the one note in that case are exactly two for one of the other. The first Do also harmonizes well with Sol (G), which is called its *fifth*, being the fifth note above it; and this is, on the same supposition, because the vibrations are in that case as three to two, which is also a symmetrical proportion. Harmony is also produced when some other notes are sounded at the same moment with those which are third above them (their *thirds*); and this may be accounted for in a similar way. Thirds, fifths, and octaves, are therefore pleasing or harmonious sounds, while seconds, fourths, sixths, and sevenths are less so. Experiments of a very curious nature have been made on this subject. It may readily be observed by the naked eye, that when one of the longer strings of the harp or piano-forte is struck, there is not only a vibration along the whole length, giving it an elliptical appearance, but there are also vibrations of shorter lengths of the same string going on at the same time. It has been found, when light pieces of paper are hung across the string, that they settle at certain places, showing that the principal subordinate vibrations correspond with octaves, fifths, and thirds. A drum, or a sonorous board, over which sand has been strewn, will, if beat, throw the sand into curious figures of a determinate and regularly recurring character. This is the result of similar subordinate vibrations along the extent of the sounding body.

There are even more curious facts connected with the harmonious notes. The *cries* of a city—that is, the scarcely articulate, but often very musical, sounds uttered by persons selling things on the streets—generally rise on thirds or fifths, sometimes on octaves; and this although few of these poor people have ever been taught music. The cry of oysters by women in Edinburgh is always on an octave. Teachers of elocution are also aware that human beings in general make such transitions of voice naturally, under the influence of certain feelings. For example, a person indifferently surprised at hearing a friend say "I was the person who did so and so," will say, "Was it you?" rising only a third at the last word. If greatly surprised, the rise will be a fifth. There may even be so great a degree of astonishment, that the word "you" will begin on one note and terminate on its octave. The answers, "Yes, it was I," will show corresponding declensions or falls of voice. We thus see how truly music is a species of natural language. Unquestionably, every shade of human feeling can be represented by successions of its sounds, apart altogether from words.

With respect to the sounds produced by wind instruments, the effect is caused by the vibrations of a column of air confined at one end, and either open or shut at the other. The length of the sounding column determines the nature of the vibrations; but along with the fundamental tone, there are inferior and subordinate vibrations. The whole column divides itself into regular portions, equal to the half, the third, and so on, of the longitudinal extent, in the same manner as we showed was the case in stringed instruments. We may observe something similar to these vibrations in the contraction and expansion of a long and very elastic string, to one extremity of which a ball is attached. A spiral spring also shows, and perhaps more clearly, the repeated stretching and recoil. If suddenly struck at one end, it will exhibit not only a vibration throughout its whole extent, but likewise partial ones, which wind vermicularly along the chain of elastic rings. If the air be struck with great force, the subordinate vibrations sometimes predominate, and yield the clearest and loudest tones. This may be observed in the dying sounds of a bell, which rise one or two octaves, and expire in the acutest note. Upon the degree of force with which the instrument is blown, depends the performance of the bugle-horn, whose compass is very small, consisting only of the simplest notes. In other wind instruments, the nature of several notes produced depends upon the length and size of the tube, or the positions of the holes in its sides. In the organ, there is a pipe for each note, and wind is admitted from the bellows to the pipes by the action of keys similar to those of a piano-forte. The organ may be played also by a barrel made to turn slowly under the keys, and to lift them in passing, by means of pins projecting at certain determinate intervals from the surface of the barrel. In wind instruments which are furnished with reeds, the tone depends on the stiffness, weight, length, &c., of the vibrating plate or tongue of the reed, as well as on the dimensions of the tube or space with which it is connected.

With a view to impart some instruction in the practice and theory of music, we have, in a subsequent part of this work, offered a complete treatise on the subject.

WORKS ON OPTICS, LIGHT, AND ACOUSTICS.

The subject of Optics and Light has attracted more attention of late years than any other branch of natural philosophy. The researches and discoveries of Dr Brewster of Edinburgh, published in various scientific journals, have gained for him much reputation. Many of his speculations and experiments, however, are more curious than useful. The French savans have been even more successful than Brewster; and the discovery of Daguerre, by which the light of the sun is made directly instrumental in producing accurate representations of objects on metallic plates, is the most important that has been made since the time of Newton. It would exceed our limits to notice all the works on Light and its connection with heat, electricity, magnetism, and galvanism, which have appeared even during the recent period in which philosophers have been so earnestly engaged in examining these subjects. Among the many general works on Optics, may be mentioned the following, adapted to persons of different capacities and attainments in science:—Joyce's "*Scientific Dialogues*, vol. v.," intended for those who have a taste for the science without having entered much into the elements of it. "*The Elements of Optics*, by James Wood, B.D." This treatise enters largely upon the aberrations produced by the unequal refrangibility of different kinds of rays, and by the spherical form of reflecting and refracting surfaces. It is rather abstruse, requiring considerable mathematical knowledge. "*A Treatise on Optics, containing Elements of the Science, in two books, by Joseph Harris*," a more easy and popular work. In the first book the elementary part of optics is explained; in the second, the subject of vision. On the latter subject Dr. Porterfield's *Treatise on the Eye* is one of the best authorities extant. "*A New and Compendious System of Optics, by Benjamin Martin*," is a popular treatise, illustrated with experiments and examples; of the latter many are worked by common arithmetic.

"*A Complete System of Optics, in four books, by Robert Smith, LL. D., Professor of Astronomy and Experimental Philosophy, at Cambridge*, 2 vols. 4to." The first part of this elaborate work is designed for the use of those who would know something of optics, but who want the preparatory learning that is necessary for a thorough acquaintance with the subject. With this view the author has avoided all geometrical demonstrations, and substituted the more entertaining sort of proof, drawn from experiments that may be repeated with little trouble or apparatus. By this means any one with moderate application may make himself master of no inconsiderable part of the doctrine of optics. The second book is a complete mathematical treatise of the science; and will require, in the reader, a large portion of geometrical and algebraical knowledge. In the third book is given a description of a complete set of optical instruments, with explanations of the various uses to which they may be applied, in Astronomy, Geography, Navigation, Levelling, &c. A history of the telescopic discoveries in the heavens, is the subject of the fourth book, which modern discoveries have, of course, rendered imperfect.

"The elementary parts" of Dr. Smith's Optics, were published by Dr. Kipling, in 1778, who added, in the form of [illegible], [illegible] explanatory propositions from other authors, chi[illegible] Dr. Barrow and Descartes.

To [illegible] works on [illegible]ence of optics gener[illegible] be [illegible]ded the following on a particular branch of it.

"*Of Microscopes, and the Discoveries made thereby; illustrated with many plates, by Henry Baker, F.R.S.*" This work, which consists of two volumes octavo, contains much useful knowledge, exhibited in a simple and perspicuous method, for the sake of persons who have not had the advantage of a learned education. The reflections which Mr. Baker draws from the various parts of these volumes, all tend to impress the reader with just ideas of the wisdom, power, and goodness of the great Creator.

CHEMISTRY.

The material world immediately under our observation, including such parts of the earth's crust as have been explored, the plants and animals upon its surface, and the atmosphere which envelopes it, is found to consist of fifty-four simple substances, just as all the words which compose a language are resolvable into a few letters. These substances, having hitherto resisted all endeavours to divide or resolve them into any others, are termed the *elements of matter*, or *simple bodies*. From the earliest stage of creation most of them appear to have been in a state of combination with each other; they are scarcely ever found otherwise.

Matter has ever been, and is now, undergoing perpetual decompositions and recombinations, some of which take place upon an extensive scale, as part of the regular functions and operations of nature, while others are effected by the ingenuity of man, to serve the purposes of his ordinary economy. Of the fifty-four simple substances, six are gases, (three of which only are permanently gaseous), forty-one are metals, and the remaining bodies are reducible under no fixed class. The investigation of the laws under which these various elementary bodies have formed the numerous compound substances which we see in nature, and the means by which compound substances can be resolved into their original elements or thrown into new combinations, are the objects of the science of Chemistry.

The term *chemistry* is of doubtful derivation; but it seems to have been applied at an early period to various methods of melting or preparing metals, and was identified with the visionary science of alchemy, which professed to be the art of transmuting copper and other base metals into gold and silver. It is only within the last sixty or seventy years that chemistry has risen to the rank of a science; but during that period it has advanced towards perfection with a rapidity unparalleled in the history of philosophy. The applications of chemistry are universal. There is no science so immediately conducive to human comfort. To whatever art or manufacture we turn our attention, we find that it has either been created by chemistry, or owes to it some of its greatest improvements. In the present sheet, it is our object to present a simple and intelligible view of the principles of this exceedingly important science, with a description of the various elemental bodies, and their more immediate combinations. We shall commence with a view of the general leading principles on which the science proceeds.

CHEMICAL ATTRACTION.

When particles of different kinds of matter are brought into contact, they frequently unite and form new substances, differing widely in many instances from those by whose union they have been formed. This is called *chemical attraction*, or *chemical affinity*, because it is said that the particles of certain bodies, having an affinity for each other, will unite, while others, having no affinity, do not readily enter into union. It might almost be supposed that there are such things as preferences and dislikes among the particles of matter. Thus, if a piece of marble be thrown into vitriol or sulphuric acid, their particles will unite with great rapidity and commotion, and there will result a compound differing in all respects from the acid or the marble. This is at once an instance of affinity between two substances, and an exhibition of stronger and weaker affinity. The commotion or effervescence in the experiment, results from the disengagement of a gaseous (carbonic) acid in combination with the basis of the marble, in consequence of the vitriolic acid having a stronger affinity for it. When a piece of caustic magnesia is thrown into vitriol, we have a case of simple affinity, with a complete change, also, of properties. But the vitriol and magnesia are eminently hurtful to life. All their elements combine, without any disengagement, and the result is the production of Epsom salts, a compound with properties entirely new. Neither ingredient has been destroyed; they can again be extracted pure from the compound; but they have changed their characters through the force of affinity. But if a piece of glass, quartz, or gold be thrown into the acid, no change is produced in either, because their particles have no affinity. This process is termed in chemical language *combination*. It is quite distinct from *aggregation*, which is the union of particles of a similar kind, forming a mass which has the general properties of the particles of which it is composed, whatever may be its structure or form. It is also to be distinguished from *mixture*, in which the particles, although they may be intimately blended, are not as it were amalgamated with each other so as to lose their own individual properties. The difference between combination and mixture will be clearly seen from the following example:—if into a crystal bottle we pour a quantity of oil and a quantity of water, and shake them well together, the two substances can never be made to unite permanently together. Although they appear to do so for a short while after the experiment is made, yet if the vessel be allowed to stand for a sufficient length of time, the particles of water, being heavier than those of oil, will descend to the bottom, whilst those of the oil will settle upon the top. Here it is evident that no chemical attraction has been exerted between the particles of the two bodies, because no chemical change has taken place. In a word, there has been a mechanical mixture without any chemical combination. But if with the water in this experiment we mix a quantity of potash, so as to form a pretty strong solution, the results will be very different. The particles of the bodies will intimately combine with each other, and a compound will be formed having properties entirely different from either the oil or the potash. The substance thus obtained is the useful article soap; and if the water be evaporated by the application of heat, it assumes a solid consistency, as in the form in which it is commonly used for domestic purposes.

It sometimes happens that two bodies will readily combine with each other, but if a third body be added, the combination will be destroyed; the first of the two bodies having a stronger affinity for the third than it had for the second. Thus, if magnesia be dissolved in nitric acid, a complete union takes place; but if lime be added to the compound, the nitric acid unites with the lime, and the magnesia, which was formerly invisible, will fall to the bottom of the vessel.

Sulphur and quicksilver, when heated together, will form a beautiful red compound, known under the name of vermilion, and which has none of the qualities either of sulphur or quicksilver. Suspend a piece of aqueous sulphate of copper (common blue vitriol), by a thread, in a glassful of water. The particles of both combine and form a stream of blue fluid, which descends from the points where they are in contact. The solid is said to be *dissolved*, that is, the cohesion of its particles is destroyed, and the compound is called a *solution* of the solid.

The restoration of cohesion to a body after it has been deprived of it, is exhibited in a great variety of instances. For example, if a quantity of sugar be dissolved in water, and the solution be allowed to stand till the water has evaporated, the attraction of cohesion will take effect between the particles of the sugar, which will again resume the solid form. Here, however, a remarkable circumstance has occurred. Whatever the state of the sugar may have been originally, it invariably, in resuming its solidity, assumes a particular form, one of great regularity and beauty. It was formerly opaque, it is now transparent; originally a shapeless mass, it is now a prism of six sides, surpassing in lustre and symmetry the products of the lapidary's wheel. This solid spontaneous production is called a crystal; and the process by which it is produced is entitled

Crystallization.—Bodies, whether solid, fluid, or vaporous, are susceptible of assuming the crystalline form, and the substances which do so are numberless. The shapes which the crystals take, and the facility with which they assume them, are various. Instances of crystallization, such as sea-salt, Epsom salts, saltpetre, are familiar to every one. Water, it is well known, when cooled to a certain degree, assumes the form of ice, which is crystalline. There are three methods of producing artificial crystals: first, by dissolving the substance in a hot liquid, and either allowing the solution to cool, or evaporating it by a continued heat; second, by making the substance assume the aërial form; and, third, by melting it by fire without the presence of a liquid, and allowing it to cool slowly. The two first are the most common methods of forming crystals, and by the third, sulphur, spermaceti, bismuth, &c., may be made to assume the crystalline state. If as much alum be put into boiling water as the water will readily dissolve, crystals will be deposited as soon as the liquid cools. The presence of the atmosphere has considerable influence upon the formation of crystals. If as great a quantity of Glauber salt be dissolved in a flask half filled with boiling water as the water will hold in solution, and the flask be corked, no crystals will be formed as the liquid cools. Remove the cork, however, and crystallization commences as the air enters, a solid crystalline mass being almost instantaneously formed. If the weather is warm, crystallization will not perhaps take place even after the solution is cool. In this case, the introduction of a small crystal into the flask will cause the liquid to crystallize.

The same body does not invariably exhibit the same form of crystals; there may be several forms of crystals belonging to one body, but in one or other of these it is sure to crystallize, and not according to any other form. It is also to be observed, that very different kinds of matter may crystallize after the same model.

The general name for the substance formed by chemical attraction is a *compound;* the substances of which it is composed are called its component or constituent parts or principles. The separation of these is termed *decomposition;* and when decomposition is performed for the purpose of ascertaining the composition of a body, it is named *chemical analysis*. The reunion of the constituent parts is denominated *chemical synthesis*. Integrant particles of a body differ from the constituent particles thus:—The latter are the most minute parts into which a compound body can be resolved by decomposition, and are hence of a different nature, both with regard to each other and the substance itself which their mutual union gives rise to. The integrant particles are the most minute parts into which any body can be resolved *without* decomposition.

LAWS OF CHEMICAL COMBINATION AND DECOMPOSITION.

There are various laws connected with, and phenomena attendant upon, chemical attraction. While, of course, it can operate only between bodies of a different nature, the qualities which characterize these bodies when separate, are changed or annihilated by their combination, and it takes place only between the atoms or most minute particles of bodies. Chemical attraction can take place between two, three, or even a greater number of bodies. A change of temperature is almost always observable at the moment of combination. The force of chemical affinity between the constituents of a body, is estimated by that which is requisite for their separation. It has been already remarked that the degree of attraction varies very considerably in different bodies; and it is evident that from this variation all chemical compositions and decompositions take place. The preference of uniting with another substance which any given body is found to exercise, is metaphorically termed *elective attraction*, or *affinity*. It is of two kinds, each of which derives its appellation from the number and the powers of the principles which may be brought into contact with each other. When a simple substance is presented to a compound one, and unites with one of the constituents of the latter, so as to separate it from that with which it is combined, and by this means producing a decomposition, it is said to be effected by *simple elective attraction*. Some substances, however, will not be thus easily decomposed; and it is found necessary to introduce two or more principles, in order to effect the end in view. When two principles, therefore, are presented to a compound body, and when the principles unite each with one of those of the compound substance, two new substances are formed; and all instances of decomposition in this manner are said to be effected by *double elective attraction*. It is to be observed, that all changes effected in this manner are permanent, and that the new compound thus formed cannot be decomposed, until a substance having a more powerful attraction for one of its constituents than they have for each other, is brought into contact with them.

To Sir Isaac Newton we are indebted for the first attempt at a rational explanation of chemical combination. He was of opinion that the minute atoms of certain bodies attract each other with an unknown but enormous force, which begins to exert itself only when the particles are at very small distances from each other, and that, accordingly, this force exerts itself, and the bodies unite, when they are brought within the requisite distance. These views slowly made their way into the science; but towards the middle of the eighteenth century, they seem to have been almost universally adopted. The term chemical affinity was substituted for that of attraction, and the strength of the affinity existing in bodies came to be measured according to the order in which they were decomposed. It is unnecessary to mention the various tables of affinity which were published previously to that of Bergman, who in 1775 gave to the world a copious table of affinities, and appears to have fixed the opinions of chemists in general to his own views of the subject. According to this philosopher, the affinity of each of the bodies, say a, b, c, d, for x, differs in intensity in such a manner, that the degree of affinity in each may be expressed by numbers. He supposed affinity to be elective, in consequence of which, if a have a greater affinity for x than b, if a be presented to the compound $b\ x$, a decomposition will ensue, b will be set at liberty, and the compound $a\ x$ will be formed.

THE ATOMIC THEORY.

This theory was not discovered all at once, and immediately acknowledged by chemists; it was gradually brought to light by the repeated experiments of successive philosophers, whose labours, however, it will be impossible to exhibit a view of in this place. To Mr. Dalton we are indebted for the first development and demonstration of the fact, that bodies unite in definite proportions; and of which we shall now attempt to present the reader with as clear and simple a view as possible. Whilst engaged in determining the composition of the two gases called severally carbureted hydrogen and olefiant gas, Mr. Dalton discovered that for complete combustion they require *different* but *determinate* quantities of oxygen gas. A volume* of carbureted hydrogen requires two volumes, whilst a volume of olefiant gas requires three volumes of oxygen gas.

The conclusions at which Mr. Dalton arrived are, that bodies consist of *atoms* incapable of further diminution or division; that in chemical combinations it is these ultimate particles which unite; and that, in the case above mentioned of the combustion of the two inflammable gases, carbureted hydrogen is a compound of one atom of hydrogen and one atom of carbon; while olefiant gas is a compound of one atom of hydrogen and *two* atoms of carbon. The atoms he considered as spheres, and represented them by such symbols as a circle with a dot in the centre, a circle with a vertical diameter, and the like. In this manner the composition of a number of the best known bodies was represented by him, and the ratios of the weights of the atoms of the simple bodies inferred. For instance, he concluded from his experiments that carbureted hydrogen is composed of, hydrogen one, and carbon five; while olefiant gas is composed of, hydrogen one, and carbon ten. Now, as the former gas consists of one atom of hydrogen and one atom of carbon, then the weights of these atoms are to each other in the relation of one to five. If the weight of the atom of hydrogen, therefore, be represented by one, that of carbon will be five. In this manner, the ratios of the weight of the atoms of all the simple bodies may be ascertained by a careful analysis of the compounds formed by the union of the simple bodies.

The combinations of mercury or quicksilver with some other bodies, afford an illustration of the theory. Its first compound with oxygen, one of the gases of which the atmosphere is composed, consists of two hundred and two parts of mercury and eight of oxygen. If, however, the metal be subjected to a considerable degree of heat, it will be converted into a red shining mass, which is also a compound of the metal with oxygen; but in the latter case, sixteen parts of oxygen have united with the two hundred and two parts of the metal. The explanation of this is, that eight is the chemical equivalent of oxygen, and two hundred and two of mercury. In every successive compound which they make, their proportions form a multiple of these equivalents. Every other simple body has, in like manner, its equivalent number, and to its compounds the same rule applies. Innumerable instances of this might be adduced, but these are sufficient to prove the remarkable truth, that when different substances combine with chemical attraction, the proportions of the ingredients are always uniform; that for every atom present of one substance, there is exactly one, or two, or three, &c., of the other. If, for instance, any quantity of sulphur, intermediate between the two combinations of that substance with mercury, be added, it will not combine with it, but remain as a foreign ingredient in the sulphuret of mercury, as the compound is termed. All bodies, however, do not unite in several proportions, thus giving rise to several distinct compounds from two elements; there are many elementary bodies which will only unite with each other in one proportion, so that any two of such substances can only form one compound. This law, however, is not universal as it is well known that water and alcohol, and water and sulphuric acid, will unite in any proportions. Water will also unite in any proportion with soluble salt, until it becomes completely saturated. Bodies which unite in any proportions form an infinite variety of compounds, and are distinguished by their being united by a weak affinity, and also by the compounds formed differing little from their simple constituents or from each other.

These remarks must be held as applying to inorganic chemistry chiefly; vegetable, or organic chemistry, presents many exceptions to the principles of combination now laid down.

EQUIVALENT RATIOS.

The result of these investigations has been the formation of scales exhibiting the equivalent ratios of chemical bodies, and which are expressed by numbers. It is evident that some body must be fixed upon, and expressed by unity. Hydrogen gas, being the lightest known body in nature, and combining in the smallest proportion by weight with the other simple substances, has been taken as a standard of comparison for the combining proportions, or *equivalent numbers*, of all other bodies; and which, in all likelihood, are simple multiples of its number. Oxygen has also, by some chemists, been taken as the standard of comparison, and represented by ten. Water is a compound of eight parts by weight of oxygen. with one part by weight of hydrogen; which two gaseous bodies we shall afterwards describe. Whenever hydrogen and oxygen gases are burnt in any proportion whatsoever, they invariably form water; and they cannot be made to combine directly in any other proportion. From this, Dalton concluded that water is a compound of one atom of hydrogen and one atom of oxygen. But the weight of the latter gas being eight times that of the former, then it followed that the atom of oxygen was just eight times heavier than the atom of hydrogen. Hence, if the latter be represented by one, then will the former be represented by eight, according to those who take hydrogen as the standard. Those who take oxygen as the standard, and represent it by 10, make the equivalent for hydrogen 1·25: the result is of course the same, the proportion of 1·25 to 10, being exactly the same as that of 1 to 8.

These observations relative to water lead us to speak of the doctrine of volumes, so generally embraced by chemists upon the Continent. The union of gases is always effected in simple proportions of their volumes; and a volume of one gas combines with an equal volume, or two or three times the volume, of another gas; and in no intermediate proportion.

ELEMENTAL BODIES.

With regard to the elements of matter, chemists have agreed among themselves to consider all those bodies as simple which have not yet been decomposed. As already mentioned, the simple bodies are fifty-four in number, and for the convenience of study they have been arranged into classes. One system of classification

* Volume, in chemistry, is a term employed to denote any quantity in bulk of a substance. It is usually applied to the gases. Thus, one volume of hydrogen gas is, say, a cubic foot, yard, or any other quantity; then two volumes are of course just double the cubic foot, yard, or whatever other quantity was previously mentioned

is dependent upon the elements being metallic or non-metallic.

The non-metallic elements are divided into *gazolytes*, or bodies which are permanently gaseous; *metalloids*, or bodies which resemble the metals in their chemical relations; and *halogens*, or bodies which produce salts when in union with the metals. The non-metallic elements are thirteen in number; namely, oxygen, hydrogen, nitrogen, chlorine, iodine, bromine, fluorine, carbon, boron, silicon, sulphur, selenium, and phosphorus. The three first are the gazolytes, the next four the halogens, and the remaining six the metalloids. The metallic elements are forty-one in number, namely, potassium, sodium, lithium, calcium, barium, strontium, magnesium, aluminum, thorium, glucinum, zirconium, yttrium, manganese, zinc, iron, tin, cadmium, cobalt, nickel, arsenic, chromium, vanadium, molybdenum, tungsten, columbium, antimony, uranium, cerium, bismuth, titanium, tellurium, copper, lead, mercury, silver, gold, platinum, paladium, rhodium, osmium, iridium. These metallic elements are again divided into three orders, the first twelve being the bases of the alkalies and earths; the next twenty-one being metals whose oxides are not reduced by heat alone; and the remaining eight, metals whose oxides are reduced by a red heat. From these fifty-four elementary substances is formed all the beautiful variety of terrestrial objects. Nor is there any thing either very wonderful or mysterious in this fact, since, as we have seen, any given two of them, if made to unite in different proportions, can be made to produce the most opposite substances. These, again, united with each other, give rise to new compounds, which are susceptible of being combined, and so on through an almost infinite rotation of chemical union.*

HEAT OR CALORIC.

In our investigations of the phenomena of the material universe, we perceive two kinds of motion, which result from the two principles *attraction* and *repulsion*. Of the former we have already spoken, and it only remains to say a few words upon the latter. Repulsion, like attraction, takes place both at sensible and insensible distances. The former is exemplified by the flying off of the same light bodies which have been first attracted, after they have been some time in contact with a piece of excited resin or glass, and also by the recession from each other of the two similar ends of two magnetized needles. Repulsion at insensible distances, which is chiefly excited by heat, or, as it is called in chemical language, caloric, is exhibited in a great variety of phenomena.

The principal effects of heat are expansion, liquefaction, vaporization, evaporation, and ignition. With few exceptions, bodies are capable of expansion by means of heat; the gases being the most expansive, fluids less so, and solids least of all. When the iron rim of a coach or cart wheel is to be put on, it must first be heated to a considerable degree. The reason of this is obvious; when hot, the circle is larger than when cold, and thus slips easily upon the wheel; as it cools, the circle decreases, and thus firmly binds the woodwork together. The expansion of aeriform substances is illustrated by a bladder being partly filled with cold air, and held before the fire. The air will swell out with the heat, and become in some instances so expanded as to burst the bladder. As regards fluid bodies, the same fact is illustrated in the cases of the thermometer and barometer. By the accession or loss of heat, the alcohol or mercury expands or contracts, as shown by the index attached. The general law, therefore, is, that the expansion and contraction of matter are, with a few exceptions, dependent upon the increase and diminution of heat. The quantity or condition of heat that is discoverable by the thermometer, or by the organs of sensation, is called *temperature*. We are unacquainted with the extremes of temperature relative either to heat or cold. It has been compared to a chain, the extremities of which are concealed from view, whilst only a few of the middle links are exposed to observation. Although the universal result of an increase of temperature is an increase of bulk to the body thus subjected to heat, yet all bodies are not alike expanded by the application of the same quantity of heat. It of course follows as a general law, that different bodies at equal temperatures do not contain the same quantities of caloric. This quality of matter is called the capacity of bodies for heat, and the quantity of heat which is necessary to raise any particular body to a certain temperature, is called its *specific* caloric. Heat, however, in some cases causes contraction instead of expansion. Thus water is of greater bulk at a temperature of 32° (the freezing point) than it is at 39½° Some solids, also, as iron, antimony, bismuth, and many salts, contract when melted and expand as they become solid.

Vaporization is the rapid production of a thin vapour, as when water is converted into steam. The boiling point of water, in a vessel exposed to the ordinary atmospheric pressure, is 212°, and although more heat be applied to the vessel in which it is contained, the temperature of the water is not increased. If this degree of heat be continued, the watery particles separate from each other and become steam or vapour. Steam is colourless, transparent, and invisible, resembling the atmosphere, and is 1696 times greater in bulk than water. Steam may be condensed, or its particles brought nearer to each other, either by removing the heat which is the cause of the repulsion, or by mechanical pressure, and the result is its return to the form of water.

Water can be made to boil at a lower temperature than 212° by removing the pressure of the air. If a flask be half filled with water, the water made to boil, and as the steam escapes, a cork be put into the mouth of the flask, upon the heat being removed, the water will continue to boil, the heat in it being sufficient for that purpose when there is no pressure from the air. If the flask be put into cold water, the boiling will increase, from the steam being more effectually condensed; whereas, if the flask be put into boiling water, so as to prevent the condensation of the steam, the ebullition will immediately cease. Steam, as is well known, from its great force, and the manner in which it can be applied to propelling machinery, is of the greatest usefulness in manufactures.

Distillation is the converting of a liquid into vapour, which is afterwards carried off through a pipe and condensed in what is called a refrigerator. This is a vessel filled with cold water, round the inside of which the pipe is wound; and as the vapour passes through the pipe, it is condensed by the lower temperature of the water in the vessel.

Liquid substances give off vapour from their surface at temperatures below the boiling-point, which is termed *evaporation*. It is called spontaneous evaporation when this takes place at the ordinary temperature of the atmosphere. A large quantity of vapour is given off from the surface of the earth and sea, which eventually forms clouds, or is condensed into rain and dew. Evaporation always produces cold when heat is not applied; the heat necessary for it being derived from surrounding objects. A current of air or a higher temperature tends greatly to quicken evaporation, as may be observed in the rapidity with which the surface of the earth dries when a brisk wind passes over it.

* From recent experiments in chemistry, there is reason to believe that all substances whatsoever are but modifications of one primitive substance. The absolute truth of this startling theory remains to be practically demonstrated.

All substances become luminous when heated to 800° in the dark and 1000° in daylight, unless they are converted into vapour at a less elevated temperature. The light is red at first, and in this state a body is said to be in a state of *ignition*. If more heat is applied, the body becomes white, when it is said to be *incandescent*.

When a body changes from the solid to the fluid state, there is a quantity of heat absorbed, which has no effect in raising the temperature. This has been called *latent* heat, a discovery effected by Dr. Black, and which we shall shortly explain. For a demonstration of this doctrine, we may have recourse to water. If ice at a temperature below 32° be exposed to a warmer atmosphere, it receives caloric, and gradually rises to that point of the thermometrical scale. But as soon as it reaches it, the rise of temperature ceases, the ice begins to melt, and during the whole period of its liquefaction, its temperature, as also that of the water flowing from it, remains stationary at 32°. It is evident that, as caloric has continued to be communicated, a quantity of it has disappeared, and become absorbed during the fusion. The same phenomenon takes place when a liquid is converted into vapour; and the inference drawn from it is, that when a body passes from one state into another, a quantity of heat or caloric is lost, becomes latent, or passes into the body without raising its temperature. Dr. Black was of opinion that this latent heat became chemically combined with the solid, and was the cause of fluidity. Dr. Irvine, his pupil, took a different view of the subject. He supposed that the absorption of heat into the latent state is not the cause of liquefaction and vaporization, but the effect. The absorption he attributed to what is called change of capacity for heat, or that quality of matter which causes one kind to be more or less heated than another, by the addition of the same quantity of heat. He concluded, as a general law, that the capacity of all solids for heat is increased by fusion, and that of all fluids by evaporization. It is impossible to enter further into this interesting subject at present; but, before quitting it, we may mention an exception to the law of expansion by heat in the case of water. It is well known that water freezes at 32°, but it does not increase in density below 39½°. It is then at this maximum, and above or below that point its density diminishes. Hence ice is specifically lighter. The earth alumina, which will be afterwards described, also possesses the remarkable property of being contracted by heat.

LIGHT.

The nature of light, like that of heat, is still unknown to us. There are two theories respecting it: the first is, that light is a substance emanating from the sun and from all luminous bodies, from which it is projected in right lines with great velocity; the second is, that the sensation of light is produced by the vibration of a subtile fluid filling space—and is hence called the undulatory theory. Luminous bodies, according to this view of things, are merely stimuli, which excite these vibrations. An examination of these theories, however, cannot be here entered into. The connection between light and heat is so obvious, that it is scarcely possible to examine the one independently of the other. If a mass of iron be put into a fire for some time, no change is produced except the expansion of the metal and the elevation of its temperature. Gradually, however, as the heat is communicated, a remarkable occurrence will be observed. The iron becomes ignited or red hot; in other words, it emits light, and renders objects visible. The original sources of light are, first, the celestial bodies, as the sun and stars; and, secondly, terrestrial bodies, as a common fire or candle. Light passes freely through the atmosphere, and, striking upon objects, is reflected or thrown back by them; and thus they become visible. By means of a wedge of glass called a prism, light can be separated into seven colours, which are violet, indigo, blue, green, yellow, orange, and red. But it is only with the chemical agency of light that we have to do. Its influence in this way is conspicuous in a variety of natural and artificial processes. In vegetation it is indispensable, as without it plants do not acquire their due elementary constitution. They are weakly, inodorous, and fail to exhibit their natural colour. Vegetables which grow in the dark have a blanched appearance. The power of light to dispel vegetable colours is manifest in bleaching, where a dingy web becomes pure and white by exposure to the sun's rays. Its energy is still more decisively seen in the influence which it exerts in promoting chemical combination and decomposition, and the latter effect has been made use of as a measure of its power. Light enters into a kind of transitory union with certain substances, rendering them visible in the dark. Bodies which possess this property are called phosphorescent; such are the shells of fish, the bones of land animals, marble, limestone, and the like. The glow-worm is a remarkable instance of phosphorescence in living animals.

A remarkable recent invention, the Daguerreotype, is wholly dependent for success upon the action of light. It consists in having a thin plate of silver, prepared with iodine, so placed that the rays of light reflected from an object to be sketched will fall upon it. This is done by putting the plate in a camera-lucida, and the action of the light upon the iodine and silver is such, that when the plate is subjected to the vapour of mercury a complete representation of the object is given. A beautiful illustration of the action of light may also be seen in photogenic drawing. Paper for this purpose is prepared by steeping it in a weak solution of nitrate of silver or bichromate of potassa. The paper must be kept from the light during the preparation; and if it is now exposed to the sun's rays with a leaf or other object upon it, a complete representation of the object will be obtained. The part exposed to the sun becomes darkened, while that covered by the leaf remains of a light colour.

For a further definition of the principles of light, we refer to the article Optics.

COMBUSTION.

Combustion is a process not yet perfectly understood. It is usually described as the union of a *combustible body* with a *supporter of combustion*, attended with the evolution of *light* and *heat*. The combustible body is that which *burns*, but, in general, will neither support combustion, nor burn except in the presence of a supporter of combustion. The supporter, again, does not itself burn, though necessary to the burning of a combustible. Oxygen gas, the ingredient which enables the air to support combustion, possesses, when pure, a high degree of the supporting quality. If a lighted taper, a combustible body, be plunged into this gas, the taper burns vividly, but the gas itself is not ignited. If, on the other hand, the taper be plunged into a combustible gas, such as pure coal gas, the gas is instantly ignited, but the taper is extinguished. These are general rules, relating to supporters of combustion and combustible bodies. By examining the effects of combustion, in the case of a candle burning in the air of the atmosphere, it has been proved pretty clearly that a chemical action of the following kind takes place:—The combustible matter of the candle consists chiefly of two simple bodies, hydrogen gas and carbon, while oxygen is the supporter of combustion in the air. On burning a candle under a bell-shaped glass, filled with common air, a fluid gathers on the glass, which proves, on examination, to be pure water. The hydrogen of the burning body has here entered into combination with part of the oxygen of the air, forming water, a compound of the two. The carbon of the burning body also enters into union with a portion of the atmospheric oxygen, forming carbonic acid gas, which is left floating in place of the original quantity of oxygen. The presence of these can be proved, and the same process takes place in the case of coal, wood, &c. Thus it is seen that combustion only changes the forms of the burned bodies, and does not annihilate them. Plants, moreover, will soon extract the carbon again from the carbonic acid, and the hydrogen from the water, leaving the oxygen once more in the atmosphere to support combustion, and fulfil its other uses; while the other principles render wood combustible anew. This round of changes goes on unceasingly, without any ingredient being destroyed.

The phenomena of combustion are thus so far explicable, but unfortunately the source of the *light* and *heat* yet remains a mystery. It is unknown whether the chemical action is the cause of the light and heat being evolved, or the evolution of these the cause of the chemical action. Where all is doubt, it would be vain to dwell on this point. The laws stated respecting combustible bodies, and supporters of combustion, only apply generally, it is also to be observed, and under ordinary circumstances. Under the oxy-hydrogen blowpipe, the most incombustible bodies can be made combustible; and combustion can be shown to take place under an exhausted receiver, without the presence of any supporter, at least of a gaseous kind. We must wait in patience for a solution of these difficulties, until the genius of man has discovered more delicate instruments of philosophical investigation than any with which we are as yet acquainted.

AIR AND WATER.

Air.—By the examinations of modern chemists, it has been shown that air is not an element, but is a compound body, consisting chiefly of two gases, oxygen and nitrogen. It also appears that the oxygen is the really active agent in relation to animal respiration, and that the nitrogen is a mere diluent in the mass, on the same principle as water may be made a diluent of spirits. We subjoin the exposition of Mr. Hugo Reid (*Chemistry of Science and Art*) on this subject:—"The air consists mainly of nitrogen and oxygen, in the proportion, if these ingredients are alone regarded, of

	By measure.	By weight.
Oxygen, - -	210	231
Nitrogen, - - -	790	769
	1000	1000

It also contains, as constant ingredients in every situation, a little carbonic acid gas and vapour of water. In volume, the carbonic acid forms about 1-2000th part; or 0·5 parts in 1000 by measure; which is equal to 0·75 parts in 1000 by weight. In some situations the carbonic acid is so much as 0·62 volumes in 1000—at other places, only 0·37 volumes in 1000. Its proportion is greater in summer than in winter, during night than in the day time, in elevated situations than on the plains. The watery vapour is more variable in proportion. The mean is supposed to be about 10 parts in 1000 by weight, 15 by volume. The quantity is determined by the temperature, heat being the sole cause which sustains the vapour in the aërial state. The various methods of analyzing atmospheric air proceed upon the principle of withdrawing the oxygen. This may be done by a stick of phosphorus suspended over water or mercury in a jar of air; or, which is the best mode, by the combustion of hydrogen mixed with the air to be examined. The presence of carbonic acid gas is shown by agitating a quantity of air with lime-water. The carbonic acid and lime unite, and form the insoluble carbonate of lime, which, diffused through the liquid, renders it milky and opaque. On exposing to the air a saucer of lime-water, a thin crust or pellicle of carbonate of lime will be soon found on the surface of the liquid, formed in the same manner. The quantity of carbonic acid may be judged of by passing a little solution of caustic potash into a vessel of air over mercury, and observing how much of the gas is withdrawn, this substance removing the carbonic acid, or, by adding water of baryta gradually to a large quantity of air in a bottle, and agitating. The carbonic acid neutralizes the baryta; and the liquid is added until there is a slight excess of baryta, as indicated by a slip of turmeric paper being now rendered brown by it. The liquid added previously has exactly neutralized the carbonic acid; and in doing so has combined with an equivalent proportion of that substance, the quantity of which is thus indicated. The presence of watery vapour in the air may be demonstrated by exposing chloride of calcium or caustic potash. It absorbs the moisture, melts, and is found to have increased in weight. Strong sulphuric acid abstracts the moisture from air, increasing in bulk and becoming weaker. The dewpoint hygrometer also indicates the presence of moisture in air, and points out the precise quantity. The four bodies which enter into the composition of the air are regarded as mechanically mixed, not chemically combined with each other. It is known from the nature of aërial bodies that they would mix thus, though not combined—that they would not separate and arrange themselves according to their respective specific gravities—but would each be diffused through the whole space to which it had access. The only two likely to be chemically combined are the nitrogen and oxygen; and the great facility with which the oxygen is separated from the nitrogen, as well as not being in equivalent proportions, shows that they are not in close chemical union. The oxygen is the chief agent in the important operation of breathing or respiration of animals. Each individual is supposed, on an average, to breathe about twenty times every minute—to take in about sixteen cubic inches of air (12·8 nitrogen + 3·2 oxygen) at each inspiration—to return nearly the whole of the nitrogen (12·8 cubic inches), and 4·5ths of the oxygen (2·56 cubic inches), and to replace the remaining 5th of oxygen by an equal volume of carbonic acid (·64 cubic inch)." The oxygen of the air is the great means of procuring heat and light, by its action with combustible bodies.

Water.—Water was also at one period believed to be a simple element in nature; but this supposition has given way before the examination of chemists. Water is now known to be composed of oxygen with hydrogen gas, in the relative proportions of 8 of oxygen to 1 of hydrogen. Into these substances can it be resolved by the action of electricity or fire, but at such a cost as to render the process unsuitable for economic purposes. Pure water, in chemistry, is called an oxide of hydrogen. It may be formed by exploding a mixture of oxygen and hydrogen in a tube by the energy of electricity. Sea-water (see article OCEAN) contains, in 1000 parts, about 46 of foreign matters, chiefly chloride of sodium. Its specific gravity is 1·027.* Mineral waters, in a similar manner, contain various foreign bodies; as, for example,

* *Specific Gravity* is the relative gravity or weight of any body or substance, compared with that of some other body which has been fixed upon as a standard. By universal consent, pure distilled water has been assumed as a standard; and it fortunately happens that a cubic foot of pure water weighs exactly 1000 ounces avoirdupois. Water is indicated by unity—thus, 1. When, therefore, it is expressed that any body has a specific gravity of 2, then, bulk for bulk, it is just twice the weight of water. If there be more figures than one, and there be a dot or point between them—thus, 2·5—the unit is here divided into ten parts, and the body is twice and five-tenth times, or two and a half times, heavier than water. If two figures occur—thus, 10·40—the unit is supposed to be divided into a hundred parts, and the body is ten and forty-hundredth part times heavier than water. If there are three figures, the unit is supposed to be divided into a thousand parts; if four, into ten thousand parts, and so on; the number and value of the figures always indicating the exact specific gravity of the body according to the above principle. Common air is sometimes taken as a standard with which to compare gases, as in the instances mentioned in the text. It is a simpler and more intelligible way of comparing the relative weights or densities of aërial substances. But all the solids and fluids are estimated with regard to water

carbonated waters, which contain carbonic acid; sulphureous waters, which hold sulphureted hydrogen; and chalybeate waters, which contain sulphate or carbonate of iron. Water may be impure, either by the chemical union of these and other foreign bodies, or by the mechanical mixture of substances. The latter may generally be removed by filtration, but when the union is chemical, distillation and other processes are requisite to produce a pure liquid. In nature, water is never altogether pure. When it contains a chemical compound of lime, it is said to be *hard*, and in this condition it decomposes the soap which is employed with it.

ACIDS.

Acids are a most important class of chemical compounds and have the following characteristic properties:—The greater number of them have a sour taste, and are very corrosive. With few exceptions, they change vegetable blues to red, they are mostly soluble in water, and they unite with the alkalies, earths, and metallic oxides, forming what are called salts—an order of bodies of the highest importance in the arts, manufactures, &c. Some acids are destitute of a sour taste, but their affinity for the three classes of bodies above named is a universal characteristic. Acids are all compound bodies, and some of them have more than one basis or radical. There are a number of acidifying principles, but oxygen (which shall be immediately described) is the most extensive one. The acid is distinguished by the name of its base, and its degree of oxidation, that is, the quantity of oxygen it contains, by the termination of that name in *ous* or *ic*, or the prefix *hypo* (under). The highest degree of oxygenation is marked by the termination *ic*, as nitric acid, and the salt which is formed from it is made to terminate in *ate;* the next by that of *ous*, as nitrous acid, and the salt which is formed from it is made to terminate in *ite;* and the lowest by *hypo*, as the hyponitrous acid. Sometimes oxygen combines in a greater quantity with the acidifiable radicals, in which case the product is said to be superoxygenated. All acids are not susceptible of these various degrees of oxygenation, some being limited to only one. There are a considerable number of acids, and the number is continually increasing by the discovery of new ones; but of the most important there are few, and these we shall notice as we come to treat of their bases.

SALTS.

This term has been usually employed to denote a compound, in definite proportions, of acid matter with an alkali, earth, or metallic oxide. When the proportions of the constituents are so adjusted that the resulting substance does not affect the colour of infusion of litmus or red cabbage, it is then called a neutral salt, because the peculiar powers of both bodies are suspended and concealed; they are rendered neutral or inactive. When bodies combine in such a way as to satisfy their mutual affinities, they are said to *saturate* each other. When the predominance of acid is evinced by the red of these infusions, the salt is said to be acidulous, and the prefix *super* or *bi*, is used to indicate this excess of acid. If, on the contrary, the acid matter is deficient, or short of the quantity necessary for neutralizing the alkalinity of the base, the salt is then said to be with excess of base, and the prefix *sub* is attached to its name. These must be understood, however, only as general rules. There are exceptions to be found in the case of some salts, as the compounds formed by an acid and an alkali, an earth, or a metallic oxide, are denominated. For example, a certain salt formed by nitric acid and lead, though the acid be perfectly neutralized, reddens vegetable blues; and a salt formed by boracic acid with soda retains the powers of an alkali, in the respect in question, though with a double proportion of acid in it.

METALS, OXIDES, EARTHS, AND ALKALIES.

We arrange these classes of substances together, because, although they are to a certain extent distinct, yet they have all a very remarkable relationship, as we shall shortly see.

Many of the metals, such as iron, lead, &c., are familiarly known to every one, but there are a great many others which are very rarely to be met with. The following are some of the characters which distinguish metals from other bodies:—They are, for the most part, hard and heavy, and are all opaque; insoluble in water; they possess a peculiar lustre; admit of being so highly polished as to reflect light; are capable of being melted by heat, and recovering their solidity by cooling; most of them may be extended by hammering, and all are rapid conductors of electricity. They are of various colours, and require different degrees of heat to fuse or melt them. They generally occur in the earth in what are called *veins*, and are seldom found in the pure metallic state, but generally in combination with some other substance, in which state they are called *ores*. The metals, which are all simple bodies, will be individually described afterwards.

Most metals, when subjected to heat until they become melted, combine with the oxygen of the atmosphere, and form what are called *oxides*. Oxides are destitute of those properties which distinguish the metal from which they are formed. Instead of being bright, shining, elastic, and ductile substances, they are generally a dry, earthy-looking powder. Other substances besides metals, however, are capable of being converted into oxides; and it must be kept distinctly in view, that in every case there is not so much oxygen imparted as will produce *acidification*. Oxygen frequently combines in various proportions with a substance, rendering it an oxide, but without advancing it to the state of an acid. In order to distinguish each compound thus formed, the language of chemistry is very systematic. The first is called a protoxide; the second, a deutoxide; and a third, a paroxide.

The term *Earths* was formerly, and is still, but in a modified sense, applied to several substances which compose all the various rocks, stones, gems, mountains, and soils, covering the surface of the globe. They are tasteless, inodorous, dry, uninflammable, sparingly soluble, difficult of fusion, and of moderate specific gravity. These bodies will be more particularly described when we come to treat of their metallic bases. *Alkalies* may be defined as bodies which combine with acids so as to impair or neutralize their activity, and produce what are called salts. They are distinguished by properties the reverse of acids, and the two classes are generally looked upon as antagonist substances. Besides the power of neutralizing acids, there are four alkalies, namely, potash, soda, ammonia, and lithia, which possess the following properties in a high degree:—They change vegetable blue to green, red to purple, and yellow to a reddish brown; they have an acrid and urinous taste; they are powerful corrosives of animal matter, with which they combine so as to produce neutrality; they also unite with oils and fats, forming the well-known substance soap; they combine with water and alcohol in any proportion. Four of the earths, namely, lime, baryta, strontia, and magnesia, possess alkaline properties to a considerable extent, and are hence called alkaline earths. These bodies differ from the pure alkalies, inasmuch as they become insoluble in water when neutralized by carbonic acid. Moreover, alkalies possess the power of changing vegetable colours *after* being saturated with carbonic acid, and by this criterion they are distinguished from the alkaline earths.

It was long observed that the properties of earths very nearly resemble those of the compounds of oxygen and metals called metallic oxides; but it remained for the brilliant genius of Sir Humphry Davy to show that both the earths and alkalies are metallic oxides It thus appears, then, that the globe is one vast mass of various kinds of metals, disguised by various substances, but chiefly by oxygen. Earths and alkalies are simply metallic oxides; whilst a farther impregnation of these substances with oxygen produces an acid; and, lastly, the union of acids with alkalies, &c., gives rise to that very numerous and important class of substances called salts.

Of the elemental substances at present known, six seem capable of combining with all the others. When combined with a certain portion of the other simple bodies, they form *acids;* and when with the rest, they constitute *bases* or *alkaline bodies,* which are capable of uniting with and neutralizing the acids, as we have formerly observed. To these six bodies the name of *supporters of combustion* has been given. The eighteen bodies, which, when combined with the supporters, become acids, have been distinguished by the name of *acidifiable bases.* The thirty-one bodies, which, when united with the supporters, become alkalies, have been called *alkalifiable bases.* The *simple* supporters of combustion are as follow:—Oxygen, chlorine, bromine, iodine, fluorine, and sulphur.

OXYGEN.

Oxygen gas is a permanently elastic fluid, that is, one which no compressing force, or degree of cold, hitherto applied, has ever been able to reduce to a liquid or solid form. It forms, as we have already observed, one of the constituents of the atmosphere, is colourless, and destitute of taste and smell. Its specific gravity is 1·1111, that of common air being reckoned unity. Combustible bodies burn in it with more brilliancy, and more light and heat is evolved, than when combustion takes place in the atmosphere. If a candle, the wick of which is red-hot, be introduced into a vessel containing oxygen, the candle will instantly be lighted. Oxygen has the power of combining with every other simple body; the multifarious compounds which it thus forms, such as oxides, acids, and bases or alkalies, we have already adverted to. In the act of respiration, oxygen, in the nice economy of the human body, is made to unite with, and becomes a portion of the human frame. Vegetables also inhale and exhale it at certain seasons, so as admirably to supply what is absorbed by animals. It is the intensely rapid chemical union of oxygen with the combustible body, which gives rise to the light and heat in our common fires, candles, &c. It may be readily procured from a variety of substances, as, for instance, from saltpetre or the black oxide of manganese. These may be introduced into a gun-barrel, with the touch-hole plugged up. From the orifice of the barrel let a tube be conducted into an inverted glass jar, filled with water. When the other extremity of the apparatus is subjected to heat, the oxygen gas is expelled from the manganese, and entering the glass jar, displaces the water and fills the vessel. This is a cheap and easy method of obtaining this remarkable aëriform body.

Oxygen can be prepared by putting 1000 grains of binoxide of manganese into a retort with an equal weight of aqueous sulphuric acid. This is done by means of a retort fixed over a spirit-lamp. The bent tube of the retort enters a pneumatic trough, in which jars are placed for receiving the gas as it passes from the neck of the retort.

HYDROGEN.

Hydrogen gas is a permanently elastic fluid, transparent and colourless, and when *pure,* destitute of taste or smell. It can scarcely be said to exist in an isolated state, but it forms one of the constituents of water, from which it can be disengaged by various simple processes. It is the lightest body with which we are acquainted, and is employed in combination with other gases to inflate balloons. A bladder filled with this gas will ascend in the atmosphere, in the same manner as a piece of cork or wood plunged by force to the bottom of a vessel of water. Hydrogen will not support combustion, but is itself remarkably combustible. When one volume of oxygen is mixed with two of hydrogen, it burns with a loud explosion, by an electric spark, or the contact of a red-hot fire. The product of this experiment is water It is said that a few cautious draughts of this gas may be taken, but it cannot be inspired for any length of time without occasioning death. Frogs live in it for a long time, showing these animals to be very tenacious of life. By far the most important compound of hydrogen with any other substance is that with oxygen, forming the indispensable fluid which covers nearly two-thirds of our globe, water. It unites with the other supporters of combustion; but the compounds, except muriatic acid, already mentioned, are not of any great importance.

Hydrogen may be prepared by putting 500 grains of zinc into a common beer bottle, and pouring upon the zinc three ounces of water and five drachms of aqueous sulphuric acid. The hydrogen is disengaged, as the acid, the oxygen in the water, and the metal combine. By means of a bent tube from the bottle, the gas can be conveyed into jars placed in a trough.

AZOTE, OR NITROGEN.

This gas is permanently elastic, transparent, colourless, and inodorous. It is a very little lighter than oxygen. When breathed, it destroys animal life; and a burning body, if immersed in a jar containing it, is instantly extinguished. It is not combustible; it enters extensively into combination; it is an abundant element in animal matter; and its existence in such large quantity is a chief distinction between the constitution of animal and vegetable life. Its existence in the atmosphere we have already adverted to. Whether it is chemically united with oxygen in that compound, or only mixed with it, is not precisely known. That it has the property of combining with all the supporters of combustion, there can be little doubt; but the subject has not yet been thoroughly investigated. With oxygen it unites in no fewer than five proportions; by far the most important being

Nitric Acid, or Aquafortis.—This virulent substance is a compound of one volume azotic, and two and a half volumes of oxygen gas. Common nitric acid is of an orange colour, on account of its containing a little muriatic acid, as also a little sulphuric acid and water. Light has likewise an effect upon it. The specific gravity of the strongest procurable nitric acid is 1·55, and then it contains one-seventh of its weight of water; that of commerce is about 1·423, and contains two-fifths of its weight of water. Nitric acid has very remarkable effects upon water with regard to the production of heat. If diluted with half its weight of water, heat is evolved; but if the water be in the state of snow, intense cold is the result. Hence, this compound is employed to produce great degrees of cold. If nitric acid highly concentrated be thrown upon phosphorus, charcoal, or oil of turpentine, it inflames them. It is very extensively used in the arts, and forms a numerous and important class of salts, having the generic name of *Nitrates,* such as nitrate of silver, nitrate of potash, &c. Some of these we shall notice afterwards. *Nitrous acid* is a compound of the same kind, but with a lesser quantity of oxygen. Amongst the other compounds of azote and oxygen, that entitled the *protoxide of azote,* or, as it was formerly called, *nitrous oxide,* is the most remarkable. Davy discovered that we may breathe it for a short while without any effect being produced, except an exhilaration of the mind. Combustibles burn in it more brilliantly than in common air. There is also a *deutoxide of azote* and a *hyponitrous acid;* but these do not require minute detail. Azote combines likewise with chlorine and bromine. Nitric acid can be procured by filling a glass retort about one-third full of equal weights of aqueous sulphuric acid and common nitre. The retort is then subjected to heat, and a vapour is distilled over, which, condensed, is nitric acid.

Ammonia, or *Hartshorn*.—This important substance is formed by the combination of azote with hydrogen, and is obtained in the state of gas, by means of the salt called *sal ammoniac*, which is a compound of muriatic acid and ammonia. This substance is to be introduced into a retort, along with quicklime, and then subjected to heat. Ammonia is driven off in the form of gas, and is to be collected in glass jars standing over mercury. Ammoniacal gas is colourless, has a strong pungent smell, an acrid caustic taste, and cannot be drawn into the lungs. Its specific gravity is 0·59027. Water absorbs 780 times its volume of this gas, and in this state it is employed for chemical purposes. When the gas is mixed with chlorine, a sudden combustion and detonation take place. The chlorine unites with the hydrogen of the ammonia, and forms muriatic acid, whilst the azote is disengaged in the state of gas. The muriatic acid formed, combines with a portion of ammonia, and forms sal ammoniac. Ammonia is an alkali, and possesses the properties distinguishing this class of substances in a very decided manner. It of course neutralizes acids, and the salts which it forms are numerous, and of considerable importance.

CHLORINE.

This is a gaseous body, of a yellowish-green colour, a strong suffocating smell, and of a pretty strong astringent taste. Reckoning air as unity, its specific gravity is 2·5. If breathed undiluted, it destroys animal life; however, it not only supports combustion, but possesses the remarkable quality of setting fire to many of the metals, even at the common temperature of the air, when beaten out into thin leaves, and introduced into it. The combinations of metals with chlorine are called *Chlorides*. Chlorine possesses the property of destroying all vegetable colours, and of rendering vegetable bodies, exposed to its action, white. This property has occasioned the introduction of chlorine into bleaching; for if unbleached linens be exposed to its action, the matter which gives them their gray colour is destroyed, and the substance assumes a brilliant whiteness. Chlorine, however, must be used cautiously, for if applied in its pure and not sufficiently diluted state, it destroys the fibre of the cloth. Chlorine combines with oxygen in four different proportions; two of them contain so much oxygen as to form acids; these are, chloric acid and perchloric acid; but as the other two do not manifest any acid properties, they are to be considered as oxides, and are called protoxide of chlorine and peroxide of chlorine. Besides uniting with oxygen, chlorine combines with hydrogen, and forms the well-known acid called

Muriatic Acid.—If chlorine and hydrogen be mixed together in equal volumes, and exposed to common daylight in a glass flask, they will in a little time combine, and even explode in combining, if exposed to sunlight or the light of a candle; two volumes of muriatic gas result. Its specific gravity is 1·8244; in its pure state this gas is transparent, colourless, and elastic: under very strong pressure it condenses into a liquid. Water absorbs this gas with avidity. One cubic inch at 69° absorbs 417,822 cubic inches of the gas; heat is produced, and, when cold, the bulk of the water is increased to 1·3433 cubic inches. This is liquid muriatic acid. With these proportions of constituents, its specific gravity is 1·1958; one hundred grains of it consist of 40.39 of real acid, and 59·61 of water. It is a colourless liquid, and, when exposed to the air, it smokes, because the gas exhaled condenses the moisture of the atmosphere. It extinguishes both flame and life, and is not inflammable. It is of a pungent, suffocating, and somewhat aromatic smell. It powerfully reddens vegetable blues. The best method of obtaining it is by pouring sulphuric acid upon an equal weight of sea-salt, and collecting the gas which is given off, over mercury. An immense number of salts are formed from the combination of muriatic acid with oxides; such as common sea-salt, which is a muriate of soda. These are very extensively used, both in the arts and medicine. Chlorine combines with azote, and forms what is called

Chloride of Nitrogen.—This is an oily liquid, and the most powerfully explosive compound known. In this respect it is one of the most dangerous substances of nature; it consists of four volumes of chlorine combined with one of azote. Chlorine combines with carbon, but the compounds are unimportant.

BROMINE.

The term *bromine* is from a Greek word, signifying "a strong disagreeable odour." This substance was discovered only so lately as the year 1826; it resembles chlorine in many of its habitudes. It is of a brownish-red colour, very disagreeable smell, sharp strong taste, powerfully corrosive of organic bodies, and, when taken internally, a violent poison. Its specific gravity is 2·96; it destroys vegetable colours almost as powerfully as chlorine. Like chlorine, it sets fire to certain metals when brought into contact with it; it is not combustible, and it extinguishes combustion; it becomes solid at a little below zero; but if combined with water, so as to form a hydrate, it affords fine red crystals at 32°. An acid is formed by the combination of bromine with oxygen, and is called bromic acid; another with hydrogen is called hydrobromic acid. Chlorine also combines with it, and forms a chloride. There are numerous other combinations of bromine, but the compounds are unimportant.

IODINE.

This substance was first discovered in 1811, by a saltpetre manufacturer of Paris. It is derivable from sea plants, and in some of its properties much resembles chlorine, which is also a marine production. If common sea-weed be powdered dry, and treated with sulphuric acid whilst subjected to heat, a violet-coloured vapour is expelled, which, if collected in a vessel, condenses into scaly dark-gray crystals, with somewhat of a metallic lustre. These are iodine, so called from the violet-colour of its vapour; iodine being a Greek word, and signifying "violet-coloured." Its specific gravity is 3·0844. Its smell is disagreeable, its taste acrid and hot, and it possesses poisonous properties. It is a powerful stimulant, and has of late been much employed as a medicine. It destroys vegetable colours, but not so completely as chlorine. It melts when heated to 224½°, and volatilizes at 351½°. It forms a beautiful blue colour when mingled with water holding starch in solution; it is itself slightly soluble in water, but more so in alcohol and ether. Iodine combines with oxygen in three proportions, forming iodic acid, iodous acid, and oxide of iodine; with chlorine, forming chloriodic acid; with bromine in two proportions, forming bromides; and also with azote and hydrogen. A compound of iodine and azote is exceedingly explosive. But a particular account of these substances do not require to be given in this place.

FLUORINE.

The existence of this substance, strange to say, is conjectural; yet its separate identity is supported by the strongest analogies. It exists, or rather is supposed to exist, in fluor or Derbyshire spar, and is thus provisionally called fluorine. If some of this mineral in powder be distilled with strong sulphuric acid, from a leaden retort (a vessel somewhat of the shape of common Rupert drops) into a leaden receiver kept cold with ice, an intensely active fluid is produced. "It has," says Davy, "the appearance of sulphuric acid, but it is much more volatile. When applied to the skin, it instantly disorganizes it, and produces very painful wounds. When it is dropped into water, a hissing noise is produced, with much heat, and an acid fluid is formed." This substance has been called *hydrofluoric acid*, because it is conjectured to have fluorine as a base, combined with hydrogen, to form an acid, upon the principle which we have formerly described. Other views have been adopted with respect to this substance, but the above is the one now generally admitted.

CARBON.

Carbon or charcoal is found in many different forms, and can be prepared by burning wood, coal, &c., in close vessels. The diamond is pure carbon, and plumbago or black-lead is principally composed of this substance with a little iron. It burns in oxygen with considerable brilliancy, although in common air it emits but a feeble light. If carbon be burned in a close vessel, filled with oxygen, the carbon will be entirely consumed, and the oxygen so much changed, that if a lighted taper be put into it the light will be extinguished. Carbon combines with all the supporters of combustion, and with oxygen forms carbonic acid. This acid may be prepared in the pneumatic trough, by putting into the retort an ounce of hydrochloric acid, previously mixed with two ounces of water, along with a tablespoonful of the carbonate of lime. An effervescence takes place between the acid and the lime, carbonic acid gas being given off, which can be collected in the jars and condensed in water. Carbonic acid is fatal to animal life, and the gas will extinguish a candle introduced into it.

Oxalic Acid.—This substance, which is also a combination of carbon with oxygen, may be formed by digesting sugar along with nitric acid. The acid is deposited in small crystals, which have an intensely acid taste, and, when taken internally even in small quantities, destroys life. It combines with bases, and forms a genus of salts called *oxalates*. Carbon is capable of uniting with chlorine in three different proportions, with bromine in one or two, and with iodine in two. But we must pass from these compounds to those of far greater moment which it forms with hydrogen.

There are many combinations of carbon with hydrogen, and much uncertainty prevails both with regard to their number and nature; they are all designated by the name *hydrocarbons*, or more properly *hydrocarburets*.

COAL GAS.

Carbureted and bicarbureted hydrogen bear very different relations to the well-being of man: the former, when a spontaneous production of nature in mines, is one of the most terrific instruments of destruction, and a great obstacle to human industry; for, by mixing with a certain quantity of common air, it acquires the property of exploding when accidentally kindled, and thousands of human lives have fallen sacrifices to its violence, until Sir Humphry Davy's invention of the safety-lamp divested it of its terrors.

Davy's safety-lamp consists of a common lamp surrounded with wire-gauze. On analyzing the carbureted hydrogen or fire-damp, Sir Humphry Davy found that it would not explode when mixed with less than six times, or with more than fourteen times, its volume of atmospheric air, that air rendered impure by the combustion of a candle will not explode fire-damp, though the candle will still burn for a time; and that, if a candle be burnt in a close vessel, with small apertures only above and below the flame, no explosion will ensue. The flame within will be enlarged, but no explosion take place; and it was found that the gas from mines will not explode in a tube less than one-eighth of an inch in diameter.

Bicarbureted hydrogen is the chief, although not the most abundant ingredient in *coal gas*, now so generally used for illumination; the other ingredients are carbureted hydrogen, hydrogen, and carbonic oxide. Coal gas is made by introducing a quantity of bituminous coal into a large iron cylinder called a retort, close at one end, and furnished with a mouth-piece at the other, for closing or opening it; there is also a tube for carrying off the gas and other products as they form. A quick strong heat is applied round the cylinder, and a vast quantity of gas, composed of the four ingredients just mentioned, is thus extricated, with tar and an ammoniacal liquor, both of which are condensed by passing through pipes immersed in cold water. There is a great difference in the relative proportions of the gases in the mixture, as also in the quantity of tar, according to the quality of the coal and the mode of applying the heat. The more tar the gas holds dissolved, the more dense will be the flame when the gas is made to burn, and the more disagreeable will be the smell when it is not burning. A slow heat gives much tar and little gas, and that little of a poor quality; a quick heat gives much gas, of good quality, and less tar. Owing to these and other causes, the illuminating power of coal gas varies much. Before it is let through the conducting tubes for public consumption, it is well agitated in contact with a mixture of lime and water, or passed through strata of loosely strewed hydrate of lime; it is thus deprived of much of its smell, and also of some of its illuminating power. On an average, a chaldron of good Newcastle coal, weighing 25 cwt., will afford 12,000 cubic feet of gas, provided that the retorts are new. After being used a few months, the product will not exceed 11,000 feet, or even 10,000. An illuminating gas of this kind is sometimes presented ready formed by nature. A village of Fredenia, in the western part of the state of New York, is lighted with this gas as it naturally issues from a rock; the flame is large, but not quite so brilliant as that of coal gas.* A scheme was recently in agitation for lighting the towns of Newcastle and Gateshead with a natural gas which issues from the Wallsend coal-pits. This gas is diluted with about 10 per cent. of atmospheric air, but is otherwise remarkably pure. *Oil gas* being of a similar nature, it need not be particularly described. There are other less important compounds of carbon and hydrogen, and the whole correspond with the law of multiple combination already described. *Naptha* and *napthaline* are hydrocarburets; the former is a transparent volatile fluid, the other is a transparent volatile solid, which assumes the form of crystalline plates: both are obtained from coal tar by distillation.

Cyanogen.—This substance is a gaseous compound of azote and carbon. It burns with a purple flame, and destroys life on being breathed. Cyanogen unites with a variety of bodies, and forms many important compounds.

BORON.

The borax of commerce is a compound of boracic acid and the alkali called soda. Boracic acid is a compound of oxygen and boron, in the proportion, it is supposed, of one atom of the latter to three of the former. Pure boron is an opaque brownish-olive powder,

* Donovan's Chemistry, p. 117.

infusible, and not volatile at any temperature to which it has yet been subjected. It neither dissolves in nor acts upon water. At about 600°, it takes fire, and combines with oxygen, forming

Boracic Acid.—This substance evinces the usual properties of an acid, but it is not a powerful one at ordinary temperatures. At high temperatures, however, it displaces the strongest of the other acids, and is exceedingly useful in fluxing out the baser metals from the nobler. When the acid is detached from borax, by vitriol being poured upon that compound, it exhibits itself in scaly crystals. It dissolves in rectified spirits, and, if the solution be set on fire, it burns with a green flame. Borax itself, when heated, melts into a perfectly clear glass, which is the basis of some artificial gems of considerable beauty. Borax communicates its own fusible nature to other bodies, and hence is used as a flux. Flux is a general term made use of to denote any substance or mixture employed to assist the fusion of minerals. There is a considerable number of such bodies; the alkalies are those most generally used. Boracic acid is the only known compound of boron with oxygen. There has been no compound yet discovered of boron with either bromine or iodine, but it combines with chlorine, forming a gaseous acid, to which the name of *borochloric acid* has been given; and also with fluorine, forming

Fluoboric Acid, which exists in the gaseous state. It is colourless, has an exceedingly acid taste, and a smell similar to muriatic acid. It contains no water, but possesses a powerful affinity for that fluid, and is on that account sometimes used as a test of the presence of moisture in gases. Its specific gravity is 2·362; and it seems to consist of one atom of boron and three of fluorine. The combinations of boron with hydrogen, azote, and carbon, are still unknown.

SILICON.

Quartz, or *rock-crystal*, which constitutes so considerable a portion of the crust of the earth, consists essentially of a peculiar acid substance, called *silica* or *silicic acid.* This substance is a compound of oxygen with a base which has been entitled silicon. It is a powder of a deep brown colour, and very similar to boron in its appearance and in its relations to other matter. It stains the fingers, and adheres to every thing that comes in contact with it. It can be exposed to a very high temperature without being fused; after ignition, the specific gravity is about 1·837. It dissolves in a mixture of fluoric and nitric acids with great facility, although it is not acted upon by them singly. When mixed with dry carbonate of potash or soda, and heated far below redness, it burns vividly at the expense of the carbonic acid; carbonic oxide is disengaged, and the residue is tinged black by carbon being deposited. By this process silicon is converted into silica, which is a compound of one atom of silicon and one atom of oxygen. Silicon combines with chlorine, forming a *chloride of silicon.* This is a colourless volatile liquid, having a suffocating smell, and probably acid properties. With fluorine, silicon unites and forms

Fluosilicic Acid.—This is a gaseous substance, transparent, colourless, and having a smell like muriatic acid. It smokes when mixed with moist air, and it is rapidly absorbed by water. Its specific gravity is 3·6. It combines with carbon, but no other compounds are known.

SULPHUR.

Sulphur, or brimstone, is a substance whose appearance is too familiarly known to require a particular description. In many parts of the world it is found in a state of great purity. It occurs plentifully in volcanic countries, and is an abundant ingredient in various minerals. It is a non-conductor of electricity, and when rubbed, becomes highly electric. It has a specific gravity of 2·0332. When heated to 170°, it is volatilized, and the result is a fine powder called *flowers of sulphur.* It melts at 218°, but at 340° it becomes thick, and from 482° to its boiling point, about 750°, it gets thinner. When suddenly cooled, it remains soft, in which state it is used for taking impressions. It is extensively used in the arts; for instance, in the manufacture of gunpowder. With oxygen it combines in four proportions, forming four compounds, all of which possess acid properties.

Sulphurous Acid.—When sulphur is heated to 300° in the open air, it takes fire, and burns with a pale blue flame, at the same time emitting abundance of fumes of a suffocating nature, which are sulphurous acid. It is colourless, extinguishes flame, is not inflammable, converts vegetable blues to red, forms a class of salts called *Sulphites*, and has a specific gravity of 2·2222. This gas bleaches various textures, as those of silk, wool, and straw; the liquid acid bleaches sponge. Sulphurous acid is supposed to consist of equal bulks of oxygen and sulphur. Its proportions are one part of sulphur to two of oxygen.

Sulphuric Acid, or *Oil of Vitriol.*—This acid is made in great quantities for the use of bleachers, and other manufacturers, by burning sulphur in leaden chambers. At the same time, a quantity of nitric acid from the decomposition of saltpetre is admitted into the chamber. The sulphur is converted into sulphurous acid. Five atoms of this acid unite with one atom of nitric acid, and two atoms of water, and form a white solid salt, which falls to the bottom of the chamber into a quantity of water placed to receive it. As soon as it comes in contact with the water, a strong effervescence takes place: the nitric acid is decomposed, and converts the sulphurous into sulphuric acid, while at the same time a quantity of deutoxide of azote is disengaged. This gas, coming into contact with the oxygen of the air, is converted into nitric acid, which combines with an additional dose of sulphurous acid, and is decomposed as before. Thus the process goes on as long as sulphurous acid and oxygen gas exist in the leaden chamber.* Sulphuric acid thus obtained is a colourless liquid, possessing some viscidity; and when as much concentrated as possible, its specific gravity is 1·837. Sulphuric acid is one of the most powerfully corrosive bodies known to us. The following are some of its principal properties. When mixed with water, to which it has a very powerful attraction, a decrease of volume occurs, and a considerable degree of heat is generated. It freezes when sufficiently cooled, and the crystals are sometimes large, distinct, and hard. When exposed to the air, this acid discharges whitish gray vapours, which are sulphuric acid in a dry state. Acid of specific gravity 1·896, contains about one-tenth of water, and is so volatile that it boils at 120°. The constitution of sulphuric acid is, sulphur one part, and oxygen three parts. It forms a very numerous and important class of salts called *Sulphates.* The other two compounds of sulphur and oxygen, namely, the hyposulphurous and hyposulphuric acids, it is unnecessary to notice. Sulphur unites with chlorine in two proportions. It also combines with bromine, iodine, and fluorine, but its next most important combinations are those with hydrogen.

Sulphuretted Hydrogen, or Hydrosulphuric Acid.—This is a colourless gas, having a strong fœtid smell, something like rotten eggs, and a sweetish taste. It is a non-supporter of combustion, and, when breathed, destroys animal life. Its specific gravity is 1·1805. It is combustible, and burns with a bluish red flame. Water absorbs 3·66 times its bulk of this gas; and if it be passed through water tinged with a vegetable blue, it

* Thomson.

will change the colour to red. A few drops of nitric acid let fall into a vessel filled with sulphureted hydrogen, set fire to it. This gas blackens silver, and darkens the wood-work of rooms painted with white lead, from human exhalations containing a portion of it. Its atomic constituents are said to be one atom of sulphur and one atom of hydrogen. Double the quantity of sulphur to the same proportion of hydrogen forms what is called the *bisulphuret of hydrogen*. No compound of sulphur and azote is known, but with carbon there is more than one. With boron and silicon, sulphur forms sulphurets.

SILENIUM.

This is a substance nearly allied to sulphur in its nature, although it in some respects partakes also of the character of a metal. It melts at about 212°, and on cooling becomes solid, in which state it has a metallic lustre, and a deep brown colour. It is soft and easily reduced to powder, which is of a deep red. Its specific gravity is 4·3. It is a bad conductor of heat, a non-conductor of electricity, and is also non-electric. Like sulphur, it sublimes into flowers. It combines with oxygen in three proportions, forming *oxide of silenium*, a gaseous body; *selenous acid*, which has an acid and acrimonious taste; and, lastly, *selenic acid*, which resembles sulphuric acid in its consistence and in many of its properties. It is to be remarked, that the compounds of selenium and oxygen bear a strong analogy to some of those of oxygen with sulphur. Selenium combines also with sulphur, chlorine, and carbon.

PHOSPHORUS.

This well-known substance is commonly prepared from bones, which consist chiefly of the phosphate of lime. This salt is decomposed by sulphuric acid, and after going through a difficult process, the phosphorus is distilled into a receiver in the shape of melted drops. It is an amber-coloured and semi-transparent solid. Its specific gravity is 1·748. It is so very combustible that it takes fire in the air, emitting a white smoke having the smell of garlic, and appears luminous in the dark. At the temperature of 148°, it burns with a large resplendent flame, giving out a white smoke, which is—

Phosphoric Acid.—This substance can be obtained by other processes, in which case it exhibits itself as a transparent solid body like glass. It has no smell, but an exceedingly sour taste; it is not corrosive. Its atomic constituents are supposed to be two atoms of phosphorus to five atoms of oxygen. Phosphorus also produces another acid called *phosphorous acid*, containing a smaller proportional quantity of oxygen; and a third, called *hypophosphorous*, containing still less of the gas.

Phosphureted Hydrogen.—This gas is colourless, has a smell like garlic, and a very bitter taste; its specific gravity is 1·7708. It burns spontaneously. When mixed with oxygen, *rarefaction* causes them to explode, as *condensation* produces explosion in other gases—a very remarkable property of this substance. This gas may be detonated, also, with protoxide and deutoxide of azote. When mixed with chlorine gas, it burns with a greenish-yellow flame. It is composed of equal volumes of hydrogen gas and phosphorus vapour. There are other compounds formed of these two substances; and phosphorus combines also with chlorine, bromine, and iodine, in two proportions each. It likewise unites with fluorine, carbon, sulphur, and selenium.

ARSENIC.

The *White Arsenic* of commerce is a combination of arsenic and oxygen. When mixed with *black flux* (which is composed of cream of tartar and about half its weight of nitre, heated to redness in a covered crucible), and subjected to heat, it is reduced to the metallic state. It has a bluish-white colour, is soft, brittle and easily reduced to fine powder. Its specific gravity is 5·672. When moderately heated, it evaporates, combining with oxygen, and forming the arsenic of commerce, so well known for its destructiveness to animal life. With oxygen, arsenic forms two acids, the *arsenous* and *arsenic*. *Arsenous acid* is a white, brittle, compact substance, having a weak, acrid taste, which at last leaves an impression of sweetness. It is one of the most virulent poisons known. *Arsenic acid* is quite similar in its constitution to phosphoric acid. Arsenic combines with chlorine, bromine, iodine, fluorine, hydrogen, sulphur, phosphorus, and selenium.

ANTIMONY.

This is a metal which, when pure, possesses a silver-white colour. Its compounds are well known, being much used as a medicine. Its texture is fibrous, and it is easily reduced to powder by being pounded in a mortar. Its specific gravity is 6·4366. It melts when heated nearly to redness, and at a higher heat it is sublimated in white fumes. It combines with oxygen in three proportions, and forms three compounds, two of which possess acid properties. The other is an oxide, which constitutes the base of all the active medicinal preparations of this metal. With chlorine it combines in two proportions, forming two chlorides, which are analogous to two of the compounds formed with oxygen. It also combines with bromine, iodine, fluorine, sulphur, selenium, phosphorus, and arsenic. Antimony is extensively used in the arts, particularly in type-founding and stereotyping.

TELLURIUM.

This substance is a metal, having a silver-white colour, and considerable brilliancy. It has a laminated texture, is brittle, may easily be reduced to powder, and has a specific gravity of 6·1379. It fuses at a temperature rather higher than that which is necessary to melt lead. It combines with oxygen, and forms *oxide of tellurium*. This compound possesses at once acid and alkaline properties. When tellurium is heated before the blowpipe, it burns with a blue flame, emitting a white smoke, which is the oxide. Tellurium burns spontaneously in chlorine gas, and forms a *chloride of tellurium*. It also unites with iodine, hydrogen, and carbon. The other combinations of this metal are still unknown.

CHROMIUM.

This is a metal of a whitish colour and a brittle consistency. Its specific gravity is 5·9. It requires a very high degree of heat to melt it, and is only obtained pure in small grains. No acid readily dissolves it, except the fluoric. Chromium combines with two proportions of oxygen, forming two compounds, which have received the names of *green oxide* and *chromic acid*. Chromium unites with chlorine, sulphur, phosphorus, and probably fluorine. It is used in coloured glass making, and glass and porcelain painting. It is also used in enamelling, and as a rich, strong, and durable pigment. To glass and enamel it communicates a green colour, but to the painter it affords one of his prettiest yellows.

VANADIUM.

This is a metal which was only discovered a few years ago. It is white, resembling silver, brittle, a good conductor of electricity, and is easily dissolved in nitric acid and aqua regia. When heated rather under redness, it takes fire, burns with a dull flame, and is converted into a black-coloured oxide. It combines with oxygen in three proportions, forming, first, *black oxide* or protoxide, the *binoxide*, and *venadic acid*. It combines also with chlorine, sulphur, and phosphorus, but its other compounds are unknown.

URANIUM, MOLYBDENUM, TUNGSTEN, COLUMBIUM, AND TITANIUM.

These substances are all metals, but on account of their scarcity, or from the difficulty of reducing them to their metallic state from their ores, they are but imperfectly known, and have not been applied to any useful purpose. *Uranium* has an iron-gray colour, of considerable lustre, and, when heated to redness, takes fire. It produces a deep green protoxide, which gives a black colour to porcelain, and a fawn-coloured peroxide, which communicates to porcelain an orange colour. Its specific gravity is 9. *Molybdenum* has a silver-white colour, is brittle, and has a specific gravity of 8·636. *Tungsten* is of a grayish-white colour, is very hard and heavy, having a specific gravity of 17·4. *Columbium*, when burnished, assumes a yellowish-white colour and a metallic lustre. *Titanium* has a copper-red colour, and considerable brilliancy. It crystallizes in cubes, is hard enough to scratch rock-crystal, and has a specific gravity of 5·3. All these metals combine with oxygen and some of the other supporters; but the oxides and acids so formed are not deserving of particular mention.

ALKALINE BASES.

Potassium is the base of that well-known and very useful article potash. The properties of potassium were first determined by Sir H. Davy, to whom we are indebted for the discovery of the composition of the alkaline bodies. It is a white metal, like silver. At 30° it is hard and brittle, at 50° is soft and malleable, at 132½° melts, and at a low red heat evaporates. Its specific gravity at 60° is 0·865, being lighter than water. When exposed to the air, it rapidly absorbs oxygen, and forms potash. This latter body, as found in commerce, is always combined with water, which cannot be expelled by heat. When potassium is thrown on the surface of water, which it swims upon, it decomposes that fluid with such rapidity, that the metal takes fire, and burns with a red flame. Potassium combines with two proportions of oxygen; it also unites with chlorine, bromine, iodine, hydrogen, sulphur, and several other bodies.

Sodium is a metal so similar in most respects to the foregoing, as to stand in no need of particular description. It is the base of the alkali called soda, which is formed when the metal is brought into contact with water, or when it is heated in oxygen. It decomposes water, and in its relations to other bodies, bears a strong resemblance to potassium.

Lithium.—This metal is the base of the alkali called lithia, which is of a white colour, and has a taste fully as caustic as that of potash itself. It is of course an oxide of Lithium. Lithium likewise unites with chlorine, but its other combinations are unknown.

Barium.—This metal is the basis of barytes, an alkaline earth. It is of a white silvery appearance, absorbing oxygen rapidly by exposure to the air, thus forming barytes; and it also rapidly decomposes water. Barium combines also with sulphur and phosphorus, and forms compounds with chlorine, bromine, and iodine.

Strontium.—This metal is the base of strontia, an earth very similar to the foregoing. Strontium and barium resemble each other very much in most of their properties, and their combinations with oxygen have also a very strong resemblance. Strontium also unites with chlorine, phosphorus, and sulphur.

Calcium.—This metal is the base of the well-known and indispensable commodity lime. *Lime* has been known from the remotest ages, and appears always in combination with an acid, most commonly with the carbonic, constituting *limestone, marble, calcareous spar, chalk*, and frequently with sulphuric acid, constituting *gypsum, selenite*, and *sulphate of lime*. It combines also with various other acids. Calcium is white, like silver, solid, and much heavier than water. When heated in the open air, it burns brilliantly, and quick-lime is produced. Calcium unites with oxygen in two proportions, forming lime and peroxide of calcium. Pure lime has an acrid taste, and is sparingly soluble in water. It, however, readily absorbs water poured upon it, and swells, producing at the same time a great heat. The fact is, that the water becomes solidified, and of course gives out a great quantity of heat, which accounts for the rise of temperature. This process is called slacking lime. Lime combines with chlorine, and forms *chloride of lime*, a substance which has become an important article of commerce under the name of *bleaching powder*. It is a white powder, with a hot taste, having the power of destroying vegetable colours. Calcium combines with sulphur and phosphorus.

Magnesium.—This metal is the basis of magnesia, a substance universally known from its frequent employment in medicine. Magnesium is obtained in brown scales, which, when rubbed against agate, leave a metallic stain, of a leaden colour. It burns with a red light, and, by thus combining with oxygen, becomes *magnesia*. This is a soft, elastic, tasteless powder, not sensibly soluble in water, and slowly changing vegetable blues to green. Magnesium forms salts with chlorine, bromine, and iodine.

EARTHY BASES.

This family comprehends five substances, the oxides of which are white tasteless powders, distinguished by the name of *earths*.

Aluminum.—Alumina, which, when pure, is a fine light powder of brilliant whiteness, is an essential constituent in every kind of clay, and constitutes the base of *alum*, from which substance it may easily be obtained. It is a compound of oxygen and aluminum, consisting of two parts of the former to three of the latter. This metal, when burnished, assumes a metallic lustre resembling that of tin. It is not easily fused, but at a red heat it burns with great splendour, and is converted into alumina. This substance, so useful in the manufacture of every species of pottery, is the only compound known of oxygen with aluminum. Alumina possesses the remarkable property of shrinking into less bulk according to the intensity of the heat which is applied to it; hence, it was formerly employed as a kind of thermometer or rather pyrometer, for measuring very high degrees of temperature, in furnaces for instance. A gauge is used for measuring the amount of the contraction. Aluminum combines with chlorine, phosphorus, sulphur, and selenium.

Glucinum.—Glucina, which is the oxide of glucinum, exists to about fourteen per cent. in the beryl or emerald, from which it can be extracted. Glucinum is a dark-gray powder, which, when burnished, acquires the metallic lustre. It is very difficult of fusion. When heated in air or oxygen, it burns brilliantly, and affords the oxide glucina—the only compound which it forms with oxygen. Glucina, which consists of 100 metal and 44·44 oxygen, is a soft, tasteless, white powder, which, when wet, is somewhat plastic, like alumina. It neither dissolves in water nor melts in the fire. Its salts have a sweetish taste, like those of alumina; and both of these earths are in this respect opposed to magnesia, which with acids affords salts of a bitterish taste. Glucinum combines with chlorine, phosphorus, sulphur, selenium, iodine, and bromine.

Yttrium.—Yttria, which constitutes the oxide of this metal, is obtained from a scarce mineral called gadolinite Yttrium is procured from it in iron-gray scales. If heated in common air or oxygen, it burns brilliantly, forming the earth yttria; and as far as is known, this is the only compound formed by the union of oxygen and yttrium The latter substance combines with chlorine and the combustibles.

Cerium.—This metal exists in a reddish-coloured mineral found in Sweden, called *cerite.* Cerium is a dark-gray powder, having a metallic lustre, but its properties have not yet been properly determined. It, however, combines with oxygen, chlorine, carbon, sulphur, and phosphorus

Zirconium.—The earth called zirconia is a harsh whitish powder, destitute of taste or smell. The base zirconium is composed of brilliant scales, which are probably metallic, although the substance has not as yet evinced the metallic lustre. When heated in common air, it takes fire, and is converted into zirconia, which is perfectly white. This is the only compound which it forms with oxygen. It unites with chlorine, carbon, and sulphur.

Thorium.—This is a newly discovered metal, of a leaden-gray colour, heavy, and under the burnisher shows metallic lustre. If it be heated in open air, it burns with much splendour, and the resulting snow-white oxide is the earth called thorina. This is the only compound of thorium with oxygen, and the resulting substance is distinguished from the other earths by various properties. Thorium, when heated in vapour of sulphur, burns, and it also unites with chlorine and phosphorus.

DIFFICULTLY FUSIBLE BASES.

Iron.—This well-known substance is one of the seven metals with which the ancients were acquainted; these were gold, silver, copper, iron, tin, lead, and mercury. Iron is a metal of great utility, and it is fortunately found abundantly. Almost every mineral contains it. The ore from which the iron of Great Britain is obtained, is a *carbonate of iron.* Iron, after passing through a fiery ordeal, has a grayish colour, a metallic lustre, and, when burnished, a good deal of brilliancy. Its hardness exceeds that of most metals, and, when in the state of steel, it may be rendered harder than most bodies. Its specific gravity is 7·843 after hammering. It is attracted by the magnet, and may itself be converted into a permanent magnet. It is malleable at every temperature, very ductile, and very combustible, for we see a thin wire burn in the flame of a common candle. It burns brilliantly in oxygen, with which it combines in two proportions, forming oxides. It combines also with chlorine, bromine, iodine, boron, sulphur, selenium, phosphorus, arsenic, chromium, and antimony; but the most important of its combinations with simple substances are those with charcoal, which form the important compounds *cast-iron* and *steel.* Iron forms with the acids a numerous and valuable class of salts.

Manganese.—When this substance is pure, which is rarely the case, it is rather whiter than cast-iron, of a granular texture, and may be reduced to powder by pounding. Its specific gravity is 8·013. It is attracted by the magnet only at a very low temperature. It gradually absorbs oxygen from the atmosphere, and decomposes water, a property which it loses when alloyed with iron. It is much in use. Glass-makers use it for two purposes; first, for communicating a purple or violet colour, or for destroying all colour, and rendering the glass colourless. Manganese has a strong affinity for oxygen, with which it combines in seven proportions, forming acids and oxides. It unites also with chlorine, fluorine, carbon and sulphur.

Nickel.—This metal, when pure, has a white colour, like silver; is rather softer than iron; is malleable both hot and cold; is attracted by the magnet; and, like iron, can be converted into one. Its specific gravity is 8·380 after fusion. The preparations of this metal contain poisonous qualities. Nickel combines readily with oxygen, forming two oxides. It also unites with chlorine, carbon, sulphur, phosphorus, and arsenic.

Cobalt.—This metal has a gray colour with a shade of red, and is not brilliant. Its texture is granular; it is rather soft and brittle; its specific gravity is 8·7. It is used for giving a blue colour to glass and porcelain; the tint is beautiful, and hence the metal bears a high price. It unites with oxygen, and forms two oxides; these are the preparations of cobalt used in the arts. It also combines with chlorine, sulphur, selenium, and phosphorus.

EASILY FUSIBLE BASES.

Of the eight metals composing this family, all are malleable except bismuth, which is not very brittle. They melt at a comparatively low heat. A rod of zinc throws down these metals from their acid solutions in the metallic state.

Zinc.—This metal is of a bluish-white colour, and is composed of plates adhering together. It is a hard metal, being acted on by the file with difficulty; and, after fusion, its specific gravity is 6·896. It becomes malleable at 212°, and melts at 773°, or before it is quite red. When heated red-hot with access of air, it takes fire, burns with an exceedingly beautiful greenish or bluish-white flame, and is at the same time converted into the only oxide of zinc with which we are acquainted. It is of a snow-white colour, is tasteless, and insoluble in water. With copper, zinc forms that well-known and useful alloy called *brass.* Zinc combines with, and is set on fire by, chlorine; it enters into union with phosphorus, sulphur, selenium, iodine, and various metals.

Cadmium.—This metal, which is commonly associated with the ores of zinc, has a white colour with a shade of bluish-gray, and resembles tin in its appearance. It is very malleable, and has a specific gravity after fusion of 8·6040. It unites with oxygen, chlorine, and some other supporters, but the compounds are unimportant.

Lead.—This is one of the most abundant of all the metals, and one of the softest and most fusible. Lead has a bluish-white colour, and a good deal of lustre, but it soon tarnishes. Its specific gravity after fusion, which takes place at 600°, is 11·351. Lead is very malleable, it is also ductile, but its wire possesses little tenacity. By exposure to a very strong heat, it is volatilized, and at the heat of burning hydrogen, urged by oxygen, it burns with a bluish flame. While exposed to the atmosphere during fusion, it imbibes oxygen, and is converted into an oxide. There are three oxides of lead—the protoxide, which is known in commerce and the arts as a yellow paint, under the name *massicot,* or if it be semi-vitrified, *litharge;* the deutoxide is also a paint of a brilliant red colour, inclining to orange; it obtains the name of *minium,* or *red lead;* and the peroxide, which is of a deep puce *brown* colour. When heated with sulphur, spontaneous combustion takes place. Lead also combines with chlorine, bromine, iodine, sulphur, selenium, arsenic, &c. It is rendered hard by antimony, and the alloy, mixed with a little tin, constitutes the material from which printer's types are elaborated. The salts of lead are numerous and very important. *White lead* or *ceruse,* the only white used in all oil paintings, is made by subjecting thin plates of lead, rolled up spirally, to the fumes of vinegar. The lead soon becomes corroded, and assumes a white appearance and a brittle consistency. If this substance be dissolved in acetic acid or vinegar, it becomes *sugar of lead.* Lead is never found native: by far the most common state in which it occurs in nature, is mineralized by sulphur. The common name for sulphuret of lead is *galena.* It is abundant in all quarters of the globe.

Tin.—This metal resembles lead in many of its properties. It possesses a fine white colour, with a slight shade of blue, and has a good deal of brilliancy. Its specific gravity after fusion is 7·285. It is very malleable. Tin leaf, or *tinfoil,* as it is called, is about the one-thousandth part of an inch thick, and it might be made much thinner, if requisite. It is ductile, but of inferior tenacity. It is very flexible, and produces a remarkable crackling noise when bended. It melts at 442°, but a very violent heat is required before it will evaporate. It slowly tarnishes with the air, and, when intensely heated, oxygen being supplied, it burns with great brilliancy. Tin combines with oxygen in three proportions, forming the protoxide, which is *black*, the sesquioxide, which is *grayish*, and the peroxide, which is *yellow*. It also unites with chlorine, bromine, iodine, sulphur, selenium, phosphorus, and fluorine. It alloys with various metals. It is used in coating vessels, either in a pure state or alloyed. Pewter is composed of lead and tin; the latter rendering the former, a poisonous metal, quite innocuous. English tin is the best of all, and it is affirmed that it was exported from this island 2200 years ago.

Copper.—This metal, in point of general utility, ranks next to iron. It possesses a rose-red colour, and a great degree of brilliancy. Its specific gravity, after being rolled out into plates, is 8.953. It has great malleability, and very considerable ductility. A bar of cast copper, one quarter of an inch thick, requires 1192 lbs. to break it, whilst hammered copper requires nearly 1000 lbs. more to break it. It melts at 1996°; and if the heat be increased, it evaporates in fumes, which are visible. When rubbed, it emits a smell. When heated in a hydrogen flame urged by oxygen, it burns brilliantly, emitting a dazzling green light; a piece of copper in a coal fire tinges the blaze green. When exposed to air, it oxidates into a green carbonate of copper, slowly, and when in contact with moisture. With oxygen it combines in three proportions, forming three oxides, two of which occur native; the other is not a permanent compound. Copper combines also with chlorine, iodine, sulphur, phosphorus, arsenic, and tin. Its alloys with the latter metal are very important. From eight to twelve parts of tin, combined with one hundred parts of copper, composed *bronze*, and the *metal of cannons*. Four parts of copper and one of tin compose *bell-metal*. The alloy used for the mirrors of telescopes was employed by the ancients for the composition of their mirrors. It consists of about two parts of copper united to one part of tin.

Bismuth.—This metal has a reddish-white colour, and is composed of broad plates adhering to each other. It is one of the most fusible of the metals, and communicates its fusibility to other metals. Its specific gravity is 9.833. Although not very brittle, it is not malleable, unless when heated, nor can it be drawn into wire. A mixture of tin, lead, and bismuth, is so fusible, that it melts when thrown into boiling water. A toy of this kind is well known; it is a spoon, which, when immersed in a very hot liquid, immediately melts. Bismuth combines with oxygen, chlorine, bromine, iodine, sulphur, and selenium. What is called Newton's fusible metal, is a compound of eight parts by weight of bismuth, five of lead, and three of tin. It melts at 212°.

Mercury or *Quicksilver.*—This metal has a silver-white colour, possesses great brilliancy, and remains fluid at the common temperature of the atmosphere. Its specific gravity, at 60°, is 13·56846; at 30° below zero, when it assumes the solid form, it is 15·612°. When solid, it may be beaten out with a hammer, or cut with a knife. When heated to 656°, it boils; and when heated in the open air, it oxidizes. The oxides and chlorides of mercury afford an admirable proof of the truth of the atomic theory. It combines also with bromine, iodine, sulphur, selenium, and phosphorus. The compounds which mercury forms with the other metals are usually termed amalgams. This metal occurs in South America and in Spain, in great abundance. But the mine of Idria, in Carniola, an Austrian province, is perhaps the greatest in the world, and has been wrought for more than three centuries.

Silver.—This metal is of a fine white colour, with a slight shade of yellow. When polished, it displays a great deal of brilliancy and beauty. It is very malleable, and may be beaten out into leaves so thin as 1-000,000th of an inch. It is softer than copper, and harder than gold; but its tenacity is inferior to the former metal. When melted and cooled slowly, its specific gravity is 10·3946; when hammered and rolled it is a little higher. Its melting-point is 1830°; and if it be kept melted for a long time, it absorbs oxygen; but it possesses the very singular property of parting with the oxygen on solidifying. Gay Lussac, a great French chemist, says that the presence of a little copper deprives it of this property. Silver forms with oxygen only one well-known oxide. It also unites with chlorine, bromine, iodine, sulphur, selenium, phosphorus, and arsenic. There are numerous alloys of silver, but few of much consequence. One pound of standard silver is coined into sixty-six shillings; the mint price of silver, therefore, is 5s. 6d. per ounce at present. Silver is found in all parts of the world, sometimes alloyed with a variety of other metals and substances, and sometimes in the native state.

NOBLE METALS.

Some might include silver, and even mercury, in this list, but it is more common to say that the family comprehends six metals, which all require a violent heat to fuse them. The name noble metals has been given to the family, because it contains gold and platinum, the most esteemed of all the metals; and because the other four metals belonging to it are usually associated with native platinum. Their oxides are reducible to the metallic state by the application of heat alone.

Gold.—This is the most valuable of all the metals. It always occurs in nature in the metallic state, although seldom pure. It has a beautiful yellow colour, and considerable lustre, which it retains, not being liable to be tarnished by exposure to the air. It is rather softer than silver, and after fusion it has a specific gravity of 19·2. It is the most malleable of metals, and may be beaten out into leaves no thicker than 1-282,000th of an inch, and the gold leaf with which silver wire is covered is only 1-12th of that thickness. Its tenacity is considerable, but inferior to that of silver. It melts at 2016°. It is insoluble in sulphuric, nitric, and muriatic acid; but it readily dissolves in aqua regia, which is a compound of the two latter. It is difficult to oxidize gold, and still more to burn it; but both can be accomplished. Oxygen combines with gold in two proportions, possibly in three, forming oxides. Gold also unites with chlorine, bromine, iodine, sulphur, phosphorus, and arsenic. There are a number of alloys of gold; the standard gold coin of the realm is an alloy of twelve parts of gold to one of copper or silver, or sometimes both. Gold occurs in almost all parts of the world; but Africa and America supply the chief European consumption.

Platinum.—This metal is white, like silver; its specific gravity is 21·47, so that it is heavier than gold. Its hardness is intermediate between copper and iron. It is very ductile and malleable, though much less so than gold. Its tenacity is considerable. It will not melt in the heat of our most powerful furnaces, but it may be fused by the oxyhydrogen blowpipe. Its property of resisting high temperatures without fusion is a most important one; and on this account, as well as its property of resisting the action of most chemical agents, it has been employed in the formation of vessels which it is necessary to subject to an extraordinary degree of heat. Like gold, it resists the action of all the single acids, but dissolves in aqua regia. It combines with oxygen in probably four proportions, forming oxides, and unites also, with chlorine, bromine, iodine, silicon, sulphur, selenium, and phosphorus. There are numerous alloys of platinum, but they are not of much importance. There is a form of this metal which possesses extraordinary properties; it is called *spongy platinum*. It is prepared by dissolving platinum in a mixture of nitric and muriatic acids by heat; muriate of ammonia is added, when a precipitate falls, which must be filtered and dried. If a small quantity of this powder be heated by a candle, it will become incandescent, as if it took fire. It is, when cold, fit for use. If a jet of hydrogen, from a tube of a very slender bore, be directed on it from a little distance, the metal immediately becomes red-hot, and it sets fire to the hydrogen. This may be repeated a great number of times; but the sponge at last loses its power; the smaller the quantity, the sooner its power is lost.

Palladium, Rhodium, Iridium, and Osmium.—These four metals occur in the platinum of commerce. They are procurable in very small quantities; they have not been applied to any use of moment; they possess no very remarkable qualities, and therefore do not require to be minutely described. They all unite with oxygen and chlorine, and some of them with the other supporters.

Such is a brief sketch of the fifty-four simple substances, whose numerous combinations give rise to the infinite variety of objects which are found ready formed in the laboratory of nature, or have been discovered in that of the philosopher.

ORGANIZED STRUCTURES.

The substances constituting the subjects of this branch of chemistry are those of which vegetables and animals are composed. In vegetables, for example, we have sugar, starch, gums, resin, &c.; and in animal bodies, albumen, muscle, bone, &c.

Vegetables.—Notwithstanding the infinite diversity of form which vegetable substances assume, it has been proved that they are all composed of the same ultimate elements, and these are only *four* in number; namely, oxygen, hydrogen, carbon, and azote. These, again, by uniting amongst themselves, form the compounds which constitute the vegetable structure; and being the more immediate objects of sense, in the investigation of any organization, these are called their *proximate principles*. Existing ready formed in woods, roots, &c., we find a considerable number of proximate principles, in the form of acids, alkalies, sweet principles, bitter principles, oils, exudations; some poisonous, others wholesome; some spontaneously separating, others remaining obstinately combined. We shall give a brief outline of these.

Citric Acid.—This acid exists in the juice of lemons, and, when crystallized, one hundred grains consist of—water 23¾, and pure acid 76¼, which is a compound of 42·1 oxygen, 31·58 carbon, and 2·63 hydrogen. *Sorbic acid* is the sour principle of apples, sorbus berries, and other fruits. It consists of the same ingredients as the former. *Tartaric acid* is the sour principle of grapes; when a large quantity of them are left to ferment, the result, it is well known, is wine. On the side of the vessel containing this liquor, crystals of the acid combined with potash are formed, and these, when purified, are *cream of tartar*. Twelve parts in the 100 are water; and the remaining 88 consist of oxygen, 52·97; carbon, 32·39; and hydrogen, 2·64 parts. *Oxalic acid.*—The plant called sorrel is valued for its acidulous taste, which is conferred upon it by this acid. It has no hydrogen in its composition, consisting merely of oxygen and carbon. It is an active poison, and from resembling Epsom salts in appearance, many persons have fallen victims to its virulence. The antidote is powdered chalk. *Gallic acid* is obtained from nut-galls. Its most remarkable property is that of changing the colour of solutions containing iron to an intense blue-black colour, as in the case of common writing-ink. One hundred grains consist of 56·25 carbon, 37·5 oxygen, and 6·25 hydrogen. *Prussic* or *Hydrocyanic* acid, found in various fruits and flowers, is a most powerful poison. It is formed of hydrogen and cyanogen, a noxious inflammable gas. There are a number of other acids, which, being of little use, are not worth naming. Those just described exist ready formed in fruits, &c.; they are simple *educts*. But there are others formed by chemical changes produced on certain elements contained in vegetables, which afford the base of the acid; these are acid *products:* some are produced by the agency of fire, others by the action of nitric acid. Several acids, when distilled at a high temperature, undergo decomposition, and new acids are formed. Their names remain the same, with the word *pyro* as a prefix. Thus we have *pyrocitric acid*, &c. There are other acids generated by similar means, having simple names without any prefix.

Vegetable Alkalies.—It has been ascertained that alkalies, as well as acids, exist ready formed in plants as one of their constituent parts. Those which evince alkaline properties of a weak character are entitled *alkaloids*. The alkalies are *quinina* and *chinchonia*, which resemble each other, have a bitter taste, and neutralize acids. *Morphia*, which is obtained from opium, is a white crystalline powder; *strychnia*, one of the most powerful bitters and poisons, which has of late been much used in medicine; *brucia*, also a violent poison; *digitalia*, which is procured from the leaves of foxglove; *hyosciamna*, *atropia*, *veratria*, *emetina*, &c., which are derived from henbane, deadly nightshade, &c. Of the other proximate vegetable principles, the first deserving of notice is the woody fibre which constitutes the solid basis of all vegetable structures. It is called *lignin*, from *lignum*, wood and consists of 52 carbon, and 48 of oxygen and hydrogen, in the ratio which forms water. With lignin are associated various other bodies, such as *resins*, which are various and abundant. In the different species of the pine-tree, we discover that peculiar liquid resin called *turpentine*. From resins are obtained what are called *essential oils;* because, after the resin has been heated in a distilling apparatus, an odoriferous oil distils over, and leaves the resin hard, dark, and odourless. The *essence* of the substance is supposed to have passed away in the aëriform state, hence the name. From its speedily evaporating on being exposed to the air, it is also called *volatile oil*. The seeds of plants yield another oil, which not evaporating, is called *fixed oil*. To these two oils there are two substances bearing some analogy, *wax* and *camphor*. The former, when melted, possesses some of the properties of a fixed oil, and the latter seems to possess the properties of a concrete volatile oil, although it possesses qualities distinct from those of all other bodies. *Gum*, for instance gum-arabic, has the following properties: namely, transparency, tastelessness, perfect solubility in water, viscidity of the solution, capability of cementing fragments and of affording a varnish, and total insolubility in spirit of wine. There is a class of bodies called *gum resins*, whose properties are intermediate between those of gum and resin; and somewhat allied to resins, although essentially different in most of its properties, is the substance called *caoutchouc*, or *Indian rubber*. It is the exuded juice of a peculiar tree, and is composed of carbon and hydrogen. From wheaten flour a substance is obtained, called *gluten*, from its glutinous nature. There are two principles in this substance—the one is called *gliadin*, and the other *zimomin*. A substance called *vegetable albumen* seems to be the basis of all emulsive grains in place of starch, and greatly resembles it. *Starch* is a fine white sediment, precipitated from the white and brittle parts of vegetables, particularly the tuberose roots, and the seeds of the gramineous plants. One of the most remarkable properties of starch, or, as it is called, *fecula*, is that of being convertible into sugar by the action of diluted sulphuric acid. Starch is not only afforded from various grains, but from potatoes; and, as extracted from this vegetable, it is much in demand as an article of food. *Arrowroot*, which is obtained from the roots of a West India plant, is the same kind of substance.

Sugar.—Every one, we suppose, should know what sugar is; being in particular a sweetener of the kindly beverages tea and coffee. It is derived from many sources—from the sugar-cane, maple-tree, beet-root, and grapes. Nothing is easier than its formation from grapes: grape juice is to be saturated with chalk, clarified with white of eggs, or blood, and evaporated; after a few days it assumes the form of a crystalline mass. *Tannin.*—From oak bark, or nut-galls, a peculiar substance is obtained, called tannin—so named from being the material employed in tanning leather. It is inodorous, colourless, and possesses a rough, astringent, bitter taste.

THE ANIMAL COMPOUNDS.

The chief substances which enter into the composition of animal matter, are oxygen, hydrogen, azote, carbon, phosphorus, and lime. We also find some other kinds of matter, as certain acids and metals, but in quantity so small as not to affect the truth of the above statement, that the foregoing six ingredients constitute the great bulk of the animal fabric.

Bone consists of phosphate and carbonate of lime, and two other ingredients, *cartilage* and *gelatine*. The latter is the coagulating, or rather elastic, principle in all *animal jellies*. When bones are burned in a close vessel, they form *ivory black*. *Fibrin* is obtained from the vessels; when recently obtained, it is elastic; but when perfectly dry, it is somewhat horny and transparent. There is an important substance called *osmazome*, which communicates to soups and broths their peculiar taste and smell, and the greater the quantity present, the better is the soup. The *tendons*, *ligaments*, and *membranes*, are nearly allied to gelatine in their nature.

Of the fluids of the animal body, *blood*, one of the most important, is viscid, of a red colour, exhaling a vapour of a peculiar odour. When left at rest a few hours, its appearance is very much altered, having separated into two parts—one quite liquid, of a greenish whey-like colour, and called *serum;* the other an elastic firm jelly, of a crimson red colour and thick consistence, resembling a deposit, which is called the *crassamentum*, or *clot*.

If the clot of blood be repeatedly washed with cold water, it parts with its red colour to the water, becomes white, and a fibrous matter remains, which, when subjected to analysis, proves to be *fibrin*. Serum coagulates when heated to about 160°, nearly in the same manner as the white of an egg, but the colour is not pure white. If the serum thus coagulated be cut in slices, a fluid will exude, which is called the *serosity* of blood; it consists chiefly of water, holding a little altered albumen and a little common salt in solution. Serum is composed of water, albumen, soda, and some salts of soda. Clot is composed of fibrin, albumen, red colouring matter, a little iron, and carbonic acid.

During the conversion of arterial into venous blood, nitrogen, hydrogen, and other elements, are spent in the formation of new products, while the proximate principles of the blood remain, with an increased proportion of carbon. In this state it is exposed to the atmospheric air in the lungs, the oxygen of which abstracts its excess of carbon, and forms the carbonic acid expired; and this constitutes the conversion of venous into arterial blood.

Fatty substances, as lard and oils, are formed chiefly of carbon, with a little hydrogen and oxygen, one or both. *Albumen* is a substance very abundant in animal matter. It occurs nearly pure in the white of eggs. Of this substance in the coagulated state, along with gelatine are *horns*, *nails*, and *hoofs* composed. The *brain*, the thinking organ of man, consists of water 80, white fat 4·53, red fat 0·7, osmazome 1·12, albumen 7, phosphorus 1·5, sulphur and various salts 5·15 parts in the hundred.

[WORKS ON CHEMISTRY.

The numerous applications of chemistry to industrial and commercial purposes, have served to multiply books on the subject to an almost unlimited extent. Among the general treatises on chemistry are the well-known work of Turner, which is very extensively used in schools and colleges in this country; Kane's "*Elements of Chemistry*," edited by Draper, and recently published by the Harpers, esteemed one of the best and most complete; "*First Principles of Chemistry, with Questions, by Professor Renwick*," intended for beginners, and much used in schools; "*Conversations on Chemistry*," admirable for its familiar explanations, and formerly used exclusively for schools; and Liebig's "*Chemical Letters*," entertaining essays for the general reader. For reference, Dr. Ure's "*Dictionary of Arts, Manufactures, and Mines*," already referred to, and Brande's "*Encyclopædia of Science and Art*," (Harpers, New York,) are indispensable to the student who desires to be thoroughly versed in chemistry.

Of the larger works, adapted to those who have made some progress in the science, we may mention, and recommend to general notice: "*An Epitome of Chemistry*," by William Henry, which, from a very small volume, has grown to two large and closely printed octavos, illustrated with numerous plates. "*A System of Chemistry*," in 5 vols. 8vo., by Thomas Thomson, M. D. The object of the author of this work has been to facilitate the progress of the science, by collecting into one body the numerous facts which lay scattered through a multiplicity of writings, by blending with them the history of their gradual development, and by accompanying the whole with exact references to the original works in which the discoveries have been registered. "*A System of Chemistry*," by J. Murray, in 4 vols. 8vo., to which there is added a very valuable supplement containing a view of the recent discoveries in the science; also "*Elements of Chemistry*," by J. Murray, in 2 vols. 8vo., 3d edition, which contains a very able and luminous statement of the general doctrines of the science, and forms one of the best introductions to chemistry ever given to the public. "*Chemistry applied to the Arts*," by M. T. A. Chaptal, in 4 vols. 8vo.; a very useful and entertaining work. "*A Manual of Chemistry*," containing the principal facts of the science, arranged in the order in which they are discussed and illustrated in the lectures of the Royal Institution; a new edition, in 3 vols. 8vo., by W. T. Brande, is a very useful, practical introduction to the science. "*A Dictionary of Chemistry*," on the basis of Mr. Nicholson's, in which the principles of the science are investigated anew, and its applications to the phenomena of nature, medicine, mineralogy, agriculture, and manufactures, detailed, by Andrew Ure, M. D., professor of the Andersonian Institution, at Glasgow. "*Elements of Chemistry*," &c., by M. Lavoisier, translated ino English by Mr. Kerr. Notwithstanding the various improvements and important discoveries which have been made since the death of the illustrious author of these elements, his work will still afford much satisfaction to every person who makes this science his pursuit.—*Am. Ed.*]

CHEMISTRY APPLIED TO THE ARTS.

Chemistry, or that department of physical science which recognises the nature and composition of bodies, and the changes which they undergo, is now indispensable to the proper carrying on of almost every useful art. Agriculture, which may be considered the most important of all the arts, is radically dependent on chemistry; for, without a knowledge of that science, the husbandman remains ignorant of the nature of his soils, the action of the atmosphere and sun's light, or the properties of those materials which are required to enrich his exhausted fields. Baking, brewing, distilling, and, indeed, all the operations by which food is prepared from the condition in which it is furnished by nature, are all in general a series of chemical processes. So likewise is the manufacture of pottery-ware, porcelain, glass, paper, the operations of bleaching, dyeing, and calico printing, the preparation of soap, gunpowder, ink, salt, drugs, paints, perfumery, and various other articles daily required. The applications of chemistry to the arts are in reality so numerous, that, to do the subject justice, we should require to take in nearly the whole circle of manufacturing industry. To do so, however, is beyond our limited means, even were it desirable; and our object in the present sheet is to give a short account of the manner in which chemistry is practically applied in those processes of art which we have not elsewhere alluded to. The design in view is not to teach any one art, but to incite to a *general study of chemistry* among those classes of the people who are engaged in such branches of manufacture as involve an elementary change in substance. We commence with a brief description of the apparatus requisite to carry on practical experiments in the science.

THE CHEMIST'S LABORATORY.

A laboratory is a chemist's workshop. It is the place in which he performs his experiments, and requires to be airy and spacious, to have a command of water, to be provided with suitable tables and shelves, mortars, filters, and other apparatus. Correct weighing being indispensable to every chemical experiment, an exact and very delicate balance is an essential requisite. There should be at least two balances; one for weighing heavy matters, and another for very minute quantities. The last instrument should be sufficiently delicate to weigh from 600 to 1000 grains, and downwards, indicating, distinctly and certainly, differences of an exceedingly minute amount. As it is by carefully weighing substances, both before and after being experimented upon, that the exact constituent parts of bodies are determined, and the most important chemical truths ascertained, the balance and weights should be carefully examined at intervals, and their accuracy tested. Measures are necessary for ascertaining the bulk of liquids or gases, and two integers are sufficient, the pint and the cubic inch. Measures should be made of glass, and have a graduated scale marked on both sides. They are commonly of a cylindrical shape, like a phial bottle, and possess a small spout at the orifice. The graduations on these instruments are sometimes very minute, and indicate exceedingly small quantities of the bodies put into them. The measures should be verified by weighing into them successively portions of mercury and water. A cubic inch of the former, at a temperature of 62°, weighs 3425·35 grains, and the same quantity of the latter, at the same temperature, weighs 252·458 grains. Water answers well enough for estimation down to the cubic inch, but for the tenths and the hundredths of an inch, mercury is both more exact and more expeditious.

Furnaces, Blowpipes, Retorts, &c.—Heat is one of the most powerful and extensively useful agents employed by the chemist for ascertaining the properties of bodies, and the methods of its production become of great moment to him. One of the most convenient forms in which heat can be applied to any chemical operation, is that of placing a spirit-lamp, as in fig. 1, under a glass retort, fixed to a simple kind of stand. The lamp is trimmed with cotton wick, and fed by alcohol, which gives a pure flame, and the heat which it generates is very intense.

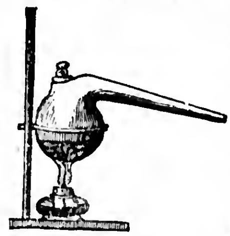


Fig. 1.

Operations on a more extended scale are carried on by furnaces. Dr. Black's portable furnace, which is much used, consists of a stout iron case, like a round stove in shape. Above is an aperture for an iron pot, to contain sand; and other openings may also be observed, for introducing tubes and different kinds of apparatus. The pipe carrying away the smoke must be prolonged or connected with a chimney. Furnaces upon a large scale are constructed in various ways of fire-brick, which resists an intense heat without fusion. This degree of heat can be produced either by propelling air upon the combustible matter by means of bellows, in which case the furnace is called a *blast-furnace*, or by forming long flues and raising a high chimney. The higher the chimney is raised, the more powerful is the draught. Upon the top of a furnace of this open kind, and also upon the flues, close by the fire, vessels containing sand, and hence called sand-baths, are placed. In these, bodies can be raised to a high degree of temperature. Charcoal is the substance most commonly used in furnaces. It produces an intense heat without smoke, but very soon consumes. Coke, or charred coal, produces a strong and lasting heat.

The blowpipe is an indispensable article in the laboratory of the practical chemist. The principle on which it operates, is that of a blast-furnace, on so minute a scale as to be capable of being held in the hand. The pipe, which is made of tin or brass, of a shape resembling that represented in fig. 2, is usually eight or ten inches in length. M is the mouth or upper end, through which the breath is impelled, and O is the small orifice, at the point of the side tube, from which the blast comes. By placing the upper end of the instrument in the mouth, and urging a stream of air upon the flame of a lamp or candle, an intense degree of heat is produced, which may be brought to bear upon any substance placed in a small spoon of pure gold or platina. If the body to be fused be not of such a nature as to sink into the pores of charcoal, that substance is commonly used. A great many important and beautiful experiments may be performed by this cheap and convenient instrument, but the proper way of blowing it requires practice. If the two gases, oxygen and hydrogen, be mixed together in the proportions which form water, and compressed to the amount of many atmospheres in a metallic box provided with a small tube, what is called an oxy-hydrogen blowpipe is formed. By this apparatus which is quite safe when properly constructed, an almost incredible degree of heat can be produced.

Fig. 2.

Crucibles are open vessels, which resist very high temperatures. They are made of various shapes, triangular or circular, and of different kinds of materials, but by far the greater number are formed of earthenware. To promote chemical action, what are called *fluxes* (which will be afterwards described) are employed. Now, it is important that the crucible be made of a substance which is not rendered more fusible by a flux. Wedgewood's crucibles are made of a close white ware; and although thin, they are not easily dissolved; and they retain fluxes at moderate temperatures longer than other crucibles. Those made of a mixture of coarse plumbago and clay are also excellent in these respects. But the most valuable in the laboratory are the Hessian and the Cornish crucibles. Charcoal and metallic ones are likewise used; those formed of platina being the most generally useful, although they are at first very expensive.

Retorts are vessels employed for many distillations, and most frequently for those which require a degree of heat higher than that of boiling water. This vessel is a species of bottle with a long neck, so bent that it makes with the globular belly of the retort an angle of about sixty degrees. One of a common form is represented in fig. 1. The most capacious part of the retort is called its belly, its upper part the arch or roof, and the bent part the neck. They are composed of different kinds of materials, those of glass being by far the most common. They answer for all operations conducted at temperatures less than that at which glass softens; and from their transparency, they admit of constant observation of the materials within: they are, besides, acted upon or injured by few substances, and may be easily cleaned. To the bent neck of the retort various tubes can be fitted, and the evaporated substance conducted into a refrigerator. For distillations or sublimations requiring high degrees of temperature, metallic and earthenware retorts are had recourse to.

A pneumatic trough is a vessel constructed so as to retain water, and large enough to admit of jars being filled in it. Shelves and supports are fixed in it beneath the surface of the water; on these, vessels may be firmly placed. If now a large open-mouthed glass jar be filled with water, inverted beneath the surface of the water in the trough, and put upon one of these stands, a tube from a retort or other distilling vessel, introduced into the inverted mouth of the jar, will convey the gaseous matter, which, displacing the water occupying the jar, can thus easily be collected in it. In this manner gases are obtained. If the jar be provided with a stopcock, they can easily be withdrawn into vessels fitted to retain them. Instead of water, mercury, which is fluid at ordinary temperatures, is used in experiments where water would absorb the gases, or where exceeding nicety is required.

A great variety of other apparatus besides those enumerated are either necessary or useful in a laboratory. Electrifying machines, galvanic batteries, air-pumps, syringes, tubes bent into various forms and of different sizes for fitting into the necks of retorts, &c., dishes for holding both solids and fluids, as well as other materials which it is unnecessary to name, are frequently required; but a very convenient small laboratory, where a vast number of interesting experiments can be performed, may be furnished at very little expense.

Portable Museums.—With a few glass retorts, jars, a spirit-lamp, blowpipe, trough, crucible, several slips of glass, and other simple apparatus, many highly interesting experiments may be performed in chemistry; and those requiring instructions in this practical method of studying the science, are recommended to peruse the small work of Dr. D. B. Reid, entitled "Rudiments of Chemistry," published in connection with *Chambers's Educational Course*. In connection with the course of experiments pointed out by Dr. Reid, there has been prepared by Mr. Macfarlane, druggist in Edinburgh, and Mr. Midgely, chemist, Strand, London, portable museums of different sizes and prices (from £1 to £10), which will be found extremely useful, because they contain a neat assortment of every elementary substance in separate phials, with some of the smaller parts of a chemical apparatus.

Tests, Fluxes, Lutes.—Acids and alkalies in a free state possess the power, even in very small quantities, of effecting certain general and regular changes in the tints of some vegetable colours. Accordingly, colours of this description are used for ascertaining the presence of these bodies when in excess or uncombined, and are called *tests*. Litmus and turmeric papers are most generally used. They are prepared by dipping unsized and bibulous paper in concentrated infusions of these substances. The litmus imparts a fine blue tinge to the paper, the turmeric a yellow one. In using these test-papers with a fluid suspected to contain free acid or alkali, or knowing that one of these substances is predominant, in order to ascertain which is so, all that is necessary is to moisten the papers with the liquid, and observe the change which is effected; if the fluid be acid, the blue colour of the litmus will immediately become red; if alkaline, the yellow colour of the turmeric will be changed to brown.

A *flux* is a substance made use of to assist the fusion and union of minerals or metals. It acts by protecting the substance from the air by dissolving impurities which would otherwise be infusible, and by conveying active agents, such as charcoal and reducing matter, into contact with the substance operated upon. Upon a large scale, limestone and fusible spar are used as fluxes. What is called crude flux, is a mixture of nitre and cream of tartar, put into the vessel along with the substance to be fused. White flux consists of the same ingredients, in equal quantities, but they are first deflagrated in an earthen crucible heated red-hot at the bottom. Black flux has the same constituents as the preceding, but the weight of the tartar is double that of the nitre.

Lutes are soft adhesive mixtures, principally earthy, used either for closing apertures existing at the junction of different pieces of apparatus, or for coating the exterior of vessels which have to be subjected to very high temperatures. The lutes employed for junctions pass into the nature of cements, which are substances used for uniting or joining together things of the same or different kinds, so as to form a whole. The best lute used for coating a vessel is made of Stourbridge clay. It is formed into a paste, which should be beaten until it becomes perfectly ductile and uniform, flattened into a cake, and then applied to the vessel which it is wished to coat. What is called *fat lute* is prepared by beating dried and finely pulverized clay (pipeclay or Cornish clay) with drying linseed oil, until the mixture be soft and ductile. Caustic lime, when mixed with various mineral and vegetable substances in solution, affords numerous cements and lutes, which become hard when dry, and are impervious to vapours. One of the best is that obtained by using white of egg diluted with its bulk of water. The fluids are to be beaten together until the mixture pours with perfect liquidity. There is then added a quantity of dry slaked lime in powder, until the mixture assumes the consistency of thin paste. A solution of glue or the serum of blood is sometimes substituted for the white of egg. White lead ground with oil also makes a very useful lute or cement. Soft cement consists of yellow wax (which alone is sometimes used as a cement) melted with its weight of turpentine, and a little Venetian red to give it a colour. When cold, it is hard like soap; but when pressed by the hand, the heat renders it pliant.

PROCESSES IN CONNECTION WITH THE ARTS.

Trituration.—As a general principle, the more minutely matter is divided, the more rapid will be the chemical action exerted between the particles. This division of matter is effected in various ways. First, by trituration, or the reduction of substances to a state of powder, which is a mechanical action not affecting the physical state of the body, and only relating to solids. In accomplishing this, the pestle and mortar are generally used. Externally, mortars are usually shaped like a flower-pot, the inside, at the bottom, being curved like the thick end of an egg. They are made of various materials, such as metal, porphyry, agate, and so on, according to the purposes to which they are applied. The pestle is generally of the same material as the mortar, and is a solid rod having a rounded bulb at one end for pulverizing the substance in the mortar. Trituration answers very well the purpose of promoting chemical action in a number of experiments, but by fusion and solution it is rendered more complete.

Fusion.—Bodies are said to be in a state of fusion, when, heat being applied to them, they assume the liquid form, a state in which all the particles of a substance move easily among themselves. When a solid body, such as a piece of sugar, is put into water, it is gradually dissolved; and when the lump of saccharine matter has disappeared, and become mixed with the water, and remains so, it is said to be held in solution by it. Heat greatly promotes the rapidity of solution; and glass vessels having a rounded bottom, such as a Florence flask, and placed upon a spirit-lamp, are very commonly employed. In processes connected with the subdivision of matter, when hot water is merely poured upon the substance, the process is called *infusion*; and when the substance is boiled, the result is called a *decoction*. There is a process of solution called *lixiviation*, which consists in the separation of a soluble body from an insoluble one by means of washing. Metals, as is well known, may be reduced to a liquid condition by melting or fusing them in a crucible over a sharp heat, or in a furnace. For the degree of heat at which most metals fuse, we refer to the previous article.

Vitrifaction is a peculiar kind of fusion, by which certain materials, when exposed to an intense heat, melt, and form that transparent substance called glass or crystal. The materials employed to form common glass are silica or sea-sand, and alkali, such as carbonate of potassa, and a metallic oxide. (See *Glass-making*, in article Miscellaneous Manufactures.) It is less generally understood that a kind of glass, soluble in water, may be made from silica and carbonate of potassa. "Mix intimately 200 grains of fine sand, and 600 of fine carbonate of potassa; fuse the mixture in a crucible capable of containing four times as much. Carbonic acid escapes, the silica and potassa combine and produce glass. Pour out the glass, which is commonly termed *silicated potassa*, on an iron plate, and dissolve it in water, the large quantity of alkali rendering it soluble in this fluid. The compound formed in this manner constitutes pure *silica soap*, having all the detergent properties of common soap; it is more active than ordinary soap, and leaves a harsh feeling upon the hand. Common silica soap is mixed with a considerable portion of common soap, and occasionally with sand."—*Reid's Rudiments of Chemistry.*

Desiccation.—The drying of substances, or desiccation, as it is usually called in scientific works, may be carried on without exhaustion by means of what are called desiccators or dryers. This is better effected in close vessels than in the open air, unless a current be taken advantage of. In these processes, sulphuric acid, chloride of calcium, carbonate of potash, quicklime, and similar absorbents, may be used. A basin of common quicklime, with a moist precipitate placed above it the whole being covered with a jar or receiver, will soon dry the precipitate.

Filtration consists in putting mixed substances into vessels which are porous enough to admit of the passage of one substance through them, but close enough to retain another. Unsized paper, cloth, flannel, tow, sponge, sand, pulverized glass, flints, porous stones, earthenware, and many other substances, are used on different occasions; but the first is almost exclusively used in a laboratory, a few of the others now and then being resorted to only on particular occasions. Evaporation is a process so simple as scarcely to require description; it is merely the assumption of the gaseous form by bodies either at ordinary temperatures, or when heat is applied to them. In this general characteristic it resembles distillation and sublimation, but it differs from these processes in this respect, that the substance evaporated is generally allowed to pass off uncollected by a refrigerator, not being that part of the mixture which is required.

Distillation and **Sublimation** mean nearly the same thing; both consist in the conversion of a body into vapour, its transference in that state, and consequent separation from other substances, and its ultimate condensation. The difference generally consists in the state assumed by the vapours when condensed; if the product be solid, the process is called sublimation; if liquid, distillation. The substance is exposed to such a temperature as causes it to assume the gaseous state, in which state it is conducted into a vessel containing water of a low temperature, where it is condensed into a fluid or solid state. A common still consists of a metal boiler for containing the substance to be distilled; a head terminating in a peak is adapted to it; the latter is made to fit into the commencement of a spiral tube, called a worm, fixed in a tub—the whole of this part of the apparatus being called the refrigerator. A worm wending through a tub of cold water is represented in fig. 3. The substance is raised into vapour in the still, and being condensed in the worm, runs out at its lower extremity. Distillations are usually effected in the laboratory by means of glass retorts and flasks; for substances, however, which require a greater degree of temperature to effect their distillation, metallic or earthenware retorts are employed. Bodies which are very volatile are distilled or sublimed in an alembic, which consists of a globular bottom and conical-shaped head, whence a nose or beak passes off in a downward direction into a receiver.

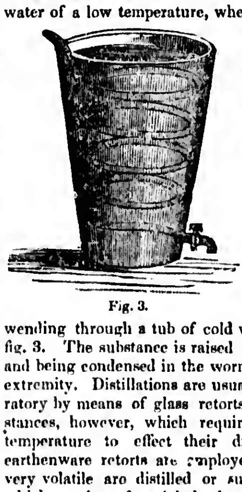

Fig. 3.

A great improvement in evaporation has recently been introduced into the refining of sugar, namely, its being boiled in vacuum pans. It is well known that there are few articles of vegetable production which are not injured by being boiled at a temperature of 212°; but to boil them at a lower temperature, it is necessary to remove the pressure of the atmosphere. This is now accomplished by using close copper vessels of a flattened spherical form. On the top is a raised part, from which a pipe proceeds, attached to an air-pump. At the side of this pipe another enters the vacuum pan, from which fresh syrup can be made to enter at pleasure by means of a stop-cock. At the bottom of the pan is another stop-cock, through which the boiled syrup can be taken out when sufficiently concentrated. The pan is heated by means of steam pipes which surround it; and the liquid boils at, or even below, 150°. The air-pump for removing the atmospheric pressure, in large sugar-refining establishments, is worked by a steam-engine. By this process the quality of any substance, particularly scents and medicinal extracts, from which liquid is to be evaporated, is greatly improved, and a saving effected by catching the vapour as it passes out.

FERMENTATION is the term which expresses the changes which animal and vegetable matter undergoes spontaneously when the principle of life is extinct; and is one of the means which nature adopts to destroy useless substances, and reduce them to their elementary properties. Chemists reckon up five distinct species of fermentation—namely, the saccharine fermentation, in which gum and starch are changed into sugar; the vinous fermentation, in which sugar is converted into alcohol; the acetous fermentation, in which alcohol and other substances are converted into vinegar; the mucilaginous fermentation, in which slime is produced instead of alcohol from sugar; and the putrid fermentation, which is the decomposition of animal and vegetable bodies.

The change of the substance of barley into sugar, or a material possessing the qualities of sugar, takes place on a large scale in making *malt*. Malt is dried barley, which has previously been caused to sprout and partially grow by steeping in water; in the course of germination or malting, a chemical union is effected between a portion of the water and the starch of the barley, and the saccharine matter is the result. A saccharine material can on similar principles be produced by boiling one part of starch in twelve parts of water, and allowing the compound to stand for a month or so. At the end of this time about one-half the quantity of starch is converted into sugar, a fifth into gum, and the remainder is found to be a starch paste somewhat altered.

Fermentation, whether of an infusion of malted grain or any other vegetable substance, is a necessary preliminary, in order to change the material into an alcoholic beverage. The actual process of fermentation, for example, in reference to wine, is as follows:—Ripe grape juice is put into a vessel, and allowed to stand for some time, exposed to the ordinary temperature of summer. At the end of a certain period, the liquor becomes muddy; an internal motion takes place, and sometimes the temperature is found to be elevated; air-bubbles rise to the surface, occasioning a bubbling noise when they break; and the bulk of the liquid being increased, it has a tendency to boil over. From this circumstance, the process is called fermentation, from the Latin word *fervere*, to boil. The bubbles created rise to the surface, involved in a viscid matter, the whole resembling froth, which, parting with the air, subsides to the bottom, and the liquor becomes tranquil and transparent. This viscid matter is well known under the name of *yeast* or *barm*, and it has the property of exciting fermentation in bodies not otherwise at the moment predisposed to it. The grape juice has now been entirely changed into an intoxicating liquor, the base of which is alcohol, and this process is termed *vinous fermentation*. A great quantity of carbonic acid is given out during this kind of fermentation, and the various chemical changes which take place have been thus briefly described:—Some of the carbon and some of the oxygen combine to form carbonic acid; while the remainder of the carbon, the remainder of the oxygen, and the whole of the hydrogen, combine to form alcohol: and we may totally neglect the decomposition of the yeast it amounting to almost nothing. Thus is this inert, solid, fixed, sweet matter, resolved by a new arrangement of its principles into substances which possess none of these properties, and one of which exert a control of so singular a nature over the animal economy.

Liquor, vinously fermented, is subject to a new series of phenomena. On being put aside for some time, a fresh commotion is observable, accompanied with the disengagement of a small quantity of gas; and floating filaments or shreds begin to thicken in the liquid, collecting into a gelatinous cake. This is indicative of another change. The vinous flavour and the alcoholic or intoxicating quality have disappeared, whilst the liquid has become at once sour and transparent. In short, the wine has become vinegar, called in Latin *acetum*; and the process is called the *acetous* fermentation. Let this vinegar be kept for a length of time, and another, and from the previous quality of the liquor, unexpected, change takes place. It becomes mantled with a green mould; the acidity and pungent acid smell disappear, and a fœtid odour becomes perceptible.

The most remarkable feature in the product of fermentation, is the intoxicating quality. This quality arises from the chemical change into *alcohol*, a concentrated spirit or essence, which, in one of its purest forms, obtained from distillation, is called spirit of wine. Alcohol exists to a lesser or greater extent in all fermented liquors, such as ale, porter, or beer; but it is more concentrated, or free of watery fluids, in the form of brandy, whisky, gin, rum, and similar intoxicating liquids. The amount of alcohol in stout porter is about 6 per cent., and in strong ale 8 per cent. The alcoholic part of such liquids stimulates but gives no actual nutrition; the only nutritive part is the undecomposed starch and gum not changed into saccharine material. Alcohol dissolves the greater number of acids, the volatile oils, the resins, tar, and extractive matter, and many of the soaps; while dissolving pure soda and potassa, it does not act on their carbonates. The composition of alcohol has been investigated by eminent chemists, and the result is, that of 100 parts there are 13·70 of hydrogen, 51·98 of carbon, and of oxygen 34·32. When alcohol is distilled along with certain acids, a peculiar compound is formed, called *ether*, an exceedingly volatile fluid, used in medicine.

While the various phenomena of fermentation, as above briefly noticed, are well understood by practical chemists, of the actual cause of the ferment little has yet been discovered. It is only known in a general sense, that fermentation is the rapid growth of microscopic vegetation (see article VEGETABLE PHYSIOLOGY), and that in the alteration of the liquor to vinegar, another wonder is performed—the change to microscopic animal life (see article ZOOLOGY, Radiati, class xix.) When this end has been accomplished, nature makes one other effort, by producing *putrefaction*, in which the material is resolved into invisible but odorous gases.

PRESERVING.—Animal and vegetable bodies may be saved from putrefaction, or the last process of dissolution, by putting them in a substance which will coagulate the albumen, that being the first part which suffers decomposition. This may be effected by steeping the bodies in alcohol, oil of turpentine, or other volatile oils. Pyroligneous acid, from containing a small proportion of creosote, has a strong power of preserving animal matter from decay. The earthy salts are also antiseptics; but common salt, saltpetre, and sal ammoniac, are the articles most generally used for the purpose of preservation. For the purpose of extinguishing the odour of offensive gases, arising from the decay of animal substances, none of the chemical products is so useful or so readily available as chloride of lime; by sprinkling a small quantity in an apartment containing an unwholesome putrefactive odour, the air is instantly deprived of its noxious properties, and is sweetened. Putrefaction goes on most rap'dly at a temperature of from 70° to 80°, but is altogether stopped at the freezing-point. Thus fish and flesh may be kept fresh for any length of time when embedded in ice. The abstraction of the oxygen gas will also preserve meat: the simplest manner in which this can be done is to enclose the meat in tin cases, leaving only a small hole in the closely soldered lid. The air may then be expelled by dipping the cases for a minute into steam; on lifting them out, a drop of solder, quickly placed on the hole, prevents the rush of air back into the vessel. On this principle of excluding the air, cases of preserved meats are now manufactured to a great extent for exportation. The proper drying of an animal substance is likewise an invariable preventive of putrescence. Animal matter should be dried at a temperature of from 120° to 140°; but even when dried, the addition of a little salt will be necessary. The salt is supposed to absorb the water from the albumen, and alcohol, sugar, &c., act in the same way.

Tanning.—Animal substances may be preserved for any length of time by being saturated with a vegetable extract, known in chemistry by the name of *tannin;* and this has given rise to the common process of tanning the skins of animals, and so making them into leather. Tannin exists in all vegetables possessing an astringent taste and quality, but is found in greatest perfection in oak-bark and nut-galls. It exists to a considerable extent in the fibrous substance of peat; bodies of men and of the lower animals, as also trunks of trees, impregnated with tannin, have been discovered in a perfect state of preservation in peat-bogs, after having lain for centuries. The principle upon which tannin acts, is the imbibing of an astringent and hardening quality by the mass of the substance, by which it is constitutionally altered. When the properties of tannin are present in a soil, the ground is said to have an antiseptic quality, and bodies buried in it are not apt to decay.

Kyanising.—All kinds of timber are liable to undergo a change of substance destructive of their useful properties, by the action of damp, seclusion from the atmosphere, and which may also be promoted by the subacid state of the wood—in common language, the timber rots. There is a peculiar kind of rottenness, called *dry-rot*, in which the decaying timber affords nourishment to the growth of fungi, which sometimes appear like a fibrous vegetation, but more ordinarily as toadstools. To avert the occurrence of dry-rot, which is a rapidly and insidiously spreading evil in the timbers of houses or ships, the only real method consists in steeping the timbers, previous to being used, in a solution of corrosive sublimate. This chemical substance may be prepared by dissolving red oxide of mercury in muriatic acid, and evaporating the solution to dryness; but there are other modes of procuring it from its basis of mercury.

The corrosive sublimate being procured, it is dissolved as a steep in water, in the proportion of one pound to five gallons of water. Such at least is the method of preparing steeps in tanks according to the plan suggested by Kyan, and for which a patent has been obtained. The process of *kyanising*, as this is termed, is very simple. The timber being immersed in the liquid, it becomes after a time saturated, and when taken out, the vegetative principle of dry-rot is completely destroyed. Only one day is required for each inch, in thickness, of boards and small timbers, commencing with two days for the first inch. On removal, the timbers require a few weeks to dry, in order to be seasoned for use. Being the subject of a patent, a license requires to be procured for liberty of steeping.

MEDICINAL PREPARATIONS.

Medicines are those drugs which in some form are applied to the alleviation or cure of bodily ailments; and they consist, for the greater part, of substances prepared from vegetable and mineral bases, by practical chemists. Retailers of medicines are usually spoken of as chemists but few are actually engaged in the elaborate processes, of drying, distilling, calcining, or chemically compounding the various drugs with which they supply their customers. The medicinal preparations of the ancients were principally vegetable, but being constantly liable to dry up and lose their virtues, no dependence could be placed on them, and they went greatly out of repute, till the method of obtaining extracts by distillation came into use. Since that was effected, the value of vegetable medicines has revived, though medical practice still relies chiefly on mineral products, which are generally more certain in their operation. A few medical preparations are from animal substances.

Some substances employed in the cure of disease, act mechanically, and others chemically, on the system; but by far the greater proportion of them act vitally. A medicine is said to act mechanically, when its effect on the body is the same as that which it exerts over inanimate matter. Demulcents, for instance, or remedies taken to remove the acrid effects of some other substance, operate simply by coating the stomach with a gummy fluid, an action which is entirely mechanical. The chemical operation of medicines may be thus explained. When an acid and an alkali are mixed in a glass of water, they unite together and form a third substance, a salt, having new properties altogether. The same chemical process takes place when sourness, or an acid, is neutralized in the stomach by soda, or any alkali. The vital action of medicines differs totally from the two former. In this case the substances are absorbed into the blood, and are conveyed by the vessels of the heart to the quarter whither their nature determines them. Diuretics, or medicines which stimulate the urinary organs, may form an example of vital action. From the stomach the diuretic is absorbed into the blood-vessels, and carried to the kidneys, stimulating them to the secretion of urine, though by what process of separation from the rest of the blood we know not. In these three divisions, mechanical, chemical, and vital agents, all the articles used in medical practice may be comprehended; and after this general explanation, we may examine the particular classes of each division, commencing with the most important, the vital agents. The class of purgatives (the strongest called *cathartics*, the weakest *laxatives*) is the best known and most commonly used of any description of medicines. They may be arranged under three heads: those of an oily or saccharine nature; those which are derived from vegetables, such as resins and extracts; and those formed by a combination of acids with earths, alkalies, and metals, termed neutral and metallic salts. The operation of all these three is of the character of an irritation upon the mucous or inner membrane of the bowels, though in their effects they differ considerably from each other. The first-mentioned seem simply to discharge the contents of the bowels; the second appear to increase the quantity of matter evacuated, by stimulating the mucous membrane, and increasing the natural flow of mucus; the third produce evacuations of a watery consistence. The principal purgatives of the oily or saccharine kind are, castor-oil, olive-oil (seldom used), manna, tamarinds, honey, and so forth; croton-oil, an essential oil (that is to say, procured by distillation, not by expression, as the castor-oil is), is scarcely to be included in the class of oils, as its great strength prevents its being used except in desperate cases. The medium dose of the castor-oil is one ounce, of the croton-oil a fraction of one drop. The former is imported in immense quantities into this country annually. It is one of the most useful and safe medicines of the purgative class. The rest mentioned are exceedingly mild in their operation, and are generally employed merely to palliate the bad flavour of some stronger drug. The second kind of purgatives includes aloes, scammony, jalap, colocynth, senna, and rhubarb. The general character of all these has been given above, though the rhubarb possesses one remarkable distinction from the others. It is supposed to act on the muscular membrane of the bowels, producing a natural discharge simply, without altering the character of the fæces. The principal neutral and metallic salts, which form the third order of purgatives, are sulphate of soda, Epsom salts (sulphate of magnesia), cream of tartar (super-tartarate of potash), phosphate of soda, and calomel (submuriate of mercury). The latter is the most universal in its application of all medicinal preparations. By proper regulation of the dose, and in conjunction with other drugs, it can be employed with benefit in almost every disease to which man is subject. But in proportion to its usefulness, so is its danger when misapplied. The dose should be very small at first, and cold ought always to be guarded against during its use. With respect to the others, little can be added to the general description already given, though it may be mentioned, that the pleasantest, though not the cheapest of all medicines, is the phosphate of soda, or *tasteless salts*.

Sudorifics, or medicines which increase the cutaneous perspiration, form another important class of vital remedies. Certain substances received through the stomach into the blood, excite through it the vessels of the skin to action, and increase the natural discharge. The mode in which this result is effected is not well known; all we know is, that, during the operation, the heart, and the blood-vessels which terminate on the surface of the skin, are roused to unusual action. Among the most active sudorifics may be enumerated warm drinks; the warm bath; the preparations of antimony, including James's powder; Dover's powder (compound ipecacuan powder); the preparations of ammonia; and all medicines generally which nauseate the stomach. Probably of all these, Dover's powder is the best. Sudorifics, in almost all cases, when early used, prevent the effects of colds, which, when neglected, prove so often fatal in their consequences.

Emetics are another class of remedies, acting through the blood, and of very general use. It may be supposed, that, as they are received into the stomach, and act directly and speedily upon it, there is no absorption into the blood necessary. Tobacco, for instance, taken into the stomach, excites vomiting; but it is from its reception into the circulation; because, if the tobacco be laid on the arm, the same effect will be produced. Some emetics, indeed, appear to act principally on the muscular covering of the stomach, exciting it to contraction, and thereby causing the expulsion of the contents. Most of them, however, simply produce nausea, which causes the inversion of the receptacle of the food. The most active emetics employed in medicine are tartar-emetic, ipecacuan root, chamomile flowers, mustard, and blue or white vitriol. The two first of these are most commonly used; the latter being the gentlest, and perhaps on that account the safest in ordinary cases.

Diuretics are those medicines which operate in promoting the flow of urine, by stimulating the action of the kidneys, the organs which secrete it. This class is very numerous, though the manner of their operation, like that of all the other vital agents, is not thoroughly understood. Those chiefly employed in practice are squills, foxglove, juniper-berries, potash, cream of tartar, acetate of ammonia, nitric ether, and Spanish flies. All these act powerfully on the urinary organs, those in highest repute being squills, foxglove, juniper, and cream of tartar. The first and the last of these are the most efficient, being more certain in their action than the others. Warm fomentations are useful accompaniments in all cases.

Expectorants are used to promote the expulsion from the lungs of those fluids which are secreted during colds, and lodge there, causing difficult breathing, and sometimes ending in injury of their structure. Thus, those remedies which promote expectoration are of great consequence to health, though often neglected. The principal medicines of this class are antimony, squills, ipecacuan, and gum-ammoniac. Syrup of squills is the preparation in greatest use.

Carminatives are those medicines which produce the discharge of flatulence from the alimentary canal. This malady is more annoying than dangerous, though it rises occasionally to a most painful height. The warm essential oils, such as caraway, anise, or peppermint, and some aromatic stimulants, as cinnamon and ginger, are the best carminatives.

All those classes of medicines which we have hitherto mentioned, are called evacuants, from the nature of their operation; and we may now describe another order of medicinal preparations, acting, like the former, through the medium of the circulation, but repressing instead of stimulating the powers of the system. There are only two distinct classes of medicines of this kind, narcotics and antispasmodics, though the first of these has sometimes been divided into two, narcotics and sedatives.

Narcotics are those substances which diminish the natural degree of action in the body, and tend to remove irritation or pain, inducing in general a state of repose. Before this quieting effect is produced, however, there is a primary excitement of short duration, which is well exemplified in the case of opium. Sedatives, viewed as a separate class, are believed to allay pain and promote sleep, without possessing any stimulating qualities; but it is far from being clear that we have any simple sedative medicines at all. Opium, which is almost exclusively employed as a sedative, is universally admitted to have a primary exciting quality. Unless where excessive pain is present, narcotics may be regarded as a class of medicines only to be used with great caution, and never free from danger. Opium and its preparations, lettuce extract, henbane, foxglove, hemlock, and tobacco, are some of the strongest narcotics. It is difficult to say which of these is the safest, when a sedative is required, though probably the preparation from lettuce has the slightest stimulating powers. Morphia, a drug procured from opium, is said to possess the sedative without the exciting effect.

Antispasmodics are used to remove spasms or convulsive contractions of the muscular fibre in the body, and are so similar in their action to the last-mentioned class, as scarcely to require a separate notice. Opium, camphor, ammonia, valerian, and assafœtida, with most of the narcotics, are the antispasmodics generally in use.

Stomachics.—There is another class of medicines, acting by absorption into the blood, or as vital agents, which cannot be ranked either amongst those which excite action, or those which repress it. These are stomachics and tonics; the former increasing the digestive powers of the stomach, the latter renovating the tone, or contractile energies, of the muscular fibre. They are slow in their operation, and augment the strength of the body without materially exciting its actions. As these two kinds of medicines are not very distinctly separable, it may be better to enumerate them together. Good nutriment is the most natural and best supporter of the bodily powers, but to effect this purpose, it is necessary that the function of digestion should be in a proper condition. Gentian root, quassia, chamomile, columba, and canella, assist powerfully this object. Amongst the tonics, Peruvian and cascarilla barks, the preparations of iron, the sulphuric and nitric acids, are in greatest repute.

With respect to the two kinds of medicinal agents, which act chemically and mechanically on the system, they are generally ranged into five classes—caustics, astringents, antiseptics, antacids, and demulcents.

Caustics are a class of substances employed to create artificial sores or ulcers, for the purpose of relieving some deep-seated malady. The operation of caustics is considered chemical, being the result of some attraction between the animal body and the substance employed. The same action takes place on the application of caustics to a portion of the dead subject. Where suppuration is going on in any internal part, they are exceedingly useful in creating a drain on the surface of the body. The principal caustics employed in medicine, are potass, blue vitriol, nitrate of silver, arsenic, and some preparations of mercury. The nitrate of silver, or lunar caustic, is the substance in most common use.

Astringents.—The action of this class of medicines is rather obscure. Their power appears to depend in a great measure on the presence of the principle called tannin, and they produce their effect by bringing into closer contact the particles of the body to which they are applied, without, in other respects, affecting its mechanical structure. They are believed to be often of service in restoring tone to the stomach, and it is evident that their astringency will be of great advantage when any laxity of the surface of that organ exists. All the vegetable astringents contain tannin, and those most generally employed are gall-nuts, catechu, kino, oak-bark, and logwood. A number of the acids, and some of the salts, those particularly in which the acid preponderates over its base, as in alum, which is a compound of vitriol and the earth alumina, possess astringent properties, although they contain no tannin. Some of the metallic salts, as superacetate of lead (sugar of lead), and sulphate of zinc (white vitriol), are ranked in this class. Cold is also a direct astringent, and is often employed in this character with great advantage in checking bleedings.

Antiseptics, though still ranked as a distinct class of medicines, are very little trusted to in the present day. They were great favourites with the ancients, and were supposed to possess the property of resisting putrefaction, or that tendency to mortification which sometimes appears towards the termination of fevers and other complaints. Peruvian bark is commonly believed to have antiseptic qualities, and, with the exception of alcohol and vinegar, is the only drug of this class worthy of notice.

Antacids.—The stomach of many individuals is liable to a continued conversion of their food, particularly vegetable food, into a species of acid, which produces the annoying feeling called heartburn. This acid may be neutralized by any of the earths or alkalies, and the process of relief is as purely chemical as if it were performed in a glass of water for experiment. The three alkalies, potass, soda, and ammonia, the alkaline earth magnesia, and carbonate of lime (chalk), are the most useful medicines of this description. The relief obtained from them is, as might be expected, merely temporary, since they do not prevent the generation of the acid anew.

Demulcents are a class of medicinal agents, the operation of which seems entirely mechanical. A poultice is applied externally to soften an inflamed or irritated part, and with exactly the same views are demulcents used to soothe any irritation of the alimentary canal. Solutions of gum, and syrups, with barley water, and other farinaceous drinks, are employed for this purpose. Iceland moss (lichen Islandicus), liquorice root, almonds, sugar, marshmallow, and others, are included in the class of demulcents.

These are all the classes of medicines that can be said to have a chemical or mechanical action on the stomach; and to complete this brief view of the principal articles used in medical practice, of the order in which they are arranged, and the nature of their action, some account may be given of rubefacients, as they are called, from reddening or inflaming the skin, and of blisters.

Counter-Irritants.—The extremities of the vessels which convey the blood from the heart over the body, are supposed, when they terminate on the skin, to divide into minute tubes, one kind of which carries the red globules, and another the colourless serum of the blood. When strong stimulants, such as mustard or Spanish flies, are applied to the skin, they are supposed to excite these minute vessels so powerfully, that those which contain serum become filled with red globules. This can only be produced during an extraordinary flow of blood to the part, and is the cause of the redness consequent on the application of mustard cataplasms or blisters. A blister is simply a rubefacient allowed to remain on the skin until a deeper layer of it becomes affected, and pus or serum exudes. Like caustics, blisters are exceedingly useful in substituting a superficial inflammatory action for one existing in some deeper and more dangerous seat, and they are therefore called counter-irritants. The principal substances employed in exciting cutaneous inflammation are Spanish flies, mustard, tartarized antimony, ammonia, turpentine, and a few other drugs of a stimulant nature. The Spanish flies are almost exclusively used in blistering, and mustard, as a rubefacient, is held in a similar degree of estimation. Latterly a new and improved method of employing Spanish flies, or cantharides, has been introduced into practice. It consists in applying an extract, which contains the essential powers of the material to the skin, by spreading it on paper. The blister so formed, which bears the name of *tela vesicatoria* (blistering tissue), produces a much more rapid effect than the common fly blister, and does not give the same pain to the patient.

The principal medicines employed at the present day for the alleviation or cure of disease, have been now enumerated in an arrangement which may show their several properties and modes of operation. Each university of importance has a list of medicinal preparations drawn up for the guidance of its own members and pupils and this list is termed its *Pharmacopeia:* with the enumeration is given a full account of the processes by which the various substances are prepared for use. This paper, which gives a pharmacopeia of a simple and popular kind, will have the effect, we humbly imagine, of dissipating some portion of that veil of mysticism which enveloped the art of medicine, and of showing what are the rational objects to be expected from the action of drugs upon the animal frame. In regard to the quantities of medicine to be employed as doses, that is a branch of the subject which we leave entirely in the hands of the medical practitioners properly empowered to administer them. It may here, however, be mentioned, as an interesting fact, that the action of the dose by no means corresponds with the quantity. The general rule seems to be, that when a too large dose of medicine is taken, nature makes an effort to expel it, and it is accordingly vomited without doing the intended good. A dose of a moderate size pushes its way to the bowels, which it irritates and causes to act with a degree of violence. A dose of a smaller size will act only on the stomach. The action of medicines in the stomach is by absorption into the system; and as the stomach is always less or more filled with fluid materials, it follows that the medicines received are diluted, and have a correspondingly weak or at least slow influence on the absorbents. Thus it has been found that a few drops of certain medicaments dropped on the tongue, by which they are absorbed at once into the system, have as powerful an effect as twenty times the quantity poured into the stomach.

Mineral Waters.—These waters, which are expelled from the earth as springs, form a distinct order of medicaments, prepared in the great laboratory of nature, and depending for their character on circumstances over which mankind have no control. Mineral waters are generally divided into four classes—acidulated or carbonated, saline, chalybeate or ferruginous (that is, containing iron), and sulphureous. Some are thermal hot others are cold. "The substances which have been found in mineral waters are extremely numerous, but those which most frequently occur are oxygen, nitrogen, carbon, and sulphur, in different combinations; lime, iron, magnesia, &c. The saline springs consist in general of salts of soda and lime, or of magnesia and lime, with carbonic acid and oxide of iron. The principal are those of Pyrmont, Seidlitz, Epsom, &c. The ferruginous waters have a decided styptic taste, and are turned black by an infusion of gall-nuts. The iron is sometimes in the state of an oxide, held in solution by carbonic acid, sometimes exists as a sulphate, and sometimes both as a sulphate and carbonate. The waters of Spa, Cheltenham, Tunbridge, Pittsburg, &c., are among them. The acidulous waters are characterized by an acid taste, and by the disengagement of fixed air. They contain five or six times their volume of carbonic acid gas; the salts which they contain are muriates and carbonates of lime and magnesia, carbonate and sulphate of iron, &c. The waters of Bath, Buxton, Bristol, Seltz, &c., are acidulous. The sulphureous waters are easily recognised by their disagreeable odour, and their property of tarnishing silver and copper. The springs at Saratoga and Ballston, Harrowgate, Moffat, Aix-la-Chapelle, and numerous others, are of this class."—*Conversations Lexicon.*

The thermal or hot springs most frequented in Europe are those of Bath, and in the grand-duchies of Nassau and Baden (there called *brunnens*). In the town of Baden-Baden, there is a saline spring, called the *Ursprung*, which gushes out at a temperature of 153½ degrees of our Fahrenheit thermometer, which is too hot to be either immediately drunk or bathed in. The quantity ejected by the spring is enormous. For two thousand years, which is as far back as any thing is known of the place, there have been thrown up, by the Ursprung alone, at the rate of three millions of cubic inches of water every twenty-four hours, and always, night and day, of exactly the same steaming heat and the same taste and composition. According to the analysis of Dr. Kœlruter, quoted by Granville, a pint of water, weighing 7392 grains, contains 23 3-20ths grains of solid matter, the principal ingredient of which is common sea-salt, there being not less than sixteen grains of that substance present. Next in importance are the sulphate, muriate, and carbonate of lime, which altogether amount to six and a half grains. The remainder consists of a small portion of magnesia and traces of iron, with about half a cubic inch of carbonic acid gas in addition.

Artificial mineral waters are now prepared of different kinds by chemists, for by analyzing these waters, their properties can be imitated. The article called *soda-water*, usually sold in bottles, is well known. Its chief ingredients are carbonate of soda and tartaric acid.

CHEMICAL ANALYSIS.

The art of analyzing the compounds of matter, or, in other words, of resolving them into the various elements of which they are framed, constitutes one of the most difficult yet important branches of chemical science. More particularly is it important in relation to numberless practical purposes of life. There are few trades which do not owe much of the success with which they are conducted, in an advanced state of society, to the light which chemistry has thrown on the nature of the substances employed in them, and the consequent improvements therein introduced. To the highest moral interest, even, of the social body, chemical analysis is of vital moment. It is the basis of medical jurisprudence. Without the knowledge of poisons possessed by the professors of that science, and their ability to separate by analysis the most minute portions of these from any compounds with which they may have been mixed, innocence might often perish under the erring severity of the laws, and guilt escape the penalty justly incurred.

The mode in which chemical analysis, so important in every respect, is conducted, may best be explained by individual examples; but a few general observations will not be out of place. As respects the apparatus necessary for the chemical analyst in his laboratory, notice has already been taken of it; and it is only necessary to add, that in performing analyses, the principal tests and preparations are also required. The latter articles amount in number to about sixty or seventy. They consist chiefly of the sulphuric, nitric, and hydrochloric acids; sulphur, phosphorus, iodine; the principal alkalies and earths, with their most important compounds; mercury, iron, lead, tin, cobalt, antimony, gold, silver, and a few other metals, pure or in a compound state; with a few of the vegetable acids, such as the tartaric, and oxalic. Tests and test-papers, most important matters in chemical experiments, are also to be procured. By boiling red cabbage, one blue solution of this character is obtained, which detects acids and alkalies, uncombined or in excess, the former turning the blue to a red, and latter to a green. Boiled litmus gives another solution, which acids redden; and turmeric in solution is changed from yellow nearly to red by alkalies. Slips of paper, soaked in these solutions, and then dried in the dark, require only to be touched by the dissolved alkali or acid, to show the change of colour at once. Iron, again, is instantly detected by infusion of galls. The presence of acids and alkalies, in almost every compound in nature, renders these tests of vast consequence in analytic chemistry.

In taking up any body of unknown composition for analysis, very minute quantities only, finely divided, and weighed, are used. The body is then, if possible dissolved, commonly in water, that the particles may be further separated as widely as possible, which is the most favourable condition for the action of other bodies upon it, and display of chemical affinities. It is possible that the body may be insoluble, or but partially soluble in water at a common temperature. In these cases, the processes of infusion, digestion, or decoction, will be tried by the analyst, heat adding powerfully to the solvent powers of water. Lixiviation and maceration are also resources of the chemist. Sometimes alcohol or other solvents must be employed, and at times several solvents require to be used in succession, each having the power to take up something insoluble in the others. Once dissolved, the body, or portions of it separately, can be treated with tests; and, happily, there is not one substance in nature which has not such affinities for one or more substances, in preference to all others, as readily to betray its own nature. The common results of adding one body as a test to another in solution, are either alteration of colour, precipitation, or gasefaction. In the first case, the two bodies may form a compound, soluble, but of new colour; in the second place, an insoluble substance may be thrown down to the bottom of the solution; and, in the third, a gas may be set free. All of these results may be combined in some cases. The experimenter may, moreover, vaporize and crystallyze: fusion and condensation are processes also at his command. When simple solution can be effected in no way, and at no temperature, the experimenter may then have recourse to other agents. Chemical action may be induced by pressure, by electricity, and sometimes by light.

These are the general ways and means by which the chemical analyst prosecutes his investigations. By way of particular example, let us take a case in the department of medical jurisprudence. Let us suppose a medical man called upon to examine a case of poisoning, where the only cause of death that can be suspected is the use of copper vessels when corroded by articles of food. The object, then, is to analyze the vegetable or animal fluids remaining on the stomach, or preserved otherwise, in order to detect the copper, if it exists. Being boiled, the fluid in question is treated or mixed with diluted acetic acid or vinegar, which dissolves out the copper from among the other matters present. Well aware that sulphur has so strong an affinity for copper as to unite with it whenever they meet favourably in solution, forming a compound of both, called a sulphuret of copper, Professor Christison then directs the introduction of sulphur, in the shape of sulphureted hydrogen gas, after the following preparations have first been made:—"The suspected mixture having been prepared by the addition of acetic acid, is to be subjected to filtration, and any matter left on the filter is to be washed, collected, and dried, the washings being, of course, added to the fluid which first passed through. The process here divides itself into two; for the oxide of copper may be left on the filter in the form of an insoluble salt, or it may have passed through in solution. But it may be observed in passing, that very few of the salts of copper are insoluble in diluted acetic acid, so that if copper is present at all in a suspected mixture, there are many chances in favour of its being found by the first branch of the analysis.

"*First branch.*—The solution is to be examined first, both because it is the more likely quarter in which to find the copper, and because the analysis is more easy than that of the solid matter. The solution, then, is to be treated in the usual way with a stream of sulphureted hydrogen, and immediately boiled to expel the excess of gas. If a brownish-black, or even pale-brown precipitate is then thrown down, there is a presumption in favour of the existence of copper: if there is no precipitate or brown colouration, there is no copper in the fluid. In order to ascertain precisely the nature of the precipitate, which is some metallic sulphuret, the superincumbent fluid, after ebullition and subsidence of the precipitate, is to be cautiously withdrawn, and its place supplied with water; and when the washing has been several times repeated in the same manner, the precipitate is to be transferred into a watch-glass, or, still better, into a white porcelain cup, and dried. It is next to be collected, and incinerated in a glass tube, to destroy any adhering vegetable or animal matter. The last step in this branch of the process is to convert the sulphuret into the sulphate by the action of a few drops of nitric acid, aided by a gentle heat; and then to add to an excess of ammonia, either without or with previous filtration, according to the degree of muddiness in the nitrous solution. If copper is present, the usual deep violet-blue tint will be struck.

"*Second branch.*—If copper is not detected in the filtered part of the suspected matter, it will be necessary to examine also what remained on the filter. This proceeding, which constitutes the second branch of the analysis, will be seldom required in ordinary medico-legal researches, being rendered necessary only by the possibility of the oxide of copper having, either originally or after mixture with the suspected matter, assumed the form of an inorganic salt, insoluble in water or acetic acid.

"The matter on the filter is first to be well dried, and then heated to redness in a crucible till it be completely charred. The copper which is thus reduced to the metallic state, is next to be treated with nitric acid, diluted with its weight of water, and aided in its action by gentle heat. A solution is then procured, which is to be removed by filtration, and tested with ammonia, and the other liquid tests." Ammonia, or hartshorn, has a strong affinity for copper, and when added to a saline solution of the latter, throws down a deep blue powder, called the ammoniuret of copper.

The analysis of mineral waters, where the nature and amount of the whole ingredients, and not of one only, form the subject of inquiry, is a task of very great difficulty. Generally, however, non-professional experimenters upon liquids of this description, are anxious merely to ascertain the existence or non-existence of certain ingredients, without entering into minute proportional quantities, or the like details. The report of a case where a clergyman, the Rev. W. Robertson, junior, of Inverkeithing, examined a mineral spring at Fordel, now lies before us, having been communicated to the *Philosophical Journal* of Professor Jameson. It may give a fair idea of the way of going to work under such circumstances.

A gas bubbled up through the spring, which Mr. Robertson first examined. The elementary as well as compound gases have properties and affinities as well marked as those of fluids or solids, and can be as readily detected. For example, the gas called carbonic acid, present so largely in nature, has such an affinity for lime, that, on contact, it is at once absorbed by lime-water, and renders that liquid turbid. By trials with a graduated glass tube, where the gas or air containing carbonic acid is brought into contact with lime-water, the loss of the acid gas by absorption may be measured, and the proportion of it present in the examined air at once determined. So with other gases, when tested in relation to their respective affinities. Having satisfied himself about the gases present in the spring of Fordel, Mr. Robertson then tried the following preliminary experiments to determine the substances contained:—"Even when recent, it did not perceptibly redden tincture of litmus, though the tint was compared with the colour of the tincture diluted to a similar extent.

"It did not affect the colour of Brazil wood or turmeric test-paper. With tincture of galls it gave a slight tinge of purple, and ultimately a scanty purplish-brown flocculent precipitate, showing the presence of iron, and by the purplish tinge, also, the presence of earthy or alkaline salts.

"The water, next day, gave no tinge with the tincture, showing the iron to be principally in the state of a carbonate.

"When the water was evaporated by a gentle heat, flocculi of oxide of iron were deposited.

"The water, upon being boiled, gave a considerable yellowish-white precipitate, indicating carbonates. This precipitate was soluble, with considerable effervescence, in nitric acid.

"The water decanted off from this precipitate gave no tinge with tincture of galls, but, on boiling it with a few drops of nitric acid, to peroxidise the iron which it might contain, the excess of acid being afterwards neutralized by ammonia, it gave unequivocal traces of iron, by a darkish tinge with the tincture. From this it was inferred that the iron in it was in the state of protoxide. A portion of this water, after being thus treated, also gave a red tinge, with sulpho-cyanate of potash.

"With ferro-cyanate of potash, and a drop of muriatic acid, the water, when recent, gave a whitish precipitate, becoming blue by exposure to the air, indicating iron in the state of protoxide.

"With lime-water, the recent water gave a copious flocculent precipitate, the lime uniting with the excess of the carbonic acid, and the whole of the carbonates falling down together. This precipitate was redissolved, on adding more of the mineral water, which showed a considerable excess of carbonic acid; and it was also soluble with effervescence in dilute acetic acid.

"With the bicarbonate of potash there was no precipitate, the whole being kept dissolved by the excess of carbonic acid.

"With ammonia, and also with potash, a flocculent white precipitate took place, partly owing to the abstraction of free carbonic acid. With the carbonates of potash, soda, and ammonia, there were similar precipitates, but more scanty; they were all soluble in a dilute acetic acid.

"With a solution of soap in alcohol, a great milkiness

"With acetate of lead, a considerable milkiness, and a precipitate insoluble in acetic acid.

"With oxalate of ammonia, a considerable precipitate, indicating lime.

"With carbonate of ammonia and phosphate of soda, an immediate milkiness, and a precipitate, after standing, indicating magnesia; the precipitate soluble in acetic acid. With carbonate of ammonia or phosphate of soda, separately, no milkiness, after standing for the same length of time.

"With muriate of baryta, a slight precipitate, insoluble in muriatic acid, indicating sulphuric acid.

"With nitrate of silver, a copious precipitate, white while secluded from the light, becoming rapidly purple on exposure to light, indicating muriatic acid.

"Two ounces of the water, evaporated to dryness, gave, with nitro-muriate of platinum, slight traces of potash.

"The water, very much concentrated by evaporation, gave, with starch and sulphuric acid, no trace of iodine.

"From the above indications, it was concluded that the water contained sulphuric, muriatic, and carbonic acids, together with protoxide of iron, lime, magnesia, and a little potash. The presence of alumina was inferred to be incompatible with that of the earthy carbonates, neither could any be subsequently detected." The determination of the quantities of each substance present was the next object with Mr. Robertson; but it is not necessary here to carry our notice of the subject beyond generalities.

The agricultural chemist proceeds in a similar way and with similar instruments. He has the advantage, generally, of knowing beforehand the probable character of the matters on which he operates, and the point is to determine in what proportions they exist in the particular soil under examination. Where a less exact analysis will suit the purposes of the agriculturist, the following simple plan of ascertaining the qualities of soils may be adopted. We quote, with some slight alterations, from Mr. Young's "Letters of Agricola."

"In the field to be examined, take earth a little below the surface, from four separate places, about a quarter of a pound from each. Mix them together, and again separate them into four quantities of a quarter of a pound each. Then take one quantity and expose it to the sun, or before the fire, till completely dry; and turn it over frequently, that it may be well mixed together. Being thus powdered, pass it through a fine sieve, which will allow all the particles of sand and gravel to escape, but which will hold back stones, small fibrous roots, and decayed wood. Weigh the two parts—the fine and the rough—separately, and take a note of each. The stones and other bulky materials are then to be examined apart from the roots and wood. If they are hard and rough to the touch, and scratch glass easily, they are silicious and flinty; if they are without much difficulty broken to pieces by the fingers, and can be scraped by a knife to powder, they are aluminous or clayey; or if, when put in a wine-glass, and common vinegar poured upon them, small air-bubbles ascend to the top of the liquid, they are calcareous. The finely divided matter which ran through the sieve, must next undergo the test of experiment. After being weighed, agitate the whole in water, till the earth be taken up from the bottom and mechanically suspended, adding water till this effect be produced. Allow the mass then to settle for two or three minutes, and in that time the sandy particles will sink to the bottom. Pour off the water, which will then contain the clay in suspension, and the insoluble earth arising from animal and vegetable decomposition. The sand should be first attended to, and if from inspection it be thought either silicious or calcareous in its nature, the requisite tests may be instantly applied. By this time the mixture in the poured-off water will leave deposited at the bottom of the vessel the clay and other earths, with the insoluble animal and vegetable matter. After pouring off the water, dry the sediment, and apply a strong heat by placing it on the bottom of a pot ignited to redness, and the animal and vegetable matter will fly off in aëriform products. The remainder lying in the bottom will be found to consist of clay, lime, or magnesia.

"To obtain accuracy, another quarter of a pound may be taken, and the whole process gone over a second, a third, or even a fourth time, so that the operator may rectify any blunders he had previously committed, and be satisfied as to the results of the experiment. He should provide himself with a pair of fine scales, and a set of weights divided at least into half and quarter ounces and drachms. Although vinegar will detect lime by effervescence, it does not dissolve it so effectually as the nitric or muriatic acids, small quantities of which may be obtained from the druggists at a small expense."

Having ascertained by these, or any other inquiries, what is the composition of the soil, a pretty accurate notion, other things considered, may be obtained respecting its capacity for productive husbandry. If it be necessary to enter on a course of improvement, the defect in composition may be remedied by the application of materials of an opposite quality—an excess of calcareous matter being counteracted by sand and clay, an excess of clay by the admixture of sand, or an excess of sand by the application of clay, peat, &c. An excellent soil for bearing wheat has been found to contain in 100 parts—carbonate of lime, 28; silica, 32; alumina, 29; and of animal and vegetable matter, with moisture, 11. Oxide of iron, to the extent of 3 or 4 in the 100 parts, is not unusual in good soils.

COMBUSTIBLES.

The class of combustibles in the manufacture of which a knowledge of chemistry is more particularly required, includes gunpowder, fulminating powders, the material of Congreve and sky rockets, bomb-shells, percussion-caps, rapidly igniting matches, and of fire-works generally. The term *Pyrotechny* (from *pur*, fire, and *techne*, art) has been applied to the art of making and compounding these substances. Of each of them we shall present a short account, with an explanation of the principles on which they fulminate and explode.

The leading ingredients in most explosive combustibles are charcoal, saltpetre or nitre, and sulphur. In making fireworks of a varied kind, however, numerous other substances are employed. The chief are chlorate of potass, fulminating silver, and mercury, preparations of steel, copper, and other metals, with various oils, spirits, and resins. Charcoal, as is mentioned in the preceding sheet, is simply wood reduced to a charred condition (pure carbon), by being burnt to a kind of blackened cinder in a vessel closed from the atmosphere. For making gunpowder, light woods, such as the willow and alder, are the best, and the pieces are stripped of their bark before being used. In preparing this kind of charcoal, it is important that the vapours be allowed freely to escape, otherwise its combustibility will be impaired. The preparation is usually effected by iron retorts over furnaces; and by a connecting tube the vapour escapes, and is condensed into a tarry acid, from which pyroligneous acid is afterwards distilled. After being thus prepared, the charcoal is ground to a fine powder. It has been properly charred if it burns without leaving any residuum.

Saltpetre, nitre, or nitrate of potass, is abundant in nature, but may also be compounded by the artificial union of its two ingredients, nitric acid and potass. It is procured largely from India, and also from Egypt, Spain, and other countries, where it is found on the surface of limestones, marls, and chalky strata, being spon aneously generated and reproduced there by some atmospheric influence not well understood. The slight silky tufts of the nitre are swept up with a broom, and are lixiviated, allowed to settle, evaporated, and crystallized. In this state it is exported; but the impurities which it contains require its subjection to successive solutions and crystallizations, ere it can be formed into gunpowder. The last process is that of fusion, in iron pots at a regulated heat. Nothing can surpass, in these respects, the nitre prepared in the government powder-works at Waltham Abbey. It is tested by adding to its solution in distilled water nitrate of silver, with which it occasions no perceptible opalescence.

Sulphur is procured in many volcanic countries, and the great emporium for it is Sicily. At the gunpowder works, it is purified for use either by distillation or by fusion. In the first instance, the pure part is distilled over, and, in the second, skimmed off, the impurities being left behind.

Gunpowder.—The three ingredients, charcoal, nitre, and sulphur, being duly prepared by trituration, and passed through fine sieves, they are ready to be mixed. There appears to be a great difference of opinion and practice in determining the relative proportions of the ingredients. The following is a scale of proportions in 100 parts, adopted by different gunpowder makers:—

	Nitre.	Charcoal.	Sulphur.
Royal mills at Waltham Abbey	75	15	10
French, for war	75	12·5	12·5
" for sportsmen	78	12	10
" for mining	65	15	20
Chaptal's proportions	77	14	9
Mr. Napier's ditto	80	15	5

The mingled ingredients are now carried to a mill, to be properly blended by the pressure of a revolving stone on edge; the stone is of a calcareous quality, and goes round on a bedstone of the same nature; no metal or sandstone is employed either about the machinery or the mill-house, in order to avoid the danger of sparks. "On this bedstone," says Dr. Ure, in his history of the manufacture, "the composition is spread, and moistened with as small a quantity of water as will, in conjunction with the weight of the revolving stones, bring it into a proper body of *cake*, but not of *paste*. The line of contact of the edge-stone is constantly preceded by a scraper, which goes round with the wheel, continually scraping up the cake, and turning it into the track of the stone. From fifty to sixty pounds are usually worked at once in each mill-wheel. When the cake has been thoroughly incorporated, it is sent to the corning-house, where a separate mill is employed to form the cake into grains or corns. Here it is first pressed into a hard firm mass, then broken into small lumps; after which the graining is executed, by placing these lumps in sieves, on each of which is laid a disk of lignum vitæ. The sieves are made of parchment skins, perforated with a multitude of round holes. Several such sieves are fixed in a frame, which by proper machinery has such a motion given to it as to make the lignum vitæ runner in each seive move round with considerable velocity, so as to break the lumps of the cake, and force the substance through the sieves, forming grains of several sizes. These granular particles are afterwards separated from the finer dust, by proper sieves and reels. The corned powder is next hardened, and the rougher edges taken off, by being revolved in a close reel or cask, turning rapidly on its axis. This vessel somewhat resembles a barrel-churn; it should be only half full at each operation, and has frequently square bars inside, parallel to its axis, to aid the polish by attrition. The gunpowder is now dried, which is done generally by a steam-heat, or by transmitting a body of air, slightly heated in another chamber, over canvas shelves covered with the damp gunpowder."

Rockets—Fireworks.—The common modern rockets, which are generally employed as signals or tokens of rejoicing, may be described as tubular cartridges of paper, pasteboard, wood, or metal, filled with combustible substances, which, on ignition, cause the cartridge to shoot rapidly through the air. The movement may be irregular, parabolic, or perpendicularly upwards, according as a small stick or guide is attached, or otherwise, to the cartridge, to direct its movements. The principle on which rockets rise in the air is simple, and may be explained here, once for all, as it applies to all varieties of flying fire-works. A vessel containing a fluid which tends to expand, will be motionless so long as the vessel is closed on all sides, because the pressure is then equal everywhere; but if an opening exist, the pressure will not be equal, and the vessel will then tend to move in the direction in which the pressure exists. If the opening be below, the tendency will be to rise; and if the expansive force be great enough, and the vessel sufficiently light, the vessel will obey the pressure and ascend. When the expansive force is exhausted, it will again descend, by the ordinary influence of gravitation. In the case of the rocket, the combustion, commencing below, creates the expansive gas, and the pressure forces the rocket upwards. Were there no opening, the pressure would be equal, and, if the force were sufficient, it would simply burst the rocket.

"The rockets which rise into the air with prodigious velocity," says Dr. Ure, "are among the most common but not least interesting fire-works." The cartridge or tube, commonly of pasteboard or pasted paper, must be very strongly formed, if large, and intended to ascend high. Inside of it is a second tube, called the *soul* or *fusee* of the rocket, the purpose of which is to leave a vacant space round the axis, that the volume of elastic gas which the ignition produces may act on a vacant space. On account of its somewhat conical form, hollow rods, adjustable to different branches or skewers, are used in packing the charge, the cartridge being sustained by a copper mould or cylinder at the time. The charge of sky-rockets varies according to the bore of the cartridge. Nitre 16, sulphur 4, and charcoal 7, are the contents and proportions of the charge when the bore is three-fourths of an inch; and the charcoal is merely increased a very little when the bore is enlarged. This is the common rocket, with the usual light of gunpowder. When a rocket with a *brilliant* light is wanted, 3 parts of fine steel-filings are added; and when the light called the *Chinese-fire* is desired, 3 parts of fine borings of cast-iron form the addition to the three ingredients first-mentioned. These are the common rockets; the sources of other kinds and colours of light will be noticed immediately.

The *garniture* of a rocket, as the crackers, showers of fire, stars, serpents, &c., are called, which are commonly attached to it, with what is termed the *pot*, are of course added before igniting the charge in the central tube or fusee. "The pot is a pasteboard tube, wider than the body of the rocket, and one-third of its length. After being strangled at the bottom like the mouth of a phial, it is attached to the end of the fusee by means of twine and paste. These are afterwards covered with paper. The garniture is introduced by the neck, and a paper plug is laid over it. The whole (for still greater strengthening) is enclosed within a tube of pasteboard terminating in a cone, which is firmly pasted to the pot. The quick-match is now finally inserted into the *soul* of the rocket, and a light rod or stick attached to the end of the whole, to keep it in a perpendicular ascent."

The beauty of the rocket depends much on the style of the garniture. These, whether stars or serpents, are charged fusees, stronger or weaker, formed into the shape wanted, and giving kinds of light modified by the ingredients. Stars which give golden showers are formed of nitre, 10; sulphur, 10; charcoal, 4; gunpowder, 16; lamp-black, 2. Petards are sealed cartridges, which burst in the air, and crackers are square boxes of pasteboard, hooped, and charged with gunpowder. But the finest accompaniment of the rocket is the Roman candle, which is a fusee so formed as to throw out in succession, as the combustion reaches them, very fine stars. These stars are small cylindrical masses of nitre, sulphur, and gunpowder, steeped in spirits and gum. The variety of rockets of course depends on the difference of size and garniture. This remark, however, must not be understood to apply to the Congreve rockets, which have a special character and purpose. The *Popular Encyclopedia* thus describes them:—"The Congreve rockets, first used in the attack of Boulogne, 1806, are of various dimensions, and are differently armed as they are intended for the field or for bombardment. Those of the first sort carry shells or case shot; the others are armed with a very combustible material, and are called *carcass rockets*. Their form is cylindrical, and they are composed of strong metallic cases. The sticks employed for regulating their flight are of different lengths, according to the size of the rocket. The carcass rockets are armed with strong iron conical heads, pierced with holes, and containing a substance as hard and solid as iron itself, which, when once inflamed, is inextinguishable, and scatters its burning particles in every direction. When this substance is consumed, the ball explodes like a grenade. The rocket is projected horizontally, and whizzes loudly as it flies through the air. The ammunition is divided into three classes—heavy, medium, and light; the heavy including all above forty-two pounds, the medium, those from forty-two to twenty-four pounds, and the light, from eighteen to six pounds inclusive." The Congreve rockets were used at Leipsic and Copenhagen, but experience has proved them to be much less efficacious than common artillery, and, besides, the secret of their manufacture is now known everywhere.

To return to artificial fire-works, made for amusement. We have only noticed the *flying*-rockets or fusees, but *fixed* fire-works, or those whose motion is confined to a spot, can be made of a much more splendid appearance. Jets, wheels, suns, trees, lances, spirals, revolving suns, double or Catharine wheels, (two suns in one axis, revolving opposite ways), and many other beautiful contrivances, have been at times exhibited, and chiefly by the two Ruggieris, renowned pyrotechnists. These individuals even displayed in public the spectacle of a luminous serpent chasing a butterfly round and round a large space, their motions being governed by unseen machinery. In all preparations of a pyrotechnic nature, nitre, sulphur, charcoal, and gunpowder, are the chief ingredients. By means of spirits, gums, resins, and oils, the quality and duration of the light is modified, and the principal articles of that description in use are alcohol, bitumen, camphor, wax, turpentine, lard, and the like. Again, the colour of the fire, on which so much of the splendour rests, is modified by employing other articles. Copper-filings and sal-ammoniac give a greenish tint to flame; zinc a fine blue; amber and very dry common salt a yellow; lamp-black produces a deep red with gunpowder, and a pink with nitre in excess; camphor gives a fine white; lycopodium gives a rose colour; and sulphate of strontia a beautiful purple light. Many other substances are at the command of the pyrotechnist, which produce beautiful variations of colour.

Instantaneous Matches.—These matches, commonly known as *Lucifers*, are nearly all made of one substance, the chlorate or oxy-muriate of potass. This substance may be made by passing chlorine gas through a solution of carbonate of potass, when the chlorate is formed and precipitated; or in a dry way, by mixing oxide of manganese, common salt, carbonate of potash, and vitriol, in a peculiar way. But it is superfluous to describe in a popular sketch a process which can be safely attempted by none but the qualified. The chlorate of potass is in white crystals. Dr. Ure's formula for making the matches is as follows:—Thirty parts of the chlorate, in fine powder, are to be mixed gently with a knife upon paper with ten parts of very fine sulphur, eight of sugar, five of powdered gum-arabic, and enough of powdered vermilion to give a rose tint to the whole. The chlorate, gum, sugar, and vermilion are then gently but well-mixed, after which as much water as will make a thin paste is added; and then the sulphur is thoroughly mixed with the whole. A great, improvement, however, has lately taken place in the use. The matches were dipped formerly in sulphuric acid; but by adding a little more of the chlorate and sulphur than is in Dr. Ure's recipe, they are lighted by friction on sand-paper or any rough substance, such as a stone floor. The convenience of matches is thus doubly heightened. No other fulminate has been so effectually used for matches as chlorate of potass. Neat, but comparatively dear and inefficient lamps have been made with spongy platinum, which kindles on receiving a stream of hydrogen.

Fulminating Powders.—There are a number of these explosive compounds known to chemists, of which the principal are fulminating gold, mercury, platinum, and silver; and one longer known than either, a mixture of nitre, sulphur, and potass. None of these have any practical importance, comparatively speaking, excepting the fulminate of mercury, which is used for *percussion-locks*. We believe that a report to the government of Great Britain in 1831, made by Dr. Ure, had the effect of introducing the improvement of percussion-locks into the public service. The formula which that report gives for the manufacture of the fulminate is as follows:—Dissolve 1000 parts of mercury in 1000 parts of nitric acid, and add the solution to 830 parts of alcohol, a large vessel being used. A gas rises, which must be allowed to escape, and at a distance from flame. When the effervescence ceases, the contents of the vessel are to be poured out on a large double paper filter in a glass funnel, and cold water thrown over it till the drainings no longer redden litmus paper. The powder adhering to the vessel is also to be placed on a filter, with a little water. The superfluous acid thus washed away, the powder of fulminate of mercury, adhering to the filter, is lifted away and opened out on plated copper or stoneware heated by steam. The powder, when dried, is in the form of small gray crystals, and is then to be packed in small parcels, and kept close from the air in bottles or boxes. Dr. Ure examines several other modes of making the fulminate, but points out defects in all; and his own, though not free from them, was the one adopted most generally, we believe. Two and a half pounds of the fulminate, when prepared for the purpose, will charge 40,000 percussion-caps, according to the calculation of French manufacturers. The preparation consists in grinding the fulminate upon marble with 30 per cent. of water, adding six parts of gunpowder for every ten of the fulminate. A dough is obtained, which, when dried in the air, is introduced in small fixed portions into the bottom of the percussion-caps. The guns on which these caps are placed have, it is well-known, no pans on the lock. In place of them a small open tube projects horizontally, on which another small tube stands perpendicularly. The cock is a hollow hammer, fitted to descend on the tube mentioned, though large enough also to grasp the percussion-cap—a thin cone, when placed on the tube. The fulminate was formerly placed dry in the bottom of the cap; but of late a most important improvement has taken place, in as far as an alloy of copper is made for the purpose, which contains the fulminate within itself, so that all chance of injury by wet, or danger from the mixture, is put entirely out of the reach of possibility.

Bomb-shells.—This species of explosive combustible possesses little interest, as regards its structure or manufacture. In their various shapes, shells are merely a modification of one arrangement—that of a circular case of metal, fitted to be discharged by cannon, and containing a central charge of gunpowder, with an extensive charge of substances fitted to spread and inflict injury on the explosion of the powder. The bombs also spread combustion where they alight. The experience of the late sieges of Antwerp by the French and Acre by the British, has shown that this species of warlike machine is calculated to rise into greater importance than it has hitherto done, rendering forts and cities untenable, when it is well used.

Explosion of Combustibles.—When gunpowder and similar combustibles are fired, they explode with a loud noise, and with an extraordinary degree of force. The explosive sound is caused by the rapid disengagement of air in the combustibles, and the shock of striking upon the volume of the external atmosphere. The explosion is, indeed, a chemical process, in which a tangible material suddenly vanishes into air, and is no more seen. The velocity of movement in the flame of ignited powder, as it rushes through the tube of a gun, is an immediate consequence of the sudden disengagement of the confined air, and is calculated to be at the rate of 7000 feet in a second, or little less than seventy miles per minute. A cannon-ball, however, though projected with this velocity, immediately encounters a retardation from the atmosphere as well as its own gravity, and does not generally proceed at a greater rate than 2400 feet per second, or little more than twenty-seven miles per minute. The degree of force with which it is impelled, of course, depends on the strength of the charge, or the quantity of elastic fluid to be expended.

SOAP AND CANDLE MAKING.

Both these arts depend on chemistry for the perfection to which they have been brought. That exceedingly useful article, soap, of which the ancients were entirely ignorant, is a compound of certain principles in oils, fats, or resin, with a salifiable base. If this base be potash or soda, the compound is used as a detergent in washing clothes. When an alkaline earth or oxide of a common metal, such as lead, which forms litharge, &c., is the base, the compound is insoluble in water. The insoluble compounds, however, are very little used, except in some few cases of surgery. Animal fat, grease, or tallow, as it is variously termed, is a compound of a solid substance called, in chemistry, *stearine*, and of an oil called *oleine*, the basis of which is carbon, with a little hydrogen and oxygen. On subjecting tallow to a hot ley of potash or soda, a chemical change takes place in the constituents, and we have the material named *margaric acid*, and a fluid, *oleic acid*, and together they enter into a saline combination with the alkali. The result, a soapy substance, is thus said to be a union of an alkaline margarate with oleate. Saponification also takes place with oils.

The commonest hard soap is that made chiefly from kelp and tallow. Kelp itself is a result of chemical action. It is made by reducing certain kinds of seaweed to ashes by burning; the result in soluble material is a crude alkali, consisting of sulphate of soda, soda in carbonate and sulphuret, and muriate of soda and potash. It was at one time manufactured in large quantities on the shores of the Western Isles of Scotland, but has latterly been disused, in consequence of the substitution of barilla, and soda-ash from the decomposition of sea-salt. Supposing kelp to be employed in making soap; to every ton of kelp, about one-sixth of new-slaked lime is added. The whole, after mixture, is put into a large tub called a cave, having a perforation at the bottom, shut with a wooden plug. Upon the materials water is very slowly poured. The liquid, after digestion, is suffered to run slowly off into a reservoir sunk in the ground. The first portion, or ley No. 1, is of course the strongest, and is reserved for the last operation in soap-boiling. Six days are required to make one boiling of soap, in which two tons or upwards of tallow may be employed. The leys 2 and 3, mixed, are used at the beginning, diluted with water, on account of the excess of sea-salt in the kelp. A quantity of ley, not well defined, is poured on the melted tallow, and the mixture is boiled, a workman agitating the materials to facilitate the combination. The fire being withdrawn, and the aqueous liquid having subsided, it is pumped off, and a new portion is thrown in. A second boil is given, and so on, in succession. Two or three boils are performed every twelve hours, for six days, constituting twelve or eighteen operations in the whole. Towards the last, the stronger ley is brought into play. Whenever the workman perceives the saponification perfect, the process is stopped, and the soap is lifted out and poured into the moulds.

The compounds of tallow or oils with potash, remain of a soft consistency, and form what are termed soft soaps, useful in scouring. We can only afford space for an account of the process of manufacturing one of the common kinds of soft soap, as lately practised by an eminent soap-boiler near Glasgow. Whale or cod oil, to the amount of 273 gallons, is put into a boiler along with four hundred weight of tallow and 252 gallons of potash ley. On heat being applied, the mixture froths up very much, but means are adopted to prevent it boiling over. There are then added at intervals fourteen measures of stronger ley, each measure holding twenty-one gallons. After suitable boiling without agitation, the soap is formed, amounting in all to one hundred firkins of sixty-four pounds each, from the above quantity of materials.

What are called toilet soaps are made from purified hogs' lard, with the addition of olive, almond, or palm oils. These, when prepared, are perfumed with various scents. The soap is cut into thin shavings with a plane, and melted in a pan placed within a hot water or steam bath. When melted, the colouring matter and perfume are added, which generally consist of vermilion, ochre, bergamot, musk, essence of orange-blossom, cinnamon, &c. Although the French excel in practical chemistry, they make very inferior soaps, either fine or common. The English, on the contrary, manufacture soaps of a superior quality; and so well is this known, that the greater number of English tourists on the continent take soap as a necessary with them.

Candles.—The process of making candles by simply melting tallow, and pouring it in a liquid state into moulds containing wicks, requires no particular notice. It is of the improved mode of making tallow-candles to resemble those of wax, and involving an intimate knowledge of chemistry, that we wish to speak.

Some years ago, M. Chevreul, a French chemist, undertook an investigation into the nature of fatty substances, which he found to be composed of what we now know them to be—two materials, *stearine* and *oleine*. He ascertained that the oil does not combine directly with the alkali, but that its two components are converted by it into two corresponding acids, the stearic and oleic, which then combine with the alkali, like the mineral acids. He found, indeed, the analogy perfect between them in every respect. They unite with all the bases, forming compounds which differ in the degree of their solubility: with potash, for instance, a very soluble compound is formed (soft soap); with soda, hard soap, which is dissolved with more difficulty; while its combination with lime gives rise to a perfectly insoluble compound. These facts have been most important to the soap-maker, in enabling him to reduce his art to scientific principles; they explain why a solution of soap may be used as a test for the purity of water; why rain water is preferred to that from the spring for washing; and why we add soda to hard water before using it with soap, for soda separates the lime which the hard water contains, and thus enables us to dissolve the soap without producing the curdy precipitate which destroys the cleansing properties of the soap.

M. Chevreul separated these acids from their compounds, and found them possessed of the following properties:—Oleid acid is a liquid, clear when pure, and closely resembling oil; stearic acid is solid, and resembles wax in so striking a manner as to be with difficulty distinguished from it. On finding he could manufacture it at a price much inferior to that at which wax is sold, he, in conjunction with M. Gay-Lussac, another distinguished chemist, took out a "brevet d'invention" for the preparation and sale of "chandelles steariques," from which they never derived any benefit, solely on account of the name, which, merely implying candles prepared from tallow, attracted no attention; whereas manufacturers, who took up the trade after the expiration of the patent, and who announced, with less regard to truth, their productions as "bougies," or wax candles, speedily made large fortunes. If the reader wishes to prepare and examine the artificial wax himself, it may be easily accomplished. Let him dissolve a little hard white soap in hot rain or distilled water, and to the clear solution, while hot, add some vinegar or other acid. The stearic being a weak acid, is easily separated from its combination with soda, as it exists in soap. Acetate of soda is formed, and the stearic acid rises to the top of the liquid as an oily substance, which, on cooling, solidifies into a cake of artificial wax, mixed with a certain portion of oleic and impurities, which render it softer than if this fluid had been expelled by pressure. A similar process is pursued on a large scale, but regard must be had for economy. The tallow is saponified, not by soda or potash, as in the preparation of soap, but by quick-lime. It is only necessary to boil the lime, tallow, and water, in a large vessel for some hours, when these ingredients are converted into a kind of hard soap. From this substance, stearate and oleate of lime, also the stearic and oleic acids, are separated by the addition of oil of vitriol. They are melted like tallow, run into cakes, and subjected to the powerful action of a hydraulic press, which separates all impurities, and leaves the stearic acid as pure and white as the finest bleached wax, which may be used immediately for the formation of candles. In France, besides plaiting the wicks, they are dipped in a solution of borax, and then dried. The borax fuses during the combustion, and forming a globule on the summit of the wick, assists by its weight to bring it out of the flame in contact with the atmosphere, and thus ensures perfect combustion, and obviates the necessity of snuffing.

It was found that the artificial wax generally crystallized in the moulds, a circumstance which prevents the formation of a solid candle. In England this difficulty was overcome in some cases by the addition of arsenic. The French, more scientific than we, had recourse to their knowledge of the laws of crystallization for the remedy. It is known that regular crystallization only takes place when the transition of the mass from a fluid to a solid state is so gradual as to allow time for its molecules to arrange themselves in those determinate forms called crystals: this condition was fulfilled in the cooling of the moulds and their contents, but by plunging them in cold water as soon as the melted stearic acid had been poured in, crystallization was prevented, and a perfectly solid candle procured. Stearic candles, which can with difficulty be distinguished from wax candles, are now manufactured on a large scale in England, and, from their comparative cheapness, are coming universally into use in the houses of the middle and higher classes of society. So much for the value of a knowledge of practical chemistry in one of the commonest of the useful arts.

COLOURS—DYEING.

There are, as is well known, two modes of imparting colours—dyeing and painting; the former applied to articles coloured by a liquid infusion, and the latter applied to the laying of a colouring substance on the surface. We *dye* cloth, and *paint* a house. The materials employed in dyeing are usually drugs, salts of some kind, or vegetable fluids; but in painting, the prepared colours are chiefly pigments. The preparation of dye-stuffs and pigments is one of the chief departments of practical chemistry.

According to the definitions of men of science, there is no such thing as material colour. The colour is not in the substance; it is only a result of the operation of rays of light on the peculiarly formed particles in the mass. It is stated that when the rays strike upon the surface of a body, they are decomposed into their elementary tints, and some substances reflecting one colour and some another, the impression is made on the eye accordingly. When the particles of the body do not reflect any of the rays, the body appears black; and when they reflect them all equally, it appears white. A piece of blue silk, for instance, absorbs six rays and reflects one, the blue, by which a blue appearance affects our eye. What is the precise constitution or figure of the particles in a substance which produces the phenomena of colours, has never been ascertained. It is certain, however, as we have just mentioned, that colouring less or more depends on the well-known principle of the refrangibility of light. (See Optics.) Both dyers and painters require to be more conversant with chemical than optical science; yet there are cases in which a knowledge of the laws of light are of importance. It is a well-known truth, that the common white ray of light can be refracted into three primitive colours—red, blue, and yellow—and that these can be recombined into the white ray. A dyer could not expect to dye white by employing an infusion of red, blue, and yellow drugs, but it is certain that the application of a little blue improves a white colour; and this is perfectly understood by paper-makers. Mixtures of Prussian blue and cochineal pink are likewise used to improve the whitening of silks. The colours resulting from a mixture of two primitive colours, as green from blue and yellow, are only a delusion of the eye. Both the component colours are present and distinct, but they are so blended that we cannot separate them by the naked sight. For instance, a gray hair, when seen by a microscope, is not actually gray, but a composition of small black points on a whitish ground.

Paints.—The colouring substances used as paints are partly artificial and partly natural productions. They are derived chiefly from the minerals by certain chemical processes; and even when animal or vegetable substances are used for colouring, they are always united with a mineral substance (an earth or an oxide), because by themselves they have no body, which they acquire only by a mixture with a mineral. In painting, the colours are ground to a great degree of fineness, and applied by means of some liquid with a brush or camel-hair pencil. Different fluids are employed for this purpose; and the difference and the material used, with the method of employing it, has given rise to the modes of painting in water-colours, oil-colours, in distemper, and in fresco (painting on damp plaster as an absorbent). Oil-paints are usually prepared with boiled linseed oil, which is drying in its nature; the colours employed all consist of metallic oxides, or salts, or of combinations of sulphur. Among the metallic oxides used as pigments are minium and masticot, from lead; the ochres, burnt sienna, umber, from iron; smalt, from cobalt. Among the salts, or saline metallic combinations, are white lead, cremnitz white, from lead; Prussian blue, from iron; verdigris, mineral green, Brunswick green, from copper. Metallic combinations containing sulphur are cinnabar, from quicksilver, and orpiment, from arsenic. The lake colours have tin or alum for their bases, and owe their tint to animal or vegetable colouring substances. Among these are the red or pinkish lakes prepared from cochineal, madder, and Brazil wood; the yellow, from fustic, &c.; the brown, from several other colouring barks; finally, indigo, which, however, is entirely vegetable. In staining porcelain and glass, the metallic colours which are not driven off by heat, and are not easily changeable, are used. Gold containing tin gives a purple, nickel green, cobalt blue, iron and manganese black, uranium yellow, chrome green. From the chromate of iron, or rather ferruginous oxide of chrome, one of the most beautiful yellow pigments is now prepared for the use of painters.

The material principally employed by respectable house painters to give consistency to their paints, is white-lead or ceruse. This substance is an oxide of lead saturated with carbonic acid. It is prepared by exposing thin plates of lead in a closed vessel to the vapours arising from hot vinegar. The vapours of the acetic acid become saturated with the metal, and change the latter into a whitish substance, which is scraped from time to time off the plates. The whitish substance is afterwards pulverized, and mixed with properly prepared oil. Much of the white-lead in common use is adulterated with whiting, that is, purified and ground chalk, which is much less durable, and may be easily washed off by an alkaline solution.

Oil or spirit of turpentine is also largely used by house-painters, chiefly for the purpose of imparting a drying quality, or of deadening the glitter of the paint. Turpentine is a fluid extract from certain kinds of fir trees, from which it exudes, and being distilled, the oil or spirit of turpentine is obtained; the residuum is resin. Turpentine is of a powerful acrid quality, and is now employed for certain purposes in medicine. All the varnishes used by painters are of the class of gums or resins, properly prepared, such as copal, mastic, sandarac, lac, gum-lac, dragon's blood, &c. All are extremely inflammable, and great caution is necessary both in their preparation and general use.

INKS, either for writing or printing, are as much the result of chemical operations as paints or dyes. Black ink is a decoction of partly vegetable and partly metallic substances, the basis of the latter being iron. The ingredients commonly used are Aleppo galls in powder, logwood, gum-arabic, and sulphate of iron, in certain proportions; but, latterly, the art of manufacturing the article has been greatly improved, chiefly with the view of giving great fluidity as well as colour. Printing-ink is quite a different substance, being a thick viscid body, resembling a black paint. Its ingredients are boiled linseed or nut oil and lampblack, in the proportion of two and a half ounces of black to sixteen ounces of oil. The preparation of the oil is one of the most dangerous processes in the arts, and great care is required to prevent conflagration of the oleaginous material. There are various qualities of ink to suit different kinds of work. The prime object of attainment in making printing-ink, is to give it a deep black colour, which will endure after exposure on the pages of a book. Unless very great trouble be taken in grinding and mingling the materials in exact proportions, the ink, on being used, will gradually become brown, by the spreading of the oil. The French printing-inks are much superior to those made in Britain.

Indian Ink.—This article is used in China for writing with a brush, and for painting upon the soft flexible paper of Chinese manufacture. It is ascertained, as well from experiment as from information, that the cakes of this ink are made of lampblack and size, or animal glue, with the addition of perfumes or other substances not essential to its quality as an ink. The fine soot from the flame of a lamp or candle, received by holding a plate over it, mixed with clean size from shreds of parchment or glove-leather not dyed, will make an ink equal to the imported.

DYEING.—A remarkable circumstance connected with dyeing, is the different degrees of facility with which animal and vegetable substances imbibe the colouring matters applied to them. Tissues composed of the former, as silk and wool, receive more brilliant colours than those composed of the latter, as cotton and linen. The cause of this difference has not hitherto been discovered.

Although in the most numerous class of cases it is easy to impart colour to various tissues, yet when these become exposed to moisture, the dye-stuff is removed. It has therefore been found necessary to employ certain chemical substances, which shall have the property of permanently fixing the colour upon the body which is dyed. These substances have obtained the name of *mordants* (from the Latin word *mordere*, to bite), because they were supposed at first, figuratively speaking, to bite the dye into the cloth. The same name has also been applied to those preparations which possess the property of altering the shade or of heightening the colour, as it is called. The latter, at the suggestion of Berthollet, are sometimes termed *alteronts*. The principal mordants are alumina, employed universally, we believe, in the form of a salt, as that of alum; the oxides of tin, employed like the former in the shape of salts, which are prepared by dissolving tin in muriatic acid. Silk and woollen dyers, however, employ nitric acid or aquafortis for forming the salts of tin which they use. The salts of lead and copper are likewise had recourse to as mordants; and the nut-gall, which contains two very peculiar vegetable substances, tannin and gallic acid, is not only employed as a mordant, but also as a powerful dye-stuff.

By varying the mordant, a great variety of shades may be derived from the same colouring matter. Indeed, the mordant itself, in many instances, supplies a colour. For example, in dyeing with cochineal, when the aluminous mordant is employed, the colour produced is crimson; but when oxide of iron is substituted for the alumina, a black colour is the result. The whole phenomena are accounted for on the principle of chemical affinity or attraction. The mordant employed should have an attraction both for the stuff to be dyed and the colouring matter, and act as it were like a third party in reconciling two inimicals. The way in which it is used must depend entirely upon the degree of affinity exerted between the stuff and the colouring matter. Where that is slight, the former should be saturated with the mordant before the latter is communicated. A knowledge of the nature and chemical affinities of the substances used is necessary, before mordants can be had recourse to as a medium of union in imparting colour to cloths or other stuffs which we wish to dye; for by an indiscriminate use of them, results the very opposite of those anticipated may take place.

Calico-Printing.—In impressing the representation of figures on calico goods, the object generally held in view is the fixing of mordants on the cloth, which is afterwards dyed in the usual way, those parts which have received the mordant only retaining the colour, the rest remaining white. In some cases the colour is removed from certain portions of cloth already dyed, so that they may either remain white, or receive some new colour afterwards. Sometimes it is applied to cloth before it is dyed blue, in order to prevent the indigo from being fixed on those parts to which it is applied, that they may remain white, or receive other colours afterwards. Substances possessed of this property are called resist-pastes. Lastly, it

is frequently employed to communicate mordants and colouring matter at once to cloth. The thickening of the mordants is of considerable importance towards the successful practice of the art. The application, or the bringing out of the colours, is an ingenious chemical process. Madder is the substance commonly used for red by the calico-printers, and the addition of sumach, fustic, or quercitron bark, will produce a variety of tints with the various mordants at one operation. "Suppose we wish to produce flowers or figures of any kind, containing red, purple, and black colours, we may apply the three mordants at once by the three-colour cylinder-machine, putting into the first trough acetate of alumina thickened; into the second acetate of iron; and into the third a mixture of the two; then drying in the air for a few days to fix the iron, dunging, and dyeing up in a bath of madder and sumach. If we wish to procure the finest madder reds and pinks, besides the purple and black, we must apply at first only the acetate of alumina of two densities, by two cylinders; dry, dung, and dye up in a madder bath. The mordants of iron liquor for the black, and of iron liquor mixed with aluminous for the purple, must be now grounded in by blocks, taking care to insert these mordants into their precise spots; the goods then being dryed with airing for several days, and next dunged, are dyed up in a bath of madder and sumach. They must be afterwards cleared by branning."
—*Ure's Dictionary of Arts.*

After the cloth is dyed, it is washed either with soda, potash, soap, or fresh water, according to the nature of the ingredients used in the dyeing process. Great care is necessary in this department; for if the washing liquor be too strong, the mordant may be injured. Cow-dung diffused through hot water, is applied to calico goods in a particular stage of the manufacture. This is done in order to dissolve and carry off from the cloth a portion of the thickening matter, and also to prevent any undissolved mordant or acetic acid from ... the blank parts of the piece. The dunging, ... called, is performed several times, generally ... the washings. The piece should be immersed, if possible, without folds, and to secure this it is made to pass through rollers. As soon as it comes out of the dung-bath, it is washed in the dash-wheel as in bleaching. The cloth is then finished by being passed through a calender, which greatly improves its appearance. The action of the solution of cow-dung in cleansing from impurities is both mechanical and chemical; as respects the chemical part of the operation, it will be understood when we mention, that cow-dung contains muriate of soda, sulphate of potash, sulphate of lime, carbonate of lime, and other matters useful in deterging.

Bleaching is the art by which various articles may be deprived of the colours which they naturally possess, and so rendered white. Formerly, it was the custom to submit textile fabrics in a moist condition to the free action of the atmosphere and sun's light; but this process of bleaching was not only imperfect but tedious, and the substitution of a chemical effect, as suggested by the celebrated chemist Berthollet (1787), was a great improvement, such as the state of manufacturing industry required. Berthollet's plan consisted in employing chlorine, which possesses a wonderful power of removing vegetable colours. The bleaching-powder, or chloride of lime, as it is usually called, is manufactured by exposing slaked lime to the action of chlorine gas, till as much of the latter is absorbed as the lime is capable of combining with under these circumstances. The chlorine in the bleaching powder, which is not applied till after sundry preparatory washings of the cloth, acts upon vegetable substances by dissolving their hydrogen, which is the colouring agent; the air would have the same effect, but would require a much longer time than can be allowed. The cloth is left in a cold solution of the bleaching-powder for about six hours, and is then taken out and washed with water. The next part of the process is called *souring*, which is immersing the cloth in a solution of sulphuric acid, so diluted that it does not injure the texture of the goods, whilst it improves their colour. The sulphuric acid dissolves and removes the oxide of iron with which the cloth is always contaminated; it also removes the lime which may have attached itself to the cloth during its previous treatment with that substance. It is again washed, boiled in an alkaline ley, and once more carefully washed in cold water. Another solution of bleaching-powder, two-thirds the strength of the former, is then prepared, in which the cloth is immersed, and left for five or six hours; it finally undergoes another process of souring, by which means it is rendered perfectly white. The acid is carefully removed by washing; and after each piece of cloth has been stretched to its full length, it undergoes a process of mangling, by being passed successively between cylinders forced towards each other by levers, to which a considerable weight is attached. The cloth being thus stretched, smoothed, and wound upon a roller, is rendered fit for *starching*. The starch is that of flour, deprived of its gluten by remaining for twenty-four hours in water, and then passed through a sieve, which retains the bran, and allows the starch to pass. A little indigo is mixed with it, and sometimes porcelain clay. The starch is applied in the state of a pretty thick paste whilst the cloth is passing between a pair of rollers. The goods are then dried and passed through a calender for the purpose of giving them a gloss and texture.

Such is the process of bleaching as practised in the large bleaching establishments on the common class of goods. The number of processes which the cloth undergoes amounts to about twenty-five, but some of the earlier ones are occasionally omitted. The expense of bleaching and finishing a yard of cotton cloth is about one halfpenny, and the time required is trifling. A bleacher in Lancashire, we are told, received fourteen hundred pieces of gray muslin on a Tuesday, which on the Thursday following were returned bleached to the manufacturers, at the distance of sixteen miles; and on the same day they were packed up and sent to a foreign market.

CONDIMENTS.

Sugar—Salt.—Two of the most important condiments in domestic use are, as is well known, sugar and salt; both of which substances are the crystallization of liquids loaded with their respective properties; each is produced by an evaporation of the watery particles, leaving the solid crystals behind. Thus, sugar is a crystallization of the juice of the sugar-cane, beet-root, or other vegetables containing saccharine matter; the residuum or uncrystallizable material being that viscid and sweet fluid called *treacle*.

Salt, called by the chemists the muriate of soda, or chloride of sodium, is found to exist in a natural state in various quarters of the globe, among others, in the county of Cheshire in England, where it is dug from a mine, and purified by being mixed with water and subjected to evaporation. The principal source of salt, however, is the water of the ocean, which is boiled for a certain length of time, to drive off the watery particles. Sea-water differs in strength; that which contains the largest quantity of salt being in the middle of the ocean, far from the mouths of rivers. From 38 to 43 per cent. is the quantity commonly found in the seas round our coasts.

The method of making salt is simple; but from the length of time required in boiling, it is not economically performed unless near mines from which coal can be cheaply procured. The plan pursued is to erect a rever voir near the sea, into which at high water supplies are taken by means of a pipe extending a good way down the beach. The pipe is generally placed near the low-water mark, in order to get the water from a point as far from the surface as possible, so that it may be the more impregnated with salt, and require less boiling. The pans are built on a range on both sides of the reservoir, from which the water is pumped into them after the impurities have settled. The pans are shallow vessels, made of sheet iron, about twenty feet long and twelve broad, with a furnace below. These are contained in a small low-roofed house, the covering of which is of deals, with an opening at the meeting of the roof and the wall, to allow the vapour to escape. When the water is boiling, a little bullock's blood is put into the pan, which brings the impurities to the surface and allows of their being skimmed off. As the water boils down, more is pumped in; and this process is repeated before the salt is first drawn. From a pan of 1300 gallons fifteen or twenty bushels, of fifty-six pounds each, are obtained in this manner, the process requiring about twenty-four hours. The salt is at first very light and floury in proportion to its bulk, and in this state is most appreciated. A still finer article, resolving into large crystals, is made with a low fire, and when a longer time is allowed in the evaporation. For use at table, the salt is refined, and usually run into large lumps.

The water which remains after the salt is crystallized, called the *mother-water*, contains a considerable quantity of the chloride of magnesium or bittern, chloride of sodium, and sulphate of magnesia. If the mother-water is exposed in tanks during winter, it will afford three successive crystalline deposits, the last of which is sulphate of soda nearly in a pure state. The chloride of magnesium deteriorates the salt very much, but may be removed by the following simple expedient, mentioned by Dr. Ure:—"Let quicklime be introduced in equivalent quantity to the magnesia present, and it will precipitate this earth, and form chloride of calcium, which will immediately react upon the sulphate of soda in the mother-water, producing sulphate of lime and chloride of sodium. The former being nearly insoluble, is easily separated. Lime, moreover, decomposes directly the chloride of magnesium, but with the effect of merely substituting chloride of calcium in its stead. But in general there is abundance of sulphate of soda in brine springs to decompose the chloride of calcium. A still better mode of proceeding with sea-water would be to add to it in the settling tank the quantity of lime equivalent to the magnesia, whereby an available deposit of this earth would be obtained, at the same time that the brine would be sweetened. Water thus purified may be safely crystallized by rapid evaporation."

The finest table salt is made in the western parts of England, from the produce of the salt mines; and, along with salt of a common quality, is exported in immense quantities. In 1836, 240,560 tons of salt were exported from the United Kingdom, the greater part of which went to the United States, Russia, Belgium, the British North American Colonies, the West Indies, &c. M. Desormes calculates that the internal consumption of salt in France is rather more than 200,000 tons annually, which is about fourteen pounds for each individual. In this country it is thought to be about 240,000 tons annually, which is upwards of twenty pounds for each individual.

[BOOKS ON THE APPLICATION OF CHEMISTRY TO THE ARTS.

AMONG the works partially or wholly devoted to this subject the following will be found worthy of the student's attention. "*Applied Chemistry in Arts, Manufactures, and Domestic Economy.* By E. A. Parnell." "*Rural Economy in its Relation with Chemistry, Physics, and Meteorology.* By Bouissangault. Translated by G. Law." "*Dr. Fresenius's Elements of Chemical Analysis.* Edited by Bullock." "*Falkner on Manures and Agricultural Chemistry.*" "*Chaptal's Agricultural Chemistry.*" "*Liebig's Agricultural Chemistry.*" "*Draper on the Chemical Organization of Plants.*" "*Encyclopædia of Chemistry.* By Professor Booth." "*Farmer's Encyclopædia.*"

Of all the practical applications of chemistry which have been prosecuted of late years, the most important is undoubtedly that which brings the science to bear upon practical agriculture. The relation of soils and manures to cereal productions, and the alternation of crops, has recently been investigated with persevering zeal by the most enlightened chemists of Europe and America, and discoveries of very great practical importance have been made. The work of the German chemist Liebig on this subject is one of very special interest. It has been translated and published in the cheap pamphlet form in this country. It still remains for some American, who understands both chemistry and agriculture, to apply Liebig's science to the soil and productions of our own country and to reduce his principles to the form of axioms, and publish them in a cheap manual for the daily use of the American farmer.—*Am. Ed.*]

ELECTRICITY—GALVANISM—ELECTRO-MAGNETISM

ELECTRICITY.

It was observed in ancient times, that when amber was rubbed, it acquired a power of attracting and repelling such light bodies as hair and feathers; and this power afterwards came to be called Electricity, from *electron*, the Greek word for amber. Although the ancients were thus acquainted with some of the more obvious phenomena of electricity, they did not investigate the subject methodically, or attempt any generalization of facts into a scientific theory. It was only in modern times, when close reasoning from truths established by the evidence of the senses began to be practised by philosophers, that the phenomena connected with electricity assumed the dignity of a science. Dr. Gilbert, an English physician, made the first step towards generalization, in the year 1600. He published a valuable treatise, in which he observed, that not only amber, but various other substances, can by friction be made to draw light bodies to them. Boyle, Guericke, Newton, and some other philosophers of that period, contributed to extend human knowledge upon this interesting subject; but the real science of electricity took its rise in a latter age. About the middle of the eighteenth century, several very remarkable facts were ascertained, particularly by Benjamin Franklin, which identified lightning with electricity; but the extensive relations which connect it with so many other departments of physical science were not discovered until the present century, nor was their importance until then appreciated. In this short era a new science has arisen, founded on that modification of electricity which is known by the name of Galvanism. The galvanic battery (which will be afterwards described), as an instrument for analyzing or decomposing chemical substances, has connected it with chemistry in the most intimate manner. Hence has sprung Electro-Chemistry, one of the connecting branches between remote divisions of the philosophy of nature. Electro-Magnetism is a still more recently discovered province of science, and which identifies as one, two powers which were previously regarded as distinct.

As the best method of conveying a clear, and, at the same time, philosophical view of this interesting science, we shall, in the first place, independently of all theory, state the most general and remarkable facts connected with it. After these have been enumerated, the reader will then be prepared for a review of the theories which have been advanced for the purpose of explaining phenomena, and for connecting the various facts in the mind. The general facts relating to this subject we think may be classed under two heads—1st, The *Excitation* of Electricity; and 2d, The *Distribution* of Electricity. Connected with each of these heads are various phenomena, which we shall notice as they occur, during the gradual development of the subject.

EXCITATION OF ELECTRICITY, AND RESULTING PHENOMENA.

If a piece of sealing-wax, amber, the glass of a watch, or any other smooth piece of glass, be rubbed upon a piece of dry flannel or woollen cloth, or even the sleeve of a cloth coat, it will be found to have acquired a new and very singular physical property. This property is exhibited by holding the body which has been subjected to friction, over small and light substances, such as shreds of paper, gold leaf, feathers, straw, cork, &c. These will be first instantly *attracted* to it, some of them adhering to its surface, others falling back to the place whence they were withdrawn whilst others are thrown off from the body as if they were *repelled* from it. Here, then, is a distinct phenomenon—a process of attraction and repulsion at the same instant of time, which requires careful examination. It is observed, as above stated, that only certain substances will become endowed with these remarkable properties, and for convenience such are called *electrics*, those which cannot be excited in the same manner are said to be *non-electrics;* for example, stone is a non-electric.

The phenomena of attraction and repulsion may be exemplified in a striking manner by a small apparatus, of which we present a representation, fig. 1. A is a stand bent at its upper extremity, and having a hook to which a fine silk thread is attached, with a very small pith ball at its end, B. Rub an electric—for instance, a dry rod of glass—and, on presenting it to the ball, B, the ball will be immediately attracted to the glass, and will remain in contact with it. After they remain in contact for a few seconds, if the glass be withdrawn without being touched by the fingers, and again presented to the ball, the latter will be *repelled* instead of being attracted, as in the first instance. By being touched with the finger, the ball can be deprived of its electricity; and if, after this has been done, we present a piece of sealing-wax in place of the glass formerly employed, the very same phenomena will take place. On the first application, the ball will be attracted; and, on the second, repelled. It is clear, then, in the first place, that both these electrics have the power of attracting another body before they have communicated to it any of their own electricity; and, secondly, that they repel the body after they have communicated to it a portion of their own electricity.

Fig. 1.

But a very remarkable circumstance takes place, if we, after having conveyed electricity to the ball, B, by means of excited glass, which was for a moment or two in contact with it, should present to it, after the former was withdrawn, excited sealing-wax: the ball, instead of being repelled, as it would have been were the glass again applied, is attracted by the wax. If the experiment be reversed, and the excited wax first presented to the ball, and then the excited glass, the latter will be found to *repel* the ball. "Hence it follows," says Sir David Brewster,* "that excited glass *repels* a ball electrified by excited glass. Excited wax *repels* a ball electrified by excited wax. Excited glass *attracts* a ball electrified by excited wax. Excited wax *attracts* a ball electrified by excited glass. From which we conclude, that there are two opposite electricities; namely, that produced by excited glass, to which the name of *vitreous* or *positive* electricity has been given; and that produced by excited wax, to which the name of *resinous* or *negative* electricity has been given.

"If, when the pith ball, B, is electrified either with excited glass or wax, we touch it with a rod of glass, its property of being subsequently attracted or repelled by the excited glass or wax will suffer no change; but if we touch it with a rod of metal, it will lose the electricity which it had received, and will be attracted either

* Article Electricity in the *Encyclopædia Britannica*, the most comprehensive, philosophical, complete, and intelligible treatise upon this interesting science which we have ever yet met with

by the excited glass or wax, as it was when they were first applied to it. Hence, the rod of glass and the rod of metal possess different properties, the former being incapable, and the latter capable, of carrying off the electricity of the pith ball. The metal is therefore said to be a *conductor*, and the glass a *non-conductor*, of electricity."

In these experiments, electricity has been produced by *friction;* but there are other methods of obtaining it, which, however, will be afterwards explained.

With regard to attraction and repulsion, a few facts remain to be stated. Some substances remain longer in contact with the electric than others, and two bodies which have both been in conduct with the same electric, mutually repel each other. If electrics of considerable size are employed, the phenomena of course are best observed; and if the experiment be performed in a darkened chamber, flashes of bluish light will be seen to extend over the surface of the electric submitted to friction, and which we shall suppose is a cylinder of sealing-wax, sulphur, or glass. Sparks, accompanied also with a sharp snapping sound, will be seen to dart round it in various directions. If a round body, as a metallic ball, be presented to it, and moved from one end to the other, a succession of sparks will be obtained as the ball passes along the surface; and if the knuckle be presented instead of the metallic ball, each spark will be accompanied by a pricking sensation. If the cylinder be brought near to the face, an unpleasant sensation of tickling is felt in the skin, as if it were covered with a cobweb. If a metallic globe be suspended in the air by silk threads, and in that situation rubbed by an electric, it will also become electrical, and exhibit the same properties as an electric. It is essential to the success of this experiment that it be *insulated;* that is, cut off by means of an electric from all communication with any substance, except the air and the electric which sustains it. The instruments employed in experiments similar to those above described are termed *electroscopes.* Besides that one, of which a representation has been given, there are various others, all of which are formed upon the same principles.

It is now proper to mention the principal electrical substances in nature. They are, amber, gum-lack, resin, sulphur, glass, talc, the precious stones, silk, the fur of most quadrupeds, and almost all vegetable substances (excepting charcoal) which have been thoroughly deprived of moisture, as, for instance, baked wood, and very dry paper.

DISTRIBUTION AND TRANSFERENCE.

We have noticed that when the excited electric was brought near the pith ball, B, the latter was first attracted and then repelled. If we now remove the electric and present to the ball which has thus touched it, a second ball which has had no previous communication with an electric, we find that these two balls attract one another, and come into contact. The same actions are repeated between this second ball and a third which may be presented to it; and so on in succession, but with a continued diminution of intensity. This diminution plainly indicates a diminished power, in consequence, as it would seem, of its being distributed among a number of bodies. It is clear, therefore, that the unknown power which we have called electricity, can, like heat, be transferred or communicated from one body to another, and that its intensity, like that of heat, is weakened by being diffused among a number of bodies. An electrified ball can be deprived of its electricity by being touched with a rod of metal of any kind; but if we touch it with glass or wax, it will not be carried off. Hence, metals are said to be *conductors*, and glass and wax *non-conductors*, of electricity. Bodies greatly vary in their power of conduction, and many of them owe it to the water which they contain. The conducting power of any substance depends on the state of the atmosphere at the time with regard to humidity, and on the intensity of the electricity employed. The following lists of conductors and non-conductors are by Sir David Brewster, and have been collected by him from various authors, with great care. The bodies are placed in the order of their conducting or non-conducting power; "but it is probable," says Sir David, "that this order would be greatly changed, if the bodies were all submitted to a new and uniform examination."

List of Conductors.—Silver copper, lead, gold, brass, zinc, tin, platina, palladium, iron heated, iron cold, charcoal well burned, plumbago, concentrated acids, powdered charcoal, diluted acids, saline solutions, metallic ores, animal fluids, hot water, sea-water, spring-water, river-water, ice above 13 degrees Fahr., snow, living vegetables, living animals, flame, smoke, steam, soluble salts, rarefied air, vapour of alcohol, vapour of ether, moist earths, anthracite, powdered glass, flowers of sulphur, resins rendered fluid by heat, glass heated to redness.

List of Non-conductors.—Shell-lack, amber, resins, sulphur, wax, jet, glass, vitrifications, mica, diamond, transparent gems, various minerals, raw silk, bleached silk, dyed silk, wool, hair, feathers, dry paper, parchment, leather, air and all dry gases, baked wood, dry vegetable bodies, porcelain, dry marble, and siliceous and argillaceous stones, camphor, caoutchouc, lycopodium, dry chalk, lime, phosphorus, ice below 13 degrees Fahr., ashes of animal bodies, ashes of vegetable bodies, oils (the heaviest being the best conductors), dry metallic oxides.

The two qualities of a capability of excitation, and a power of conducting electricity, appear to be incompatible with each other, for the one always diminishes in proportion as the other increases. Hence it follows, as an invariable law, that *electrics* are *non-conductors*, and, on the other hand, that conductors are *non-electrics.* The most perfect *non-conductors* of electricity are also called *insulators*, from their power of insulating an electrified body, or preventing any of its electricity from escaping along its support. The insulating power of atmospheric air depends upon two circumstances—its density and its dryness. Air of the ordinary density of the atmosphere, if perfectly dry, is a remarkably good insulator, and no change of temperature appears to affect its insulating power; but rarefaction diminishes its power of confining electricity, and, when greatly rarefied, it may be classed among conductors. The conducting power of air of the ordinary density depends upon the quantity of moisture which it contains, water being a very good conductor of electricity. Changes of temperature and also of form affect the conducting powers of most bodies. Thus, though water, in its ordinary liquid state, is an excellent conductor, yet, when it appears in the solid form of ice, its conducting power is much impaired, and at a very low temperature it ceases entirely. Glass, when cold is a non-conductor, but when heated to redness it conducts tolerably well. Hence, although some bodies are said to be perfect non-conductors, yet this is not strictly true. In Dr. Faraday's interesting researches on this subject, he gives the following summary of conditions of conduction in bodies, which, although they apply chiefly to voltaic electricity, are yet true within certain limits of ordinary electricity:—

1. All bodies conduct electricity in the same manner, from metals to lac and gases, but in different degrees.

2. Conducting power is in some bodies powerfully increased by heat, and in others diminished, yet without our perceiving any accompanying essential electrical difference, either in the bodies or in the changes occasioned by the electricity conducted.

3. A number of bodies insulating electricity of low intensity when solid, conduct it very freely when fluid, and are then decomposed by it.

4. There are many fluid bodies which do not sensibly conduct electricity of this low intensity; there are some which conduct it and are not decomposed, nor is fluidity essential to decomposition.

5. There is but one body yet discovered (periodide of mercury), which, insulating a voltaic current when solid and conducting it when fluid, is not decomposed in the latter case.

6. There is no strict electrical distinction of conductors which can as yet be drawn between bodies supposed to be elementary, and those known to be compounds.

There are various other circumstances upon which the conducting power of bodies depends. That of silk, for instance, is affected by the colour of the thread, or rather by the nature of the dye-stuff by which it has been tinged. When of a brilliant white, or a black, its conducting power is the greatest; and a high golden yellow or a nut-brown renders it the best insulator. Mr. Coulomb, who has investigated the subject with great ability, assigns three causes as chiefly operating in depriving a body in a state of imperfect insulation of its electricity—first, the imperfection of the insulating property in the solids by which it is supported; secondly, the contact of successive portions of atmospheric air, every particle of which deprives the body of a portion of its electricity; thirdly, the deposition of moisture upon the surface of the insulating body, which establishes communications with its remote ends, thus virtually increasing its conducting power. There is another very remarkable circumstance relating to the dissipation of electricity, namely, the shape of the body which holds the electricity. Its retaining power is materially affected by the form which it possesses. The spherical shape is that most favourable to its retention; whilst, from bodies of a pointed figure, especially if the point projects to a distance from the surface, electricity escapes most readily. On the other hand, these bodies receive electricity more readily than those of any other form.

OF THE TWO KINDS OF ELECTRICITY.

It will be understood, from the preceding explanations, that there are two kinds of electricity—namely, a *vitreous* or *positive* electricity, and a *resinous* or *negative* electricity. Although we have thus two electricities, there does not appear to be the smallest difference between them when they are taken individually. The distinction is only observable when brought in contact; they then display a marked a contrariety, or mutually opposive force, that they may be viewed as agents having opposite qualities, which completely neutralize one another by combination, just like an acid and an alkali. It is remarkable that the excitation of one species of electricity is always accompanied by the presence of the other, and both are produced to an equal extent. Thus, when a piece of glass is rubbed by silk, just as much resinous electricity is produced in the silk as there is vitreous electricity produced in the glass; and whatever electrified bodies are repelled by the one, are attracted by the other. Of course, these two surfaces, having acquired opposite electricities, invariably attract each other. A white and a black ribbon rubbed against each other between the finger and thumb, exhibit electrical phenomena in a very marked manner. The black is resinously and the white vitreously electrified; of course, they attract each other; and, if separated, the one attracts the light bodies which the other repels. When two pieces of the same ribbon of the same length are rubbed, the one being drawn lengthways and at right angles over a part of the other, the one which has been subjected to friction in its whole length, acquires vitreous and the other resinous electricity. In like manner, when the whole length of the bow of a violin is drawn over a limited part of the string, the hairs of the former exhibit a vitreous, and the latter a resinous electricity. It is to be observed, that the body whose excited portion is of the least extent, is generally found to be resinously electrified.

To know the species of electricity evolved, it is merely necessary to communicate beforehand, to the slips of gold leaf, a known electricity, either from excited glass or sealing-wax. If they be divergent with the former, then the approach of a body similarly electrified will augment the divergence, but that of one oppositely electrified will cause their collapse.

No visible relation can be pointed out between the nature or constitution of substances, and the species of electricity developed by their mutual friction. The only general law among the phenomena is, that the rubbing and the rubbed body always require opposite electricities. Sulphur is vitreously electrified when rubbed with every metal except lead, and resinously with lead and every other kind of rubber. Resinous bodies rubbed against each other acquire alternately the vitreous and resinous electricity; but rubbed against all other bodies, they become resinously electrical. White silk acquires vitreous electricity with black silk, metals, and black cloth; and resinous with paper, the human hand, hair, and weasel's skin. Black silk becomes vitreously electrical with sealing-wax, but resinously with hares', weasels', and ferrets' skins; with brass, silver, iron, the human hand, and white silk. Woollen cloth is strongly vitreous with zinc and bismuth; moderately so with silver, copper, lead, and specular iron. It is resinous with platina, gold, tin, antimony, gray copper, sulphuret of copper, bisulphuret of copper, sulphurets of silver, antimony and iron. Dry air impelled on glass becomes resinously electrical, and leaves the glass in the opposite state. Silk stuffs agitated in the atmosphere with a rapid motion, always take the resinous electricity, while the air becomes vitreously electrified.

Numerous experiments have been made with the view of ascertaining the conditions that determine the species of electricity exerted in the respective bodies of which the surfaces are made to rub against each other, but they have led to no satisfactory conclusions. The mechanical configuration of the surface appears to have a greater influence in the result than the peculiar nature of the substance itself. If a plate of glass with a polished surface be rubbed against one which is roughened, the former always acquires the vitreous and the latter the resinous electricity. Various substances, if rubbed when polished, exhibit a different kind of electricity than that with which they are excited, if rubbed when roughened or scratched. No purely scientific explanation has ever yet been given of these remarkable phenomena.

If a body is charged with electricity, and insulated so perfectly as to prevent the escape of the electricity which it contains, it nevertheless tends to produce an electrical state of the opposite kind in all the bodies around it. Thus the vitreous induces the resinous, and the resinous the vitreous electricity in a body that is situated in the vicinity of either of them, and this to a degree proportioned to the smallness of the distance which separates the bodies. The electricity is in this case said to be induced, and the phenomenon is called *electrical induction*. The operation of this law is a key to the principal phenomena of electricity. In illustration of it, we shall quote an able writer upon the subject:

"If an electrified body, charged with either species of electricity, be presented to an unelectrified or neutral body, its tendency, in consequence of the law of induction, is to disturb the electrical condition of the different parts of the neutral body. The electrified body induces a state of electricity contrary to its own in that part of the neutral body which is nearest to it; and, consequently, a state of electricity similar to its own in the remote part. Hence, the neutrality of the second body is destroyed by the action of the first; and the adjacent parts of the two bodies, having now opposite electricities, will attract each other. It thus appears that the attraction which is observed to take place between electrified bodies, and those that are unelectrified, is merely a consequence of the altered state of those bodies, resulting directly from the law of induction; and that it is by no means itself an original law or primary fact in the science.

The effect of induction will be in proportion to the facility with which changes in the distribution of electricity among the different parts of a body can be effected, a facility which corresponds with the conducting power of the body. Hence, the attraction exerted by an electrified body upon another body previously neutral, will be much more energetic if the latter be a conductor than if it be an electric,* which these changes can take place only to a very small extent. This is confirmed by the following experiment:—"Suspend, by fine silk threads of equal length, two small balls of equal dimensions, both made of gum-lac, but one having its surface covered with gold leaf. Place these two pendulums, as they may be called, at a little distance from one another, so as to admit of a comparison of their motions; and then present to them an excited electric, which may be either a tube of glass or a cylinder of sealing-wax. It will at once be seen that the ball with the metallic covering, which readily admits of the transfer of electricity from one side to the other, will be much more readily and powerfully attracted than the other ball, which allows of no motion in its electricity. The latter ball will, by slow degrees however, assume electrical states of the same kind as the gilt ball, and will be fully attracted. As this change is very slowly effected, so it is more permanent when once produced; and the plain ball adheres for a considerable time to the electric which has attracted it. The gilt ball, on the contrary, is sooner repelled, by its readily receiving the charge of electricity imparted to it by the electric. A degree of permanent electricity, however, is also induced on this ball, in consequence of its gradual penetration into the substance of the gum-lac."

Electrical phenomena are generally accounted for by supposing that there is an extremely subtile and highly elastic fluid, which pervades all material substances, but is itself devoid of any sensible gravity. It is supposed to move with various degrees of facility through the pores or actual substance of various kinds of matter. Hence, in proportion as they admit of the fluid passing through them with ease or difficulty, bodies have been divided into conductors and non-conductors. According to the doctrine of there being but one species of fluid, it is supposed that the electrical equilibrium which constitutes the natural state of matter is disturbed by friction, and that one of the two bodies brought near to each other, attracts to itself a surcharge of the fluid, and is *over-saturated*, whilst the other is left in a deficient state, and is *under-saturated*. For this view of the subject we are indebted to Franklin; and hence, the terms of positive or plus, and negative or minus, have arisen. But as some of the appearances cannot easily be reconciled to the hypothesis of a mere excess or deficiency of one fluid, there is another theory which supposes the fluid to be a *compound*, susceptible of decomposition by friction and other means; and hence the origin of the terms vitreous and resinous electricities. With respect to the intensity of the electric force, it resembles that of gravitation, by being inversely as the square of the distance. Like gravitation, also, it acts at all distances, and it is not impeded by any intervening body, provided it be not in an active electrical state. But whilst the particles of each fluid repel those of the same kind, they exert, as we have seen, a high attractive power over those of an opposite kind. The intensity of this attraction, also, like that of gravitation, increases with a diminution of distance. It is evident, therefore, that from the powerful attraction which they have for each other, they would always flow towards each other and coalesce, were it not that the non-conducting properties of electrics offer an impediment to their motion. When these obstacles are removed, they immediately rush into union, and give rise to the remarkable phenomena already noticed.

ELECTRICAL MACHINES.

Rubbing or friction, it will be perceived, is always requisite to produce an artificial display of electrical phenomena. Thus, in rubbing the back of a cat, in rapidly drawing off a silk from a woollen stocking, or in performing any similar action with suitable, and in all cases dry, substances, we evolve electric sparks, of lesser or greater intensity. For the purpose of producing powerful electrical results, the aid of mechanism has been found essential. There are various kinds of electrical machines, but all constructed on similar principles. We here offer a representation of that which is most commonly used, in our description of which, the essential parts constituting such instruments will appear.

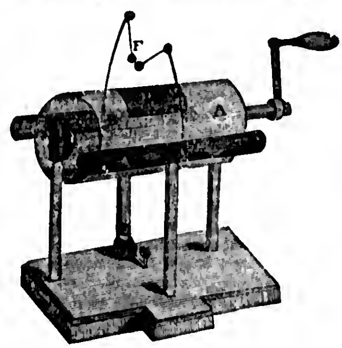

Fig. 2.

A B, fig. 2, is a hollow cylinder of polished glass which revolves upon a horizontal axis, and is from eight to sixteen inches in diameter, and from one to two feet long. For the purpose of insulation, it is supported on two upright pillars of glass, which are fixed in a wooden stand. Two hollow metallic conductors, equal in length to the cylinder, and about one-fourth of its diameter, are placed parallel to it, one on each side, upon two insulating pillars of glass, which are cemented into two separate pieces of wood, that slide across the base, so as to allow of being brought within different distances of the cylinder. To one of these conductors the cushion is attached, which is of the same length with the conductor C. The cushion is usually made of soft shammy leather, stuffed with hair or wool, so as to be as hard as the bottom of a chair, but yet sufficiently yielding to accommodate itself, without much pressure, to the surface of the glass to which it is applied. The prime conductor is a cylindrical tube, each end terminating in a hemisphere. As the electricity is only contained at the surfaces, it is made hollow, generally of thin sheet brass, copper, tin, or pasteboard covered with gold leaf or tinfoil. It must be carefully freed from all points and asperities; and if perforations are made in it for the purpose of attaching wires and other kinds of fixtures for the purposes of experiment, they should be made about the size of a quill, and should have their edges well rounded and smoothed off. The pressure of the cushion against the cylinder is regulated by an adjusting screw, adapted to the wooden base at E, on which the glass pillar that supports the conductor is fixed. From the upper edge of the cushion there proceeds a flap of thin oiled silk D, which is sewed on the cushion about a quarter of an inch from its upper edge. It extends over the upper surface of the glass cylinder to within an inch of a row of metallic points, proceeding, like the teeth of a rake, from a horizontal rod, which is fixed to the adjacent side of the opposite conductor. The motion of the cylinder, which is given by a single handle, or by a multiplying wheel, must always be given in the direction of the silk flap. That part of the cushion which comes in contact with the glass cylinder should be coated with an amalgam composed of a little tin-foil and mercury, mixed like a paste by means of hogs' lard. The amalgam should be placed uniformly over the cushion, until level with the line formed by the seam which joins the silk flap to the face of the cushion. No amalgam should be placed over this line, nor on the silk flap; and it is even requisite to wipe the silk flap clean whenever the continued motion of the machine shall have soiled it, by depositing dust or amalgam on its surface.

This machine acts in the following manner:—When the cylinder is driven round by the handle, the friction of the cushion upon it produces a transfer of the electric fluid from the latter to the former; that is, the cushion becomes negatively, and the glass positively, electrified. By the revolution of the cylinder, the fluid adhering to the glass is carried round, and its escape is at first prevented by the silk flap which covers the cylinder, until it arrives near to the metallic points, which absorb most of the electricity, and convey it to the prime conductor. This being positively electrified, the conductor connected with the cushion being deprived of this electricity, is negatively electrified; so that light balls, suspended by threads at F, being oppositely electrified, will attract each other. After the action has gone on for some time, the cushion and its conductor become exhausted of their electricity; so that a new supply must be brought from the earth, the great reservoir of the fluid. This is easily done, by establishing a communication between the cushion and the ground by means of a metallic chain or wire. In this manner, a constant stream of positive electricity flows to the prime conductor. Negative electricity is obtained by insulating the conductor to which the cushion is attached, and connecting the prime conductor with the ground, so as to carry off the fluid collected from the cylinder. If the person who works the machine be supported upon a stool having glass legs, and connected with the conductor by means of a metallic rod, or if he touch it with his hand, he is found to be in the same state of electricity; and another person standing upon the ground can draw sparks from him by presenting his knuckles to his body.*

By using the electrical machine in the above manner, we are enabled to collect a considerable quantity of electricity, and thus perform experiments upon an ample scale. A pith ball, or a fragment of gold leaf, is very strongly and immediately attracted by the electrified conductor, and, the instant after it has come into contact with it, it is repelled; but it is now attracted by the other bodies in its neighbourhood, to which it communicates its own electricity, and then is again in a state to be influenced by the conductor, and to be again attracted; and this alternation of effects will continue as long as the conductor remains charged. This alternation of attractions and repulsions accompanying the transferring electricity by movable conductors, is also illustrated by the motions of a ball suspended by a silk thread, and placed between two bells, of which the one is electrified, and the other communicates with the ground. The alternate motion of the ball between the two bells will keep up a continual ringing. This amusing experiment has been applied to give notice of changes taking place in the electrical state of the atmosphere.

The mutual repulsion of bodies that are similarly electrified gives rise to many interesting experiments. A small figure in the shape of a human head, covered with hair, when placed upon the conductor, and electrified, will exhibit the appearance of terror, from the bristling up and divergence of the hair.

The intensity of the electricity which bodies may contain, is measured by a delicate instrument, called an *Electrometer*, of which there are several invented by various distinguished individuals. Our limits, however, will not admit of our giving a minute account of them. They all depend upon the repulsive property of electrified bodies, and the distance to which the one is repelled by the other is indicated by an index of one kind or another.

We have already observed, that upon the extent of the surface of a body, its capacity for receiving electricity principally depends. Electricity is therefore supposed not to spread throughout the whole mass of a body, at least equally, but to remain principally, if not altogether, at the surface. This has been proved by experiments for trying the distance to which the electricity extended beyond the coating of the Leyden jar.

Several remarkable phenomena occur when electricity is drawn off by means of a conductor from those bodies in which the electrical equilibrium has been destroyed. A sharp snapping sound is heard, accompanied by a vivid spark, whilst intense heat is evolved in the path which the electric fluid takes. A perfect conductor offering no impediment to its course, it is unattended with light during its passage through such a body, light only appearing when there are obstacles in its path, such as imperfect conductors. Of the velocity with which it is transmitted, we have already spoken. It is so great, that in experiments performed with a chain of considerable length, each link becomes apparently instantaneously luminous. There are various methods of showing the intensity and colour of electrical light. Conductors having a rounded form give the longest and most vivid sparks, which are sometimes seen to take a zig-zag course, similar to that of a flash of lightning. This deviation in its course is supposed to be occasioned by this fluid darting to minute conducting particles, such as those of moisture floating in the air. Electrical light is similar to light obtained from other sources, and its brilliancy depends upon its intensity. Sir David Brewster found that it was capable of polarization. It displays every shade of colour, that quality being dependent upon the nature of the substance through which the fluid passes.

An interesting question arises—Whence comes the light—is it the electric fluid which thus renders itself visible? This was really supposed to be the case by the early electricians, but later philosophers have substituted other theories to account for the phenomena. That of M. Biot, a celebrated French philosopher, is, that electric light has the same origin as the light disengaged from air by mechanical pressure; "and that it is purely the effect of the compression produced on the air by the explosion of electricity." This hypothesis has been objected to, however, on the ground that electrical light is produced in the best vacuum that can be formed; and although he has replied to the objection, that no perfect vacuum can exist, yet his arguments, though they carry weight, do not bring conviction to the mind.

We have already observed, that various sounds accompany the various modes of transference of the electric fluid; a peculiar odour has also sometimes been felt

* In certain conditions of the atmosphere, electrical sparks are evolved in abundance from paper as it issues from the cylinders in the paper-making machine, the friction of the dry material on parts of the apparatus being the apparent cause of the phenomena. If a battery of Leyden jars were employed to collect these sparks, electrical experiments might be readily performed with them.

near a machine which has been sharply wrought; but whence its origin, is unknown. All sharp-pointed bodies, we have said, concentrate most of the electric fluid at their apex, from whence it has a powerful disposition to escape; and every discharge is accompanied by currents of air. Upon this principle many ingenious experiments are founded. An apparatus, consisting of wires terminating in points, and having balls annexed to them to represent the planets, may be constructed so as to revolve when electrified, and thus to imitate the planetary motions. We cannot enter further into this subject, but may state in general terms, that the appearances of the electric spark depend upon the nature of the surface from whence it issues, and towards which it is directed. When it escapes *from* a pointed body, the luminous appearance is that of diverging streams, resembling the filaments of a brush, and forming what is termed a *pencil of light*; but when the fluid goes *to* a point, the light concentrates at the point itself, and assumes the appearance of a star.

The most convenient mode of obtaining an accumulation of electricity arising from induction, is by the employment of coated glass; that is, of a plate of glass on each side of which is pasted a sheet or coating of tin-foil. Care must be taken to leave a sufficient margin of glass uncovered with the metal, for preventing the transfer of electricity from one coating to the other, round the edge of the glass; and all sharp angles or ragged edges in the coatings should be avoided, as they have a great tendency to dissipate the charge.

The form of coated glass best adapted to experiments is that of a cylindric jar; this is coated, within and without, nearly to the top. The cover consists of baked wood, and is inserted with sealing-wax, to exclude moisture and dust. A metallic rod, rising two or three inches above the jar, and terminating at the top in a brass knob, is made to descend through the cover till it touches the interior coating. The name of the *Leyden phial*, or *jar*, is applied to this instrument. It is used in the following manner:—The outer coating being made to communicate with the ground, by holding it in the hand, the knob of the jar is presented to the prime conductor when the machine is in motion: a succession of sparks will pass between them, while, at the same time, nearly an equal quantity of electricity will be passing out from the exterior coating, through the body of the person who holds it, to the ground. The jar, on being removed, is said to be charged; and if a communication is made between the two coatings, by a metallic wire extending from the external one to the knob, the electric fluid which was accumulated in the positive coating, rushes, with a sudden and violent impetus, along the conductor, and passes into the negative coating; thus at once restoring an

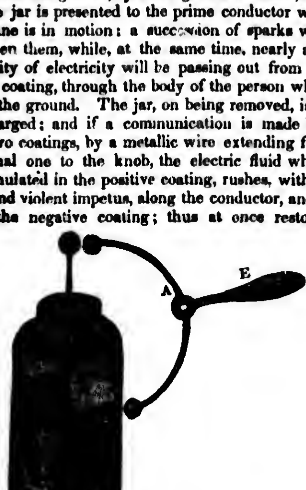

Fig. 3.

almost complete equilibrium. This sudden transfer of a large quantity of accumulated electricity is a real explosion; and it gives rise to a vivid flash of light, corresponding in intensity to the magnitude of the charge. The effect of its transmission is much greater than that of the simple charge of the prime conductor of the machine; and it imparts a sensation, when passing through any part of the body, of a peculiar kind, which is called the *electric shock*. The arrangement of the parts in a Leyden jar is shown in the foregoing figure, in which the simple bent *discharging* rod, for establishing a direct communication between the inner and outer coating of a jar or battery, and restoring the electrical equilibrium, without the operator receiving the charge of the jar, is exhibited. E represents the insulating handle, and A the bent rod of brass reaching from the ball to the external coating. When opened to a proper degree, one of the balls is made to touch the exterior coating, and the other ball is then quickly brought into contact with the knob of the jar, and thus a discharge is effected.

By uniting together a sufficient number of jars, we are able to accumulate an enormous quantity of electricity. For this purpose, all the interior coatings of the

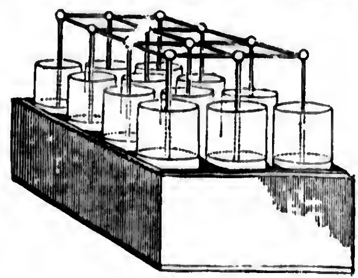

Fig. 4.

jars must be made to communicate by metallic rods, and a similar union must be established among the exterior coatings. When thus arranged, the whole series may be charged, as if they formed but one jar; and the whole of the accumulated electricity may be transferred from one system of coatings to the other, by a general and simultaneous discharge. Such a combination of jars is called an *electrical battery*. An arrangement of this description is here represented, in which twelve jars are united in one box, and the whole series connected together by wires and balls.

If we wish to send the whole charge of electricity through any particular substance which may be the subject of experiment, we must so arrange the connecting conductors as that the substance shall form a necessary part of the *circuit of the electricity*, as it is termed. With this view, we must place it between two good conductors, one of which is in communication with the outer coating; and the circuit may then be completed by connecting the other conductor with the inner coating by means of a discharging rod, to one branch of which, if necessary, a flexible chain may be added.

In forming arrangements for directing the passage of accumulated electricity, it should be borne in mind that the electric fluid will, on these occasions, always pass through the best conductors, although they may be more circuitous, in preference to those which are more direct, but have inferior conducting power; and it must also be recollected, that, when different paths are open for its transmission along conductors of equal power, the electricity will always take that which is the shortest. Thus, if a person holding a wire between his hands discharges a jar by means of it, the whole of the fluid will pass through the wire without affecting him; but if a piece of dry wood be substituted for the wire, he will feel a shock; for the wood being a worse conductor than his own body, the charge will pass through the latter, as being easier, although the longer circuit. During its traues through the human body, in like manner, the shock is felt only in the parts situated in the direct line of communication; and if the charge be made to pass through a number of persons, who take one another by the hand, and form part of the circuit between the inner and outer coatings of the jar, each will feel the electric shock in the same manner and at the same instant; the sensation reaching from hand to hand, directly across the breast. By varying the points of contact, however, the shock may be made to pass in other directions, and may either be confined to a small part of a limb, or be made to traverse the whole length of the body from head to foot.

By accurate experiments, it appears that the force of the electric shock is weakened, or its effects are diminished, by employing a conductor of great length for making the discharge. A retardation in the passage of electricity also takes place if the conductor is not of a sufficient size; and when this is the case, as well as in those instances where the conductor is not a good one, the discharge will not be effected so instantaneously or so completely. It has also a tendency to diverge from the direct line of its course, being drawn towards conducting bodies which may attract it. The motion of electricity through perfect conductors is attended with no perceptible alteration in the mechanical properties of the conducting bodies, provided they be of sufficient size for the charge of the electric fluid transmitted. On the contrary, very considerable effects are produced when a powerful charge is sent through a wire which is too small to allow the whole quantity to pass with perfect freedom, or through an imperfect conductor, though of large size, as is proved when a tree is struck by lightning.

ELECTRICITY APPLIED TO INORGANIC BODIES AND ANIMALS.

The effects of electricity passing through various substances are both of a mechanical and chemical nature. The former resemble those which would be produced by a material agent driven with great velocity through the substance of the body. But there are many changes induced by electricity, such as cannot be attributed to mechanical agency, and are undoubtedly of a chemical nature. Some of the mechanical effects have already been noticed. Dr. Priestley discovered that it expanded bodies. This is proved by passing a stream of the fluid through a capillary or thermometer tube filled with mercury; the latter will be so much expanded as to break the glass to shivers. The tendency to expand will of course be greater as the conducting power of the body which transmits it is less. Although we know nothing of the nature of electricity, yet it has been found convenient to speak of it as a fluid. Its action upon bodies which either obstruct its motion or afford it a ready passage, renders its analogy with a fluid very striking, and the laws of its equilibrium are just those of an imponderable fluid. Solid bodies are capable of being diffused into vapour by passing electricity through them, as is shown by the following experiment:—Take three strips of window-glass, each about three inches long and one wide, and having placed two narrow strips of gold leaf or leaf brass between them, so that the ends of the gold leaf project a little beyond the glass, transmit the charge of a large Leyden jar through the gold leaf. The gold leaf will be found to be melted by the shock, and driven into the surface of the glass. The outer plates of glass are generally broken in this experiment, and the middle one, which frequently remains entire, has an indelible metallic stain upon each of its surfaces. This stain is obviously the metallic vapour of the gold driven into the pores of the glass.

The metallic colours thus obtained have been employed for impressing ornamental figures upon paper or silk. In order to do this, trace the outline of the figures on thick drawing-paper, and having cut it out as in stencil plates, place it on the silk or paper intended to be ornamented. When a gold leaf is laid upon it, and a card above the gold leaf, the whole is placed in a press or beneath a weight, and an electrical charge sent through it; the metallic stain is limited to the portion of the drawing-paper that is cut away, and, consequently, any outline figure may be readily impressed upon the ground employed to receive it.

CHEMICAL CHANGES OF ELECTRICITY.

The effects of electricity as a chemical agent are strikingly displayed in its power of evolving heat, and, consequently, of inflaming and fusing bodies, and its power of promoting chemical composition and decomposition. Combustible bodies, such as a common candle, can be lighted in various ways, by passing the electric fluid through them. The heat evolved by electricity, like most other of its effects, is in proportion to the resistances opposed to its passage. Nor is its heating power in the smallest degree diminished by its being conducted through any number of freezing mixtures which are rapidly absorbing heat from surrounding bodies. Sparks taken from a piece of ice are as capable of inflaming bodies as those from a piece of a red-hot iron. Among the more striking chemical effects of electricity, or electro-chemistry, are the decomposition of water, the oxidation of metals, and the restoration of the oxides to their metallic state.

Many experiments have been made for the purpose of ascertaining the changes effected in *phosphorescent* bodies by electricity, and the results are not without importance. It has been discovered, for instance, that substances not naturally phosphorescent, such as statuary marble in its natural or calcined state, were not only rendered phosphorescent by heat after being strongly electrified, but acquired this property with a beauty, a variety, and an intensity of colour, superior to those which occur in specimens that possess natural phosphorescence. It has also very recently been discovered, that electricity exercises a curious influence upon odoriferous bodies. When a current of the fluid is made to traverse camphor, the odour gradually disappears. After being withdrawn from electrical influence, it remains odourless for some time, and then slowly resumes its former properties.

There are certain mineral bodies, which, from being in a neutral state at ordinary temperatures, acquire electricity simply by being heated or cooled. This property is possessed only by regularly crystallized minerals; and of these the most remarkable is the tourmalin. It is a stone of considerable hardness, and the form of its crystals is generally that of a nine-sided prism, terminated by a three-sided pyramid at one end, and by a six-sided pyramid at the other. When heated to between 100 degrees and 212 degrees, the latter extremity becomes charged with positive electricity, whilst the former remains negative. On cooling, the electric states are generally reversed, that end becoming positive which was formerly negative. Other gems possess similar properties, such as the topaz, some species of diamonds, &c. There are a great many substances which become electrified by passing from the liquid to the solid form, such as sulphur, gum-lac, and in general all resinous bodies. The conversion of a body into the aëriform state, is also generally attended by some change in its electrical condition.

There are some bodies which are rendered electrical by pressure. The substance which possesses this property in the most remarkable degree, is that variety of the carbonate of lime known by the name of Iceland spar. Cork, bark, hairs, paper, and wood also possess the property of producing electricity by compression. A number of substances, when reduced to powder, exhibit electricity, if they are made to fall upon an insulated metallic plate. The relation subsisting between electricity and the chemical properties of matter, is the most important branch of this inquiry. It is observed by Sir Humphry Davy, that most of the substances that act distinctly upon each other electrically, are also such as act chemically when their particles have freedom of motion; this is the case with the different metals, with sulphur and the metals, with acid and alkaline substances. Of two metals in contact, the one which has the greatest chemical attraction for oxygen acquires positive electricity, and the other the negative. There is little doubt, indeed, that electricity is not only elicited by, but is intimately connected with, all chemical action; and there is every reason to believe that electricity is essentially concerned in the processes that are carried on in the living system both of animals and vegetables.

The influence of electricity upon the human frame, whether it is administered in small quantities so as to excite and surprise us, or in the more powerful and awful form of a stroke of lightning, must be well known to every one. When the human frame forms part of the electric circuit, or when the charge of a Leyden phial is made to enter the body at one hand and pass out of it at the other, a violent concussion or shock is felt along the line of its passage across the breast and through the arms. This shock, and the motion which accompanies it, no doubt result from the body being composed of various substances of different degrees of conducting power, thus presenting various obstacles to the free passage of the fluid. If the charge is increased, the patient falls down paralyzed, suffering a temporary cessation of vital action; and if it be increased to a still greater extent, it produces instantaneous death. This is frequently exemplified in the cases of individuals who are killed by the lightning stroke. It is upon the nervous system that electricity produces the most powerful influence. A strong charge passed through the head, gives the sensation of a violent but universal blow, and is followed by a transient loss of memory and indistinctness of vision. If a charge be passed through the spine, the person who receives it loses his power over the muscles to such a degree, that he either drops on his knees, or falls prostrate on the ground. Small animals, such as mice and sparrows, are instantly killed by a shock from thirty inches of square glass. If a shock be sent through the whole body of an eel, it is irrecoverably deprived of life; but if only through a part of the body, the destruction of irritability is confined to that particular part, whilst the rest retains the powers of motion. Different persons are affected in very different degrees by electricity, according to their peculiar constitutional susceptibility.

M. Rousseau, as we learn from a paragraph in the *Athenæum*, No. 637, has suggested a means of "ascertaining the purity of certain substances, and of detecting any adulterations in them, by measuring their conducting power for electricity. Some years ago, he described a simple apparatus by means of which the purity of olive-oil might be tested on similar principles. He now states that, by these means, any adulterations in chocolate or coffee may be readily detected: he finds that pure chocolate is a non-conductor or insulator of electricity, but that in proportion to the quantity of farina or fecular matter with which it is adulterated, the more easily does it conduct electricity; and in the same way, he states that coffee is an insulator, whilst chicory, with which it is often mixed, is an excellent conductor, and hence the presence of only a small quantity of that substance is easily detected in coffee by its increased conducting power. M. Rousseau also considers that this test may be applied with advantage to the examination of pharmaceutical extracts and preparations, because they very much differ in conducting power, and therefore any mixture or adulteration will be readily discovered."

Electricity is exhibited in a remarkable degree in various living animals; for example, we find in certain fishes a regular system of electrical organs, by which they either defend themselves from the attacks of their enemies, or seize the prey nature has provided for their use. Among the most remarkable of these is the *raia torpedo*, which is capable of giving a great many shocks to a number of individuals connected together, in the same manner as in the experiment with the Leyden jar. Another is the electric eel, which, when provoked, discharges its electricity, and the shock is experienced if the hand be dipped in the water containing the fish.

Although many ingenious electrical experiments have been made upon *vegetables*, some of which seem to indicate that the fluid exercises considerable influence over vegetable life, yet the subject is still involved in too great obscurity to admit of our treating it as a branch of electricity. Plants, of course, are destroyed like animals, when a powerful charge is sent through them; but feeble electricity exerts no influence on either animal or vegetable life, as far as can be perceived.

THE ELECTRICITY OF THE ATMOSPHERE.

We have now arrived at that part of our subject which is perhaps the most generally interesting of all. The resemblance between the electric spark, and more especially the explosive discharge of the Leyden jar, and atmospheric lightning and thunder, struck the mind of Dr. Franklin with so much force, that he was determined, if possible, to verify their identity by experiment.

Having constructed a kite, by stretching a large silk handkerchief over two sticks in the form of a cross, on the appearance of an approaching storm he went into a field in the vicinity of Philadelphia, and raised it, taking care to insulate it by a silken cord attached to a key, with which the hempen string terminated. No sooner had a dense cloud, apparently charged with lightning, passed over the spot on which he stood, than his attention was arrested by the bristling up of some loose fibres on the hempen string: he immediately presented his knuckle to the key, and received an electric spark. Overcome with the emotions which his discovery evinced, he heaved a deep sigh, as if he felt conscious of having achieved immortal fame. The rain now fell in torrents, and, wetting the string, rendered it a conductor throughout its whole length; so that electric sparks were now collected from it in great abundance. The discovery of Franklin soon engaged the attention of all the philosophers of Europe, and the truth of the theory, that lightning and electricity are the same fluid, was put beyond all question.

The atmosphere is very generally in an electrical state. This is ascertained by employing a metallic rod, insulated at its lower end, elevated at some height above the ground, and communicating with an electroscope. In order to collect the electricity of the higher regions of the air, a kite may be raised, in the string of which a slender metallic wire should be interwoven. The atmosphere is almost invariably found to be positively electrified; and its electricity is stronger in the winter than in the summer, and during the day than in the night. From the time of sunrise, it increases for two or three hours, and then decreases towards the middle of the day, being generally the weakest between noon and four o'clock. As the sun declines, its intensity is again augmented, till about the time of sunset, after which it diminishes, and continues feeble during the night.

In cloudy weather, the electrical state of the atmosphere is much more uncertain; and when there are several strata of clouds, moving in different directions, it is subject to great and rapid variations, changing backwards and forwards in the course of a very few minutes. On the first appearance of fog, rain, snow, hail, or sleet, the electricity of the air is generally negative, and often highly so; but it afterwards undergoes frequent transitions to opposite states. On the approach of a thunder-storm these alternations of the electric condition of the air succeed one another with remarkable rapidity. Strong sparks are sent out in great abundance from the conductor, and it becomes dangerous to prosecute experiments with it in its insulated state.

The protection of buildings from the destructive effects of lightning, is the most important practical application of the theory of electricity. The conductors, for this purpose, should be formed of metallic rods, pointed at the upper extremity, and placed so as to project a few feet above the highest part of the building they are intended to secure; they should be continued without interruption till they descend into the ground below the foundation of the house. Copper is preferable to iron as the material for their construction, being less liable to destruction by rust or by fusion, and possessing also a greater conducting power. The size of the rods should be from half an inch to an inch in diameter, and the point should be gilt or made of platina, that it may be more effectually preserved from corrosion.

An important condition in the protecting conductor is, that no interruption should exist in its continuity from top to bottom; and advantage will result from connecting together by strips of metal all the leaden water-pipes, or other considerable masses of metal in or about the building, so as to form one continuous system of conductors, for carrying the electricity by different channels to the ground. The lower end of the conductor should be carried down into the earth, till it reaches either water, or at the least a moist stratum.

For the protection of ships, chains, made of a series of iron rods linked together, are most convenient, on account of their flexibility. They should extend from the highest point of the mast some way into the sea, and the lower part should be removed to some distance from the side of the ship, by a wooden spar or outrigger.

One of the main advantages of scientific study, *is the acquisition of that degree of knowledge which liberates the mind from superstition, and explains the natural causes of those phenomena which fill the ignorant with alarm.* The study of electrical science has been of peculiar service in these respects. We learn from it, that thunder and lightning are a natural electrical result of certain conditions in the atmosphere, and are no more wonderful than the occurrence of clouds or rain. We learn from it, also, that the meteoric appearances called falling-stars, fire-balls, streamers, will-o'-the-wisps, silent lightning, &c., are simply electric phenomena, which need give no cause of alarm whatsoever. That such is the case, we refer to our article METEOROLOGY, in which the aurora borealis, and the various other appearances just mentioned, are explained on the principles of intelligible science.

GALVANISM.

THIS branch of electrical science took its origin, about the close of the last century, from a trivial accidental circumstance which occurred in the house of Signor Galvani, an Italian philosopher. A recently killed frog, having been accidentally touched in the limb with the blade of a knife which was held by a person who was experimenting with an electrical machine, was immediately thrown into violent convulsions. Galvani was not present when this occurred, but being informed of the circumstance, he lost no time in repeating the experiment, and extending his observations upon the phenomenon. He found that other metals besides that composing a knife answered the purpose, and very justly inferred that they owed this property of exciting muscular contractions to their being good conductors of electricity.

Galvani proceeded with his experiments upon animals by means of metallic substances, and arrived at the conclusion, that the different parts of an animal are in opposite states of electricity, and that the effect of the metal is merely to restore the equilibrium. But this theory was proved to be erroneous by Volta, a celebrated philosopher of Pavia, who, about the year 1801, discovered the *Galvanic* or *Voltaic pile*. He was led to it by meditating on the development of electricity at the surface of contact of two different metals. He tried the effect of his compound plates of metal upon animals, and was led to infer that the electricity is derived, not from the living system, but from the action excited between the metal and the humid animal fibre; that the animal matter acts merely as a medium conducting this electricity; and that the effects produced are to be ascribed to the stimulus of the electric fluid passing along the nerves and fibres, as in a shock from a Leyden jar. Volta further discovered, that the metallic plates which he used, such as silver and zinc, are excited, the former negatively, and the latter positively; and also that the galvanic energy could be greatly augmented by employing several pairs of plates, connecting them in such a manner that the electricity excited by each pair should be diffused through the whole; and this constituted the voltaic pile. From these, and numerous other experiments, it became apparent that electricity could be produced from the action of two different metals immersed in a suitable menstruum, and in some manner connected with each other. On this elementary truth the structure of galvanic science was reared.

In order to form a galvanic circle on the principle now mentioned apparatus of the most simple kind is sufficient. For instance, if a small slip of zinc be laid *upon*, and a piece of silver *under*, the tongue, we have two perfect conductors in the metals, with one imperfect one, the tongue, or the fluids which surround it; and by this apparatus, simple as it is, galvanic action is produced. In all action of this nature, and particularly when powerful acids are employed, the metals, as a matter of course, are eaten away or decomposed, and precipitated in the liquid. The knowledge of this fact has explained the cause of the gradual disappearance of metals, when two of an opposite electric quality were adjoining each other. Thus, in the sheathing of ships, it is necessary to use bolts of the same metal which forms the plate; for if two different metals be employed, one of them oxidates very speedily, in consequence of their forming, with the water of the ocean, a simple galvanic circle.

Compound galvanic circles, or galvanic batteries, are formed by multiplying those arrangements which compose simple circles. Thus, if plates of zinc and of silver (or of zinc and copper), and pieces of woollen cloth of the same size as the plates, and moistened with water, or, what is better, with diluted acid, be piled upon each other in the order of zinc, silver, cloth; zinc, silver, cloth; and so on, for twenty or more repetitions, we have the voltaic pile. The power of such a combination is sufficient to give a smart shock, as may be felt by grasping in the hands, previously moistened, the wires connecting the upper and lower extremities of the pile. The shock may be renewed at pleasure, until, after a few hours, the activity of the pile begins to abate, and finally ceases altogether, till the plates are cleaned and new diluted acid added.

After various improvements in the mode of eliciting galvanic action, the apparatus found to be best adapted for experiments, is that of a trough or open box of wood, well joined together and secured from leakage by being lined with some kind of resinous material or pitch. Into a trough of this kind plates of zinc and copper are put vertically, like so many cross divisions, the supports being grooves cut in the sides; a wire is led from each extremity of the row of plates, to act as conductors in any experiment to be performed. One wire represents the positive, and the other the negative pole of the electricity. The liquid in the trough occupies the cells between the plates. Figure 5 is a representation of a trough of this kind. The plates are usually about eight inches long, by

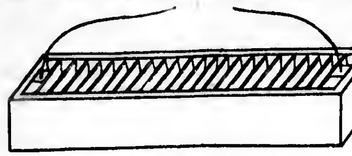

Fig. 5.

five or six inches broad; and in all arrangements, whether one or many troughs are employed, care must be taken to place the plates in one unvarying order, the zinc and copper succeeding each other alternately throughout the series. When several troughs are connected together, as in figure 6, the apparatus is called a *battery*. The cells

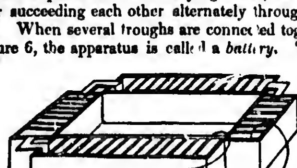

Fig. 6.

are usually charged with acids diluted with water to a certain extent; muriatic acid being diluted with five parts, and sulphuric acid with fifty parts of water. By experiments, it has been ascertained that increase of galvanic power is not in the ratio of an increased size of plates, but in the ratio of an increased number. Several troughs of small plates will thus have greater power than one trough with a greater superficies of metal. It may be farther mentioned, that if a battery is to consist of a certain number of square feet of plates, then, for producing calorific effects, or the ignition of metallic leaves and other combustibles, the plates ought to be large; for chemical effects, the size ought to be small, and the plates numerous; and for physiological effects, that is, for operating on the animal system, they ought to be made of an intermediate side.

The chemical changes effected by the electricity of galvanic action, are among the most remarkable phenomena in physical science. We shall instance a few of these facts, gathered from the best authorities. If a plate of zinc, and another of copper, be immersed in very dilute sulphuric acid, without touching or communicating with each other, the zinc will be acted upon by the acid; part of the water will be decomposed, its oxygen combining with the zinc, and forming oxide of zinc, and its hydrogen will be disengaged in the form of gas from the surface of the zinc plate. The copper is not acted upon. If the metals be brought into contact, the oxidation goes on with greater rapidity and energy, although without the evolution of the same quantity of hydrogen gas from the oxidating surface. But, from the whole fluid, hydrogen is disengaged in quantity exactly corresponding to that of the oxygen derived from the water, and the greater portion of it rises in a copious stream of bubbles from the surface of the copper plate, which remains unacted upon as before.

If, however, an acid, such as nitric acid, capable of acting upon the copper as well as upon the zinc, be employed instead of the sulphuric acid, similar phenomena will take place, with this additional circumstance, that the action of the acid upon the copper will cease the instant the galvanic circuit is completed; and instead of nitrous gas being formed on the surface of the copper, which happens before the circuit is formed, only bubbles of pure hydrogen will make their appearance; and the copper is protected from all further action, the zinc being, as in the former case, oxidated and dissolved with additional energy. It is on this principle that Sir Humphry Davy effected the protection of the copper sheathing of ships from the corrosion of sea-water, by placing in contact with it pieces of zinc or iron, on which sea-water exerts a greater chemical action than on copper. Among the simplest effects of galvanism upon fluid conductors, is the resolution of water into its two gaseous elements, oxygen and hydrogen. If the water employed be not perfectly pure, other substances besides the two components of water make their appearance at the two wires employed in the experiment. The apparent formation of these substances greatly puzzled the early experimentalists; but Sir Humphry Davy proved that, when the water is perfectly free from any foreign ingredient, only the two simple gases of which it is composed are obtained. He also discovered, that, under the influence of voltaic electricity, neutral salts existing in any solution were decomposed, the acid portion being accumulated around the positive wire on the same points where oxygen was disengaged; while the basis, whether earthy, alkaline, or metallic, were at the same moment transferred, along with the hydrogen to the negative wire.

Phenomena of a still more extraordinary nature presented themselves to Sir Humphry Davy in the further prosecution of these inquiries. It was discovered that the elements of compound bodies were actually conveyed, by the influence of the electric current, through solutions of substances, on which, under other circumstances, they would have exerted an immediate and powerful chemical action, without any such effect being produced. Acids, for example, may be transmitted from one cup, connected with the negative pole, to another on the opposite or positive side, through a portion of fluid in an intermediate cup, tinged with any of the vegetable-coloured infusions, which are instantly reddened by the presence of an acid, without occasioning the slightest change of colour. The same happens also with alkalies. If three cups be arranged, and connected with each other in a series by moistened cotton, the middle cup, and also the one next to the positive side of the battery, being filled with blue infusion of cabbage or of litmus, and the cup next to the negative side containing a solution of sulphate of soda on the series being placed in the voltaic circuit, a red tinge will soon be perceived in the water of the positive cup, which will become strongly acid. It is evident that the sulphuric acid so transferred must have passed through the fluid in the middle vessel, but without affecting the coloured solution in its passage. By reversing the connections with the poles of the battery, a similar transfer of the alkali will be made: it will be collected in the tinged water of the negative cup, which it will render green; but the intermediate portion of fluid will not, either in this or in the former case, exhibit any trace of the substance which is carried through it by the influence of electricity. Cohesion, however, where powerful, as might have been expected, intercepts the transmission of the substance. So powerful is this mysterious agent, that the minutest portions of a substance, acted upon by either of the wires, is collected around it.

"An interesting class of experiments are due to Mr. Crosse, on the employment of electricity, in a state of high tension, to form mineral and other substances. There is a cavern near Broomfield, of which the vault is covered with arragonite, and carbonate of lime, and fine crystals. The water which drips from this vault holds in solution ten grains of carbonate of lime, and a little sulphate of the same to each pint. A glass filled with this water was submitted to the action of a battery consisting of 200 pairs of plates, and at the expiration of ten days the negative pole was found to have formed rhomboidal crystals of carbonate of lime, accompanied by some gas-bubbles, and in less than a month after, the wire was covered with regular and irregular crystals; whence it follows that the bicarbonate was decomposed into carbonate and carbonic acid gas. He also let the water drop on a piece of brick subjected to a current from 100 five-inch plates, the brick being supported by a funnel which conducted the water into a vessel below; after four or five months the brick near the negative pole of battery was covered with carbonate of lime, while near the positive pole were disposed prismatic crystals of arragonite; and the same experiment being repeated with fluosilicic acid, regular hexahedral pyramids, similar in all respects to quartz, were obtained; those which were left in a dry place acquired sufficient hardness to scratch glass; the others had not that power, and gradually lost their transparency. In his varied experiments of this nature, he has succeeded in forming, by means of the galvanic battery, the following minerals:—carbonate of lime, arragonite, quartz, protoxide of copper, arseniate of copper, and its blue and green carbonates, phosphate of copper, carbonate of lead, chalcedony, &c."—*Penny Cyclopædia.*

Why compounds, when placed in a galvanic circuit, are decomposed, and why their elements collect, some around the positive and others around the negative pole of the battery, are questions which have never been satisfactorily solved. Sir Humphry Davy suggested the theory that all bodies possess natural electrical energies, which are inherent in them, whether they are in a state of combination or not. Oxygen, chlorine, iodine, and acids, according to the theory, are naturally negative; while inflammables, as hydrogen, sulphur, &c., and metals, are naturally positive. Hence, when the combinations of these substances are subverted by the galvanic influence, the substances are evolved in the electric state natural to them; and as it is a law of electricity that bodies in opposite states attract each other, the oxygen, being negative, is immediately attracted by the positive wire, while the inflammable or metallic base, being naturally positive, is attracted by the negative wire. In this way, the uniform appearance of these bodies at their particular poles are accounted for. Thus, if hydrogen is naturally positive, and oxygen naturally negative, according to the laws of electricity, they must attract each other; and if these opposite states are sufficiently elevated to give them an attractive force superior to the power of aggregation, they may be expected to combine; and, in like manner, other bodies, whose particles are in different states, may from this cause be united together. If a body, also, whose electrical energy exceeds that of one of the substances combined, be brought to act upon these, it may expel that ingredient, and take its place; and this may be the cause of what is called decomposition from elective affinity.

The agency of the galvanic apparatus, then, in producing decomposition, it is conceived, is this—that the two wires placed in contact with the compound are in states of electricity more intensely elevated than the natural states of the two ingredients; hence the attraction of these two highly electrified points overcomes that subsisting between these ingredients: they are separated, and immediately drawn to the respective poles—the positive constituent to the negative wire, and the ingredient which is naturally negative to the positive wire.

With respect to the physiological effects of galvanic action, it may be observed that the shock received by the human body from the voltaic pile is similar to that resulting from a large electrical battery very weakly charged. Twenty pair of plates are generally sufficient to give a shock which is sometimes felt in the arms. With a hundred pairs, it extends to the shoulders. A continued flow of the current through the body is accompanied by a continued aching pain. The impression made upon some of the nerves of the face when they form part of the circuit, is accompanied by the sensation of a vivid flash of light. When a piece of zinc and a piece of copper are placed, the one above and the other below the tongue, which must be in a moist state, a peculiar taste is experienced. This is supposed to arise from the saliva of the mouth having been decomposed by the galvanic action, and not merely the effect of a direct impression of the electric current on the nerves of the tongue. When the current of voltaic electricity is made to pass along a nerve distributed to any of the muscles of voluntary motion, they are thrown into violent convulsive contractions. The susceptibility of some animals is very great, and numerous curious experiments may be performed with them. If an earth-worm be placed upon a crown piece which lies upon a plate of zinc of larger size, it will suffer no inconvenience as long as it remains in contact with the silver only; but the moment it has stretched out its head, and touched the zinc, so as to complete the galvanic circle, it suddenly recoils, as if it had felt a severe shock. If the battery be powerful, small animals may be easily killed. Striking effects are produced by galvanism in the muscles of an animal after death, as long as they retain their contractility. The convulsions are so general, as often to impress the spectator with a belief that the animal has been restored to the power of sensation, and that it is suffering the most cruel torture. The eyes open and shut in their sockets spontaneously, as if re-endued with vision; the nostrils vibrate, as in the act of smelling; and the movements of mastication are imitated by the jaws. The experiments which are calculated to produce the greatest terror and astonishment are those made upon the bodies of recently executed criminals; but for any account of these operations we cannot afford room in our limited pages.

The effects of galvanism upon the functions of secretion are the most remarkable as well as the most inexplicable. That it acts especially, and in a peculiar manner, upon the gastric juice, a fluid essentially subservient to the process of digestion, there can be no doubt. Perhaps the various functional parts of the body form a sort of galvanic battery, by which a regular circulation of this subtile and mysterious fluid is kept up. On the supposition that such is the case, galvanism has been applied with good effect in medicine, in the cure of nervous disorders. Tic doloureux, which is a chronic derangement in the nervous energy, has been subjected to the influence of galvanic currents, and these, in particular cases, have completely removed the complaint. It is perhaps necessary, by way of precaution, to say that all such applications ought only to be made under the special direction of a skilled medical practitioner.

Galvanism has lately been applied to the protection of plants from worms and slugs, as appears from the following notice in a Liverpool newspaper:—"The protector consists of a conical ring of zinc about four inches in height, the top end flanked off about a quarter of an inch, and cut into numerous vandyked points; and immediately under is a ring of copper neatly fitted. The bottom of the zinc ring is pressed into the soil until the lower edge of the copper ring is an inch and a half above the surface, care being taken to enclose within the ring the stems of such plants as require them, otherwise the mollusca will find a road to them by the stems. The mollusca may crawl up the zinc with impunity, but on coming in contact with the copper, will receive a galvanic shock and fall to the ground. The apparatus acts in wet or dry weather, and is always in operation. Its appearance is like a flower-pot, and it is cheap and durable. After a trial of twelve months by Mr. Cuthbert, the inventor, he found that not a plant to which it was applied was injured."

Electrotyping.—In 1839, the galvanic principle, in relation to the deposition of metal from a metallic solution, was applied by Mr. Thomas Spencer of Liverpool, to the multiplying of plates of engraved copper, medals, &c. The nature of this most ingenious discovery, which was first brought into public notice at a meeting of the Liverpool Polytechnic Society, (Sept. 12, 1839,) will be best understood by describing the process which is now ordinarily pursued.

We take a trough or box, which may be represented by Fig. 7. This box is divided lengthwise by a thin partition P, composed of sycamore, that being a porous and durable material. C is a copper plate suspended in one of the cells by a wire attached to an upper rod of metal R, traversing the mouth part of the box. In the other cell is similarly placed a plate of zinc, nearly the size of the copper. The zinc is similarly suspended by a wire from the traversing rod above. A wire passing over direct from the copper to the zinc, would answer the same purpose of communication, but the plan of an intervening rod with attaching screws is found to be more convenient. Into the cell containing the copper we put as much water as will about four-fifths fill it; then into this we place crystals of sulphate of copper, which soon dissolve and form a solution. Into the other cell, containing the piece of zinc, we place a similar quantity of water, into which pulverized sal ammoniac is put, so as to form a solution likewise. The preparatory process may now be said to be complete; but, unless the copper has been previously prepared to receive the deposition on one part only, the deposition would take place all over it. To guard against this, the copper, before being placed in the trough, must have been coated on the back and edges with a mixture of sealing-wax dissolved in spirits of wine. This mixture or varnish may be of such a consistency as may be laid on with a camel-hair pencil. The copper is not put into the trough till the varnish is hard. The wire of the copper must likewise be varnished; and it is also necessary explain, that the wire must be flattened at both extrem es—one extremity being soldered to the back of the copper, and the other fastened beneath the screw to the rod. The wire for the zinc is to be flattened at the extremities, and attached in the same manner. No varnishing is necessary on the zinc.

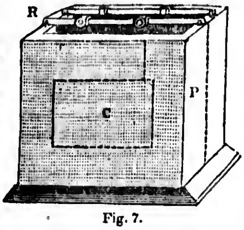

Fig. 7.

We have now described all that requires to be done in the first instance; and the trough may be put aside to allow the process time to operate. This operation will consist of a galvanic current, commencing with the action of the sal ammoniac upon the zinc, proceeding up the wire, and through the rod to the copper plate; porosity in the dividing partition being also essential to the current. As the action proceeds, it will be observed that an effervescence is going on in the zinc cell; and this indicates that the deposition of metal from the sulphate of copper is taking effect on the plate. The length of time occupied in perfecting the process will vary from four to six days; but during this interval it will be necessary to add fresh material, both of sulphate of copper and sal ammoniac. In some boxes a small shelf is put, to contain the sulphate of copper during its dissolution. The copper plate may be occasionally examined, to ascertain the extent of the deposition; and when this deposition is as thick as a shilling, it may be separated from the plate. We have now procured a fac simile of the engraved copper plate *in relief*—in point of fact, a substantial piece of copper formed from a solution. The copy in relief is of no value in the arts; and to be of use, it must be subjected to a fresh process, in which *it* receives the deposition. This second deposited cake of metal is a *fac simile* or duplicate of the original plate; and by thus using the relief plate again and again, we may obtain any number of engraved copper plates of the same subject that we may think proper. As engraved copper plates are soon worn out by printing, the value of the above simple and inexpensive means of creating duplicates is very evident. Such is the fidelity of the process, that the slightest scratch on the original plate will be shown on the duplicate copy.

Various other objects may be multiplied by this kind of *electrotyping*, as it has been named; for example, dies for seals, medals, plaster-casts, &c. Mr. Barclay, a seal-engraver in Gerrard Street, Soho, London, has carried the practice of electrotyping metal seal stamps to great perfection. A small tract which he has published on the subject, furnishes the following observations on the method to be pursued. It will be noticed that he multiplies the dies or seals from impressions taken in sealing-wax:—"The paper on which the impressions are to be taken should be thick and soft, like that on which music is printed, dried over the light, and spread flat—the wax should not be put into the light, or allowed to flame; when on the paper, it must be kept fluid, while by stirring to the required size and gradually diminishing the heat, all bubbles are removed: when nearly cool, make the seal of the same temperature as the wax, or sufficiently warm as to be bearable on the back of the hand. If the seal be too hot, the impression will be blackish, and unequal on the surface; if much too hot, the wax will adhere. A little dry vermilion, sparingly powdered over the seal with a camel's hair brush, will greatly assist in preventing adhesion, and considerably improve the appearance of the impression, without any apparent diminution of its sharpness; dry black-lead will answer also for this purpose. After powdering, strike the side of the seal smartly against the table, in order to shake off the loose and coarse particles. The seal must be put down and taken up perpendicularly and without hesitation; before the wax is cold a weight should be put round it on the paper to keep it flat, by means of a small box, wine-glass or tumbler, according to the size of the impression. The facility of taking impressions, or casts, in this or other non-conducting substances, called the attention of Mr. Murray, in January, 1840, to the best means of obtaining upon them conducting surfaces, and to him we are indebted for the use of plumbago, or black-lead, a discovery not the result of accident, but of judgment, and without which the electrotype would be deprived of half its advantages.

"In the application of black-lead, much misconception has arisen as to the quantity requisite to insure a deposit. On sealing-wax, barely a tint is sufficient. On waxed plaster, more is required; and it is liable to be washed off if disturbed in the solution before it is covered by the deposit; and this is also the case with fruit and vegetables, with smooth skins. Having the jar, porous tube, and zinc, with copper wire attached, take a wax impression, make the end of the wire warm, and press it against the side of the impression till it adheres firmly. Then take a soft tooth-brush, dip it into a little dry black-lead, and with it gently brush the wax every direction, until the black-lead is equally distributed. Scrape a small portion of the metal inserted into the wax clean; and, on the point of a knife, take a little damp black-lead, with which make good the contact between the black-leaded surface and the copper wire; varnish over the remainder of the wire, and those portions of the impression where a deposit is not required, except that part covered with the damp black-lead; place the whole in the apparatus as before the deposit will shortly commence on the damp black-lead, and subsequently spread over the whole surface not covered with varnish. When the deposit has obtained sufficient thickness, hold the wax in warm water, till it becomes gently heated, when it may be readily separated from the metal. The deposit will always accumulate most rapidly at the edges; therefore, to insure as great a thickness as possible on the subject, the extremity should be well varnished; but if the action be violent, it will extend over the varnish; in that case it should be taken out and washed in cold water, and that portion only on which deposit is not wanted, wiped dry, and again varnished.

"Plaster casts (Mr. Barclay proceeds to mention) are, next to seal impressions, most easy of attainment. To electrotype from these, it is necessary to soak them in melted white wax, stearine, or tallow, which is thus best effected:—Take a shallow vessel, in which put a little wax, and hold it over the flame of a lamp; when melted, drop in the plaster cast, face upwards, taking care the wax does not overflow the surface; in a short time, by keeping it warm, the wax will ascend in the plaster, and when it is observed to have equally pervaded the surface, it must be removed and placed on a piece of blotting-paper, to absorb the superfluous wax, which it will better effect by being kept warm for a short period. It must then be laid by for twelve hours at least, after which time it may be well brushed with a soft brush and black-lead, without fear of injury. To attach the copper wire, use melted bees-wax at the back of the cast, having a bent portion of the wire near the surface, with which to make the connection with the black-leaded surface, or the wire may be made to surround the cast. As in the case of the wax impression, varnish the wire and the parts of the cast on which no deposit is required. Having equally oiled the subject, a plaster cast may be made as follows:—Take *fresh* plaster, and having a little water in a basin, drop from between your finger the plaster into it, pour off the superfluous water, and then stir it gently; take a hog-hair brush and brush a portion of the plaster well into the subject, then pour as much as will make the required thickness. Coins and medals can be readily copied by means of sealing-wax impressions; if the relief be very prominent, they are best attained from plaster casts; a coin can be silvered, or gilt, as hereafter described, or bronzed, by brushing it well with black-lead, then making it hot, and again brushing it. Various degrees of heat will give different tints; should the first attempt not give satisfaction, it may be well washed with hot water and soap, and the process repeated. Having well black-leaded a wood-engraving, take a strip of tin-foil, and bind it close round the sides, carefully pressing the edge all round, to bring it in contact with the black-leaded surface; then, with the wire attached to the zinc, which being long enough to surround the whole, bind it tight, and varnish as before. Wood, from its buoyancy, will float, unless a firm, stout wire be used to retain it in its vertical position, which is essentially requisite; for, if it incline at an angle, with the lower part at the greatest distance from the zinc, the new deposit will be formed in ridges. After this has once occurred, it will be impossible to obtain an equal deposit: because the copper accumulates only on the most prominent parts, and the hollows remain proportionately thin, as at the first deviation from an equal surface. This applies to every kind of deposit, whether seals, medals, or copper plates. A similar result will also take place in a weak solution, or in a deep trough, from the liquid losing its particles of copper, and becoming lighter, rising in a regular channel to the surface; the deep trough giving space for a descent of the denser portion of the liquid containing the metal in solution. These copies from wood-engravings have an advantage above the ordinary process for obtaining duplicates for printing, being made perfect direct from the wood, whereas the stereotype copies frequently require re-touching by the engraver, arising from the friability of the plaster from which they are cast."

Mr. Smee, whose researches in electro-galvanism are well known to the philosophical world, has suggested a still more extraordinary kind of electrotyping, namely, the making a copperplate engraving without an engraving in the first instance. He describes it in a paper in the *Philosophical Magazine*, No. 105, from which we extract the following passage:—"First, draw the required subject upon a smooth copper plate, with any thick varnish or pigment insoluble in water, and then expose the plate in the usual way to the influence of the current, when first copper will be thrown down upon the uncovered parts and will gradually grow over the drawing, and the electrotype, when removed, will be ready for printing. Very thick oil paint should be used, else sufficient depth will not be obtained to hold the ink. As an additional advantage to its cheapness, this method does not require the artist to reverse the design. An opposite effect to this may be produced by placing a piece of copper similarly drawn upon at the oxygen end of the battery, when the metal will be acted upon, leaving a drawing in basso-relievo."

Electric Telegraphs.—Galvanism, and its twin-principle electro-magnetism, have performed other wonders in application to the arts. One of the most interesting of their powers in this respect, is that of transmitting telegraphic signals through wires to any assignable distance. The general principle on which such an operation is founded, is that of causing the galvanic current to deflect or turn a needle poised on a centre, and by certain arrangements the needle is made to point to any letter on a dial-plate. The discovery of this kind of telegraphic action is by no means new. From a passage in Arthur Young's Travels in France, published in 1787, it appears to have been at that period known, and to some extent practised, by a M. Lomond. But like many other remarkably ingenious devices, it was long in being heard of popularly after science had established its capabilities. Even now, it is one of those practical improvements which, to a certain extent, remain under public suspicion. Twelve years ago, Dr. Ritchie made some attempts to complete the plan of an electric telegraph; Sir Humphry Davy and others also engaged in a similar undertaking. In 1837, the model of an apparatus for communicating by galvanic action, was exhibited by Mr. Alexander before the Society of Arts in Edinburgh; and this, as far as we know, was the first time the thing was brought in a tangible form before the public. Mr. Alexander's telegraph was in the form of a chest, containing thirty copper wires, answering to the twenty-six letters of the alphabet, three points, and an asterisk to denote the termination of a word. At one end, in connection with the wires, were keys like those of a piano-forte, and underneath these were a pair of plates, zinc and copper, forming a galvanic trough: at the other extremity of the wires were thirty steel magnets, and, any one of these being affected by the electric agency produced by touching the key, it was turned to the right or left, and unveiled a particular letter. On removing the finger from the key, the magnet sprung back, and the letter was screened from observation. Thus any letter could be instantaneously exposed, or words spelled letter by letter, according to the will of the operator. As galvanism requires a complete circuit for its operation, it might be supposed that a duplication of the thirty wires would have been necessary, but by a happy arrangement of Mr. Alexander, with one return wire to serve for all, this encumbering of the apparatus was avoided.

Since this time, considerable improvements have been effected on the mechanism of electric telegraphs, by Professor Wheatstone and Mr. Cook, one material object having been the reduction of the number of wires, which has been effected with a surprising degree of skill. A writer in *Chambers's Edinburgh Journal*, (July 25, 1840,) thus describes what he saw of the process on the occasion of a visit to the professor's class-room at King's College, London:—"The professor showed two varieties of the apparatus, one being the latest invention, and the most deeply interesting from its simplicity. It may be briefly described as consisting of two small galvanic troughs or batteries; four lengths of copper wire; an object resembling a brass clock, with a small opening or dial on the surface sufficient to show a single letter at a time; close by this case of mechanism stood an upright pivot of brass about three inches high, having a circular top inscribed with the letters of the alphabet all round, and from each letter a spike pointing outwards like the spokes from a capstan. The whole stood on a table, except the wires, which, being four miles in length, and warped in numerous convolutions through the vaults of the college, were observable only at their extremities in connection with the apparatus.

"With respect to the principle of the process, it will suffice to state, that the electricity or galvanic property generated in the batteries, was made to proceed along the wires, and in its passage to affect the mechanism in the case. In the construction of this mechanism, the great merit of the invention consists. It is a beautiful combination of brass wheels, and other details, the object of which is to produce a desired letter or figure at the exterior opening or dial. To bring any particular letter into view, the capstan is turned by the finger till the metal point projecting from a similar letter upon it is made to touch a corresponding point near the side of the case. Thus, there is a sympathy, as I may call it, between the letters in the case and the letters on the capstan. A touch of the point opposite L, will bring L into view on the dial, and so on with any other letter. Nothing can be more perfect, or apparently simple. To appearance, the letters can be exposed at the rate of two in every moment of time. A lady, turning the capstan with her finger, brought into view the word L o n d o n, in the time it could be uttered letter by letter, although the idea had to travel through four miles of wire.

"In the transmission of the electric influence through the wires of this or any other apparatus, distance is of no consequence as respects time, for electricity is supposed, with some degree of probability, to travel with the velocity of light, or 192,000 miles in the space of a second. In point of fact, therefore, no longer time would be occupied in transmitting intelligence to the uttermost ends of the earth, than would be required for sending it across a room or a table. Distance is a matter for consideration only as regards expenditure of galvanic force. The electric agency has a tendency to weaken in its progress, according to circumstances, and this must necessarily be provided for by increasing the number of batteries to the desired amount and power. It has been supposed that the difficulty of perfectly isolating and preserving the wires from injury in their course, would be an insuperable bar to their establishment on an effective footing; but fears need be no longer entertained on this score. Each of the four wires in the above apparatus is wrapped round with a well-rosined thread, and the whole are then tied together with a cord, possessing a similar coating, so as to present the appearance of a tightly-bound rope. This it is proposed to place in a small iron tube, like that used for bringing gas into houses, and the tubes united to any length, are laid below the ground, or in a wooden case on the surface, to preserve them from injury. Yet another difficulty here presents itself. What if the rope, or any particular wire, should be fractured somewhere in its course? How would the precise point of injury be discoverable? This the professor has likewise provided for, as far as it possibly can be. He proposes that there shall be a signal-case at an interval of every ten miles along the whole line, and therefore should any injury be sustained by the wires, it will be speedily discovered in what portion it has taken place, and a new and complete section of rope inserted in connection with the other pieces. To avoid a very remote chance of delay in the transmission of intelligence from this cause, it would be easy to lay two sets of wires, one of which could be employed while the other was in course of being repaired.

"The capabilities of the principle have been fully tested in a practical manner on the line of the Great Western Railway. In September, 1839, when the wires of the electric telegraph were carried as far as West Drayton, a distance of fifteen miles, the following account was given of it in one of the London papers:—

"'The space occupied by the case containing the machinery (which simply stands upon a table, and can be removed at pleasure to any part of the room) is little more than that required for a gentleman's hat-box. The telegraph is worked by merely pressing small brass keys, (similar to those of a keyed bugle,) which, acting by means of galvanic power upon various hands placed upon a dial plate at the other end of the telegraphic line, as far as now opened, point not only to each letter of the alphabet, (as each key may be struck or pressed,) but the numerals are indicated by the same means, as well as the various points, from a comma to a colon, with notes of interrogation and interjection. There is likewise a cross (+) upon the dial, which indicates that where this key is struck, a mistake has been committed in some part of the sentence telegraphed, and that an erasure is intended. To a question—such, for instance, as the following: "How many passengers started from Drayton by the ten o'clock train?"—the answer could be transmitted from the terminus to Drayton and back in less than two minutes. This was proved on Saturday. This mode of communication is only completed as far as West Drayton station, which is about 13½ miles from Paddington. There are wires (as may be imagined) communicating with each end, thus far completed, passing through a hollow iron tube, not more than an inch and a half in diameter, which is fixed about six inches above the ground parallel with the railway, and about two or three feet distant from it. It is the intention of the Great Western Railway Company to carry the tube along the line as fast as the completion of the rails takes place, and ultimately throughout the whole distance to Bristol. The machinery, and the mode of working it, are so exceedingly simple, that a child who could read would, after an hour or two's instruction, be enabled efficiently to transmit and receive information.'

"It being thus ascertained, by practical working, that the electric telegraph can perform all that its designers have proposed, it only remains that it should be spread in different directions over the country, or at the least laid in communication from London along the great lines of thoroughfare.

"The method of working the apparatus will be readily understood. At each extremity of the line of rope—for it would work both ways—there would be an office for receiving and communicating intelligence, at a price conformable to the extent of the message. Being despatched from one end, the communication would be instantaneously received at the other by an officiating clerk, and forthwith made known by a note to the party concerned. Thus intelligence of the rise and fall of stocks, foreign news, orders for goods, or any other species of communication of an urgent nature, might with the utmost facility, and at a trifling cost, be transmitted to any imaginable distance."

Still more lately the galvanic principle has been applied to the regulation of clocks, with a view to preserve a uniformity of motion in all the clocks in a town, or in a public office, to which wires may be led. The manner in which this is accomplished is now (or was lately) exhibited at the Polytechnic Institution in London.

ELECTRO-MAGNETISM.

Before noticing this electric quality, it seems necessary to give a short explanation of magnetism, or the properties of the magnet. Anciently, there was found in Magnesia, in Asia, a certain kind of iron ore, in which the remarkable property was discovered of attracting other kinds of iron or steel; this ore afterwards received the name of *loadstone*, but from Magnesia, the place in which it was originally found, we derive the terms *magnet* and *magnetism*. Latterly, loadstone ore has been discovered in Siberia, Sweden, Piedmont, the kingdom of Naples, and various places in North America. This magnetic iron ore, which is of an excellent quality for making steel, is of a dark colour, and generally occurs crystallized in the form of regular octahedrons; its attractive quality is strengthened by exposure to the air. It has likewise been found that meteoric stones, which are composed of iron and nickel, possess a strong magnetic virtue resembling the loadstone of the earth.

Although the ancients were acquainted with the attractive property of the loadstone, it was left for the moderns to discover that the property could be communicated to the iron which the magnetic stone attracted. Since this important discovery was made, artificial magnets, composed of bars or slips of iron, have been easily constructed; and these possess all the attractive virtues of the loadstone itself. Besides iron, a few other metals are susceptible of being attracted, such as pure cobalt and nickel; but the power is weak and of no avail in the arts.

Independently of attracting iron, magnets possess the extraordinary property of *polarity*. When a small magnetic bar is poised at the centre, so as to be free to move in any direction, one end points towards the north pole of the earth and another towards the south. It is true, there are variations in the direction at different parts of the globe, but with these slight exceptions, the magnetic needle, as it is called, offers one point to the north and another to the south. Hence the application of the compass to navigation. (See the Article Ocean.) From what will be immediately mentioned, no room is left for doubting that the magnetic virtue is referable to electricity. When two magnets are brought near together, the north pole of the one repels the north pole of the other, and the same with the two south poles; but poles of opposite names attract each other. These phenomena are evidently analogous to the demonstrations of positive and negative electricity.

Artificial but permanent magnets are usually made in nearly the form of a horse-shoe, by which the two poles are brought near each other, and are connected at the extremities by a small piece of soft iron called the keeper, which serves to increase the strength of the magnet when not in use. A magnet of this form is represented in Fig. 8. M is the magnet, furnished with a ring R at the top, by which it may be suspended. K is the keeper, into which a hook is fixed supporting weights beneath, so as to exhibit the strength of the magnetic influence.

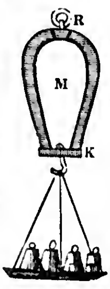

Fig. 8.

In 1819, Professor Oersted of Copenhagen established a most interesting relation between magnetism and voltaic electricity, thus laying the foundation of electro-magnetism. He discovered that when a wire conducting electricity is placed parallel to a magnetic needle properly suspended, the needle will deviate from its original or natural direction. This deviation follows a regular law.

1. If the needle is *above* the conducting wire, and the positive electricity goes from right to left, the *north* end of the needle will be moved *from* the observer. 2. If the needle is *below* the wire, and the positive electricity passes as before, the *north* end of the needle will be moved *towards* the observer. 3. If the needle is in the same horizontal plane with the wire, and is between the observer and the wire, the *north* end of it will be *elevated*. 4. If the needle is similarly placed on the opposite side, the *north* end of it will be *depressed*. In these two experiments the needle must be very near the wire. From these simple facts, Mr. Oersted concludes that the magnetical action of the electrical current has a circular motion round the wire which conducts it.

The metallic wire to be made use of in this experiment, should be two or three feet in length, to allow of its being bent in various directions. It is called the *conjunctive wire*. Ampère and Davy discovered two very important facts soon after Oersted had made his experiments public—namely that the conjunctive wire itself becomes a magnet, and that magnetic properties might be communicated to a steel needle, not previously possessing them, by placing it in the electric current; and the degree of magnetic power thus communicated, Davy showed was always proportional to the quantity of electricity transmitted through it. When the conjunctive wires of two distinct galvanic batteries are made to approach each other, they exhibit magnetic attractions and repulsions. Two wires of copper, silver, or any other metal, connecting the extremities of two galvanic troughs, being placed parallel to each other, and suspended so as to move freely, immediately attract and repel each other, according as the directions of the currents of electricity flowing through them are the same or different. Upon this experiment is founded the most plausible theory of magnetism, namely, that it arises from the attractions and repulsions of currents of electricity, constantly circulating round every magnet. This is conceived to explain the reason why the magnetic needle places itself at right angles to a wire conducting electricity, namely, that the current passing along the wire may coincide with that circulating round the magnet.

From these and other experiments, it seems clearly proved that electricity and magnetism are identical. A permanent magnet is supposed to be thus constituted:—It is a mass of iron or steel, round the axis of which electric currents are constantly circulating, and these currents attract all other electric currents flowing in the same direction, and repel all others which are moving in an opposite direction. The electric currents flow round every magnet in the same direction in reference to its poles. For instance, if we place a magnet with its north pole pointing to the north, in the usual position of the magnetic needle, the current of electricity flows round it from west to east (that is, the direction in which the earth and other planets revolve round the sun), or, on the eastern side of the magnet, it is moving downwards, on the western side upwards, on the upper side from west to east, and on the lower side from east to west. This is found to be a uniform law. To complete the view of this doctrine, it remains only to explain the influence of the earth on the magnet, by which the needle is kept always in one position, nearly coinciding with the meridian. It is conjectured that currents of electricity, analogous to those which circulate round every magnet, are constantly flowing round the globe, as the current of electricity in a galvanic apparatus moves in an unbroken circuit from the negative to the positive pole, and from it, by the connecting wire, round again to the negative pole. The direction of these currents is inferred to be the same as has been stated with regard to artificial magnets; and it is simply by the attractions and repulsions of these terrestrial currents, bringing the currents round the needle to coincide with them, that the latter always points to the north.

By means of a galvanic battery, iron may be temporarily magnetized, that is, endued with an attractive power, so long as the iron is in connection with the seat of power in the trough. When a metallic wire of great length is coiled round the iron, forming what is called a *helix*, the magnetic power of the magnet is correspondingly increased. The wire requires to be previously coated with silk varnished, to prevent the electric current passing from surface to surface of the metal. A magnet of this kind is usually formed in the shape of a horse-shoe, as in the case of the permanent magnet already mentioned. When suspended so as to present the extremities downward, and the galvanic communication is established, the magnetic power is at once excited, and a piece of iron held to the extremities will instantly be attracted and adhere. On breaking the communication with the trough or battery, the magnetic virtue is destroyed, and the piece of iron which was attracted drops. Electro-magnets have thus been made of great power; one having been formed which would sustain a weight of 2063 pounds, or nearly a ton. There is, however, no assignable limits to the power of the apparatus.

Electro-magnets, like those formed permanently, possess opposite poles, one attracting and another repelling. From this property the attempt has been made to give rotation to a wheel, consisting of cross bars of iron; one pole attracting a bar and another repelling it, and thus, by a rapid alternation of poles, obliging the wheel to revolve. Another plan has consisted in reiterated attractions, with intervals during which the attraction is destroyed; in other words, the attraction being destroyed, as relates to one bar of the wheel, that bar is liberated and allowed to go on, while the attraction is being exerted on the next bar.

Electro-Magnetic Machines.—The possibility of moving small pieces of mechanism by electro-magnetic action, to which allusion has just been made, has been known for a number of years; but as far as we have heard, the principle was not applied practically till 1837, when it was adapted by Professor Jacobi of St Petersburg, to the propulsion of a small vessel on the Neva. Under the auspices of an imperial commission, the first attempt was made on the 25th of September, 1838. A galley or boat, 28 feet in length and 7½ in breadth, was provided with paddles similar to those of a steam-vessel, and the apparatus was put on board. The action was produced from 320 pairs of plates, arranged along the sides of the boat, and room was left for twelve persons. Owing to imperfections in the arrangements, the attempt to propel the vessel with its burden of apparatus and passengers was less successful than was expected; nevertheless, the professor succeeded in making the boat proceed against the stream, and the speed attained in still water was three English miles per hour. In this and other efforts of Professor Jacobi, his plan consisted in rapidly reversing the poles during the action.

While Jacobi was busy with his experiments in Russia, mechanicians in England and America were pursuing a similar course of investigation. In March, 1837, Mr. Davenport exhibited at New York an electro-magnetic machine of considerable power; and more lately great advances in the art of electro-magnetic motion were made in Germany by Stoehrer of Leipsic, and others, on the principles of Jacobi; and in some instances with remarkable success. According to the accounts given of their experiments, it appears that the power of the electro-magnetic machines is increased in proportion to the squares of the number of the elements of the batteries. We regret to say that this, like all other enunciations on the subject, wants the confirmation of practical men; and up till the period we now write (December, 1841) no trustworthy account has reached us, as respects either the ratio of the magnetic power or the expense at which it can be obtained.

Machines constructed on the principle of alternate attraction and repulsion being liable to several objections, those in which a reiterated series of attractions are employed are more likely to answer the end of practical working. A machine of this kind was contrived by Mr. R. Davidson, of Aberdeen, in 1839, and brought into notice by the following letter from Professor Forbes, of King's College in that city, to Professor Faraday (Oct. 7, 1839), which was published in the *London and Edinburgh Philosophical Journal*:—"Having seen a notice from Mr. Jacobi sent by you to the *London and Edinburgh Philosophical Magazine* regarding the success of his experiments on the production of a moving power by electro-magnetism, I am sure it will give you pleasure to know that a countryman of our own, Mr. Robert Davidson, of this place, has been eminently successful in his labours in the same field of discovery. For, in the first place, he has an arrangement by which, with only two electro-magnets, and less than one square foot of zinc surface (the negative metal being copper), a lathe is driven with such velocity as to be capable of turning small articles. Secondly, he has another arrangement by which, with the same small extent of galvanic power, a small carriage is driven, on which two persons were carried along a very coarse wooden floor of a room. And he has a third arrangement, not yet completed, by which, from the imperfect experiments he has made, he expects to gain very considerable more force from the same extent of galvanic power than from either of the other two.

"The first two of these arrangements were seen in operation by Dr. Fleming, Professor of Natural Philosophy in this University, and myself, some days ago; and there remains no doubt on our minds, that Mr. Davidson's arrangements will, when finished, be found available as a highly useful, efficient, and exceedingly simple moving power. He has been busily employed for the last two years in his attempts to perfect his machines, during all which time I have been acquainted with his progress, and can bear testimony to the great ingenuity he has shown in overcoming the numberless difficulties he has had to encounter. So far as I know, he was the first who employed the electro-magnetic power in producing motion by simply suspending the magnetism without a change of the poles. This he accomplished about two years ago. About the same time, he also constructed galvanic batteries on Professor Daniell's plan, by substituting a particular sort of canvas instead of gut, which substitution answers perfectly, is very durable, and can be made of any form or size. And, lastly, he has ascertained the kind of iron, and the mode of working it into the best state for producing the strongest magnets with certainty.

"The first two machines, seen in operation by Dr. Fleming and myself, are exceedingly simple, without, indeed, the least complexity, and therefore easily manageable, and not liable to derangement. They also take up very little room. As yet, the extent of power of which they are capable has not been at all ascertained, as the size of battery employed is so trifling and the magnets so few; but from what can be judged by what is already done, it seems to be probable that a very great power, in no degree [illegible] inferior to that of steam, but much more manageable, much less expensive, and occupying greatly less space, if the coals be taken into account, may be obtained.

"In short, the inventions of Mr. Davidson seem to be [illegible]sting to railroad proprietors in particular, that it would be much for their interest to take up the subject and be at the expense of making the experiments necessary to bring this power into operation on the great scale, which, indeed, would be very trifling to a company, while it is very serious for an individual by no means rich, and who has already expended so much of his time and money for the mere desire of perfecting machines which he expected would be so beneficial to his country and to mankind. For it deserves to be mentioned, that he has made no secret of his operations, but has shown and explained all that he has done to every one who wished it. His motives have been quite disinterested, and I shall deem it a reproach to our country and countrymen if he be allowed to languish in obscurity, and not have an opportunity afforded him of perfecting his inventions and bringing them into operation, when they promise to be productive of such incalculable advantages."

The following notice of Mr. Davidson's operations afterwards appeared in the *Aberdeen Constitutional* newspaper, November 6, 1840:—

"Mr. Davidson's invaluable invention is now set down, by common consent, as the desideratum that has been wanting to perfect the power of locomotive agency. Several thousands have visited the exhibition, among whom was Professor Hamel, whose opinion was decidedly favourable to the principle. At a meeting of the British Association of Science, held at Glasgow the other week, Professor Jacobi read a paper on the power of electro-magnetism, which seemed to point to some great improvement in the science: but the principle on which Mr. Davidson's machine proceeds is altogether different from that on which Jacobi's experiments were made. Professor Jacobi produces motion by changing the poles of the magnets, Mr. Davidson by cutting off the galvanic current at given points—the power alternating, as the rotation proceeds, from a neutralized magnet to a newly charged one. In both experiments, it has been clearly demonstrated that the power of the magnet is increased by increasing the diameter, and adding to the length of the helix. The power may be also increased by increasing the sizes of the bars. On the principle of changing the poles of the magnet, the advantages of this increase of power could not be made so fully available as on the principle of neutralizing the magnets—there being in the one case a back action, which retards the momentum power, while in the other the rotation is constant, which tends to increase that power. According to the proportions assigned by Jacobi, an almost indefinite amount of power may be obtained by increasing the diameter of the rods, and the quantity of wire or helix; this, too, constitutes an index of that power so simple and practicable, that it may be regulated to a fraction."

In concluding the subject of Electricity, in the various methods in which it is artificially demonstrated, it is necessary to remind the reader that the science, in all its departments, is still in its infancy, and offers great scope for the enterprise of ingenious students.

[WORKS ON ELECTRICITY, GALVANISM, AND ELECTRO-MAGNETISM.

The following works on the subject of Electricity may be mentioned as deserving the reader's notice.

Dr. Priestley's "*Introduction to the Study of Electricity,*" is excellent for the uninitiated; but it is out of print, and the plates being lost, is not likely to be brought again before the public. As a substitute for this, the sixth volume of the "*Scientific Dialogues*" may be fitly used, in which are accumulated all the common and most interesting experiments; which, being repeated, with the directions given for their performance, the young electrician will afterwards find no difficulty in the pursuit of electrical knowledge in all its branches.

"*An Essay on Electricity,*" &c., by George Adams, with improvements by W. Jones, is a valuable compilation of all the material and experiments in this branch of science.

"*A Complete Treatise on Electricity, in Theory and Practice,*" in 3 vols., 8vo, by Tiberius Cavallo, is a very proper work for those who are desirous of an extensive knowledge in every department of electricity. The first volume treats of the laws and theory of electricity, and contains a full detail of the practical branches of the science. In the second, the author describes a number of new experiments, enters rather at large on the subject of medical electricity, which was in much more estimation twenty years ago than it is at present, and treats of the electrical properties of the torpedo, &c. In the third volume will be found, among other interesting subjects, a particular account of what was then deemed *animal electricity*, but now denominated galvanism.

"*The History and Present State of Electricity,*" by Joseph Priestley, LL.D., F.R.S., &c., will always be a stock book, valuable as a work of reference, and highly interesting to those who would wish to trace the progress of the science to that advanced period in which it was when the author wrote.

"*Principles of Electricity, containing divers new Theorems and Experiments,*" &c., by Charles Viscount Mahon. This work was published on the occasion of the dispute which, more than thirty years ago, engaged the attention of electricians, respecting the best mode of securing buildings from the effects of lightning.

"*Practical Electricity and Galvanism,*" by John Cuthbertson, Philosophical Instrument Maker, contains an extensive series of interesting experiments.

"*Elements of Electricity and Electro-Chemistry,*" by Geo. Singer; "*Miscellaneous Experiments and Remarks on Electricity,*" &c., with a description of an electrometer on a new construction, by A. Brook; and "*New Experiments in Electricity,*" wherein the causes of thunder and lightning are explained, &c., also a description of a doubler of electricity, and the most sensible electrometer, &c., by the Rev. A. Bennett, F.R.S., are excellent treatises, and may be consulted with pleasure and improvement by the student in electricity.

The most elegant and scientific, and at the same time elementary account of the phenomena of electricity, explained on the simple theory of Franklin, is that contained in the Supplement to the former edition of the *Encyclopædia Britannica*, under the head Electricity, which was drawn up by the late Professor Robinson.

GALVANISM.

Of the writers on this branch of science there is but little to be said: it is even yet too much in its infancy to have admitted of a regular elementary treatise; but independently of the third volume of Cavallo's Electricity, to which we have before referred, the student should be informed of the following works:

"*Experiments on Animal Electricity, with their Application to Physiology,*" &c., by Eusebius Valli, M.D.

"*Experiments and Observations Relative to the Influence lately discovered by M. Galvani, commonly called Animal Electricity,*" by R. Fowler.

"*An Account of the Late Improvements in Galvanism, with a set of Curious Experiments,*" &c., by John Aldini. These tracts contain many judicious, well conducted, and highly interesting experiments; but they relate wholly to Galvanism, and were all written prior to the discoveries since made by means of Volta's batteries. *Am Ed.*]

METEOROLOGY—THE WEATHER.

Meteorology is the science of the Weather, and treats of the phenomena which occur in the atmosphere, their causes and effects. Men in all ages of society have been led, by motives of necessity or comfort, to study the indications of the weather in the different appearances of the skies. The mariner, the shepherd, the husbandman, and the hunter, have the strongest motives to examine closely every varying appearance which may precede more important changes. The result of these observations forms a body of maxims, in which facts are often stated correctly, but mixed with erroneous deductions and superstitious notions, such as the credulity of ignorant people always renders them ready to adopt. Hence the disposition to refer the ordinary changes of the weather to the influence of the moon, and even the stars; and to look for signs of approaching convulsions, even in the moral world, in horrid comets and strange meteors. The progress of science, which tends to separate the casual precursors from the real causes of phenomena, refutes these false reasonings, dissipates the empty terrors to which they give rise, and aims, by more patient, long-continued, and wide-extended observations, to deduce the general rules by which the phenomena of the atmosphere appear to be regulated.*

Meteorology, therefore, taken as a distinct branch of knowledge, rests on no idle conjectures or imaginary fears, but has its foundations in the ascertained truths of physical science. The phenomena to which it refers are accounted for by natural laws disclosed to us in the study of chemistry, electricity, the atmospheric properties, optics, acoustics, heat, and other departments of physics. Of all branches of learning, none, perhaps, is more serviceable in clearing the mind from superstition than that now before us; and, on that account alone, independently of all other considerations, we are anxious that it should be extensively understood among the classes whom we have the pleasure to address. That nothing may be left to doubt, we commence by a recapitulation of the leading facts connected with the atmosphere, from preceding treatises, along with some new matter of information.

THE ATMOSPHERE.

The atmosphere is an invisible aëriform fluid, which wraps the whole earth round to an elevation of about forty-five miles above the highest mountains. This great ocean of air, as we may call it, is far from being of a uniform density throughout its mass. At and near the level of the sea it is most dense, in consequence of the pressure above. As we ascend mountains, or in any other way penetrate upwards, the air becomes gradually less dense; and so thin is it at the height of three miles, as, for instance, on the summit of Mont-Blanc, one of the Alps, that breathing is there performed with some difficulty. Beyond this limited height, the density of the air continues to diminish; and at the elevation of about forty-five miles it is believed to terminate. So dense are the lower in proportion to the higher regions, that one-half of the entire body of air is below a height of three miles, the other half being expanded into a volume of upwards of forty miles.

The extreme height of the atmosphere is not observable from the situation in which we are placed on the earth. Our eye, on being cast upwards, perceives only a vast expanded vault, tinted with a deep but delicate blue colour; and this in common language is called the heavens or the sky. The blueness so apparent to our sense of sight is the action of the rays of light upon the thin fluid of the upper atmosphere, and the brightness is in proportion to the absence of clouds and other watery vapours. In proportion as the spectator rises from the surface of the earth, and has less air above him, and that very rare, the blue tint gradually disappears; and if he could attain a height at which there is no air, say fifty miles above the level of the sea, the sky would appear dark or black. Travellers who have ascended to great heights on lofty mountains, describe the appearance of the sky from these elevated stations as dark or of a blackish hue.

The atmosphere exerts a certain pressure on all objects, the degree of pressure being of course in proportion to the height of the atmosphere at the spot. The part at which the pressure is greatest is at the level of the sea, for there the atmosphere is highest. The pressure at the level is ordinarily computed to be about fifteen pounds on every square inch. At every step upward from the level of the ocean, the burden of the superincumbent mass lightens, and at the height of three miles, one-half of the weight is lost.

The Barometer.—The pressure of fifteen pounds to the square inch at the level of the sea, is found by experiment to be equal to the weight of a column of mercury of thirty inches in height; and the fact of such being the case has suggested the construction of an instrument to measure the atmospheric pressure at different points and in various circumstances. This instrument is called the *barometer*, a compound from two Greek words, signifying weight and measure.

The barometer in common use consists of a narrow glass tube upwards of thirty inches in length, and bent upwards at its lower extremity, as represented in fig. 1. The mercury is introduced into the tube with great care, so that a perfect vacuum exists at the upper extremity. The surface of the mercury in the bent part is open to the action of the atmosphere, and buoys up a small plummet or float F, to which a thread is attached; the thread proceeds upwards to a small pulley G, over which it goes, and terminates in a small ball W. The friction of the thread on the pulley turns a small index H, which points to figures on the surrounding dial. Commonly, the whole apparatus, except the dial-plate, is concealed in an ornamental frame. Barometers of this description are adjusted in such a manner that the smallest rising or falling of the mercury from atmospheric action, affects the index on the dial, and consequently shows the degree of pressure.

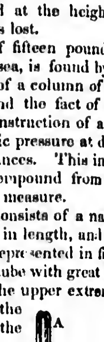

Fig. 1.

In common circumstances, the mercury ranges from twenty-nine to thirty inches. It seldom sinks so low as twenty-eight or rises to thirty-one. When it falls, an indication is given of diminished pressure; and as diminished pressure causes the air to expand, and consequently to be sensibly

* Conversations Lexicon.

cooled, moisture is liable to be precipitated in the form of rain. Hence a fall in the mercury of the barometer is considered a prognostic of rain or wet weather, and a rise the reverse. The dial of the barometer is marked accordingly.

The common rules, however, as to prognosticating the state of the weather from the action of the barometer, are in many cases very illusory, because much depends on the situation in which the barometer is placed. If situated near the sea's level, the pressure on the mercury will appear greater than if on a high ground, and, consequently, no general scale can apply to conditions so very dissimilar. In alluding to the vulgar errors entertained on this subject, Dr. Lardner remarks—"It is observed that changes of weather are indicated, not by the actual height of the mercury, but by its change of height. One of the most general, though not absolutely invariable rules is, that where the mercury is very low, and therefore the atmosphere very light, high winds and storms may be expected. The following rules may generally be relied upon, at least to a certain extent:—1. Generally the rising of the mercury indicates the approach of fair weather; the falling of it shows the approach of foul weather. 2. In sultry weather the fall of the mercury indicates coming thunder; in winter the rise of the mercury indicates frost; in frost its fall indicates thaw, and its rise indicates snow. 3. Whatever change of weather suddenly follows, a change in the barometer may be expected to last but a short time. Thus, if fair weather follow immediately the rise of the mercury, there will be very little of it; and in the same way, if foul weather follow the fall of the mercury, it will last but a short time. 4. If fair weather continue for several days, during which the mercury constantly falls, a long continuance of foul weather will probably ensue; and again, if foul weather last for several days, while the mercury continually rises, a long succession of fair weather will probably succeed. 5. A fluctuating and unsettled state of the mercurial column indicates changeable weather. The domestic barometer would become a much more useful instrument, if, instead of the words usually engraved on the plate, a short list of the best established rules, such as the above, accompanied it, which might be either engraved on the plate or printed on a card. It would be right (concludes this writer) to express the rules only with that degree of probability which observation of past phenomena has justified. There is no rule respecting these effects which will hold good."

The Thermometer.—The atmosphere possesses the capacity of receiving and containing heat from the sun's rays or any other source of warmth, but this capacity is proportionate to the degree of density of the air, and accordingly varies in different situations. It is well known that the air is more warm on low than on high grounds, and this is a peculiarity in its condition arising from the difference of density at the two places. If we take a pound weight of air near the sea's level, and another pound weight at a spot a mile above the sea, we shall find that each pound contains precisely the same quantity of heat; but in the case of that taken near the sea, the air will feel warm, and in the case of the other, the air will feel cool. This seems a contradiction, yet it is a truth. A pound weight of air taken near the sea, is compact in substance, and goes into a comparatively small bulk; but that taken from a high part of the atmosphere is thin, and occupies a much larger space. This explains why the thin air on high grounds is seemingly colder than on low situations. Aloft, the air is as warm as it is below, but there is less of it; the particles are more widely asunder, and this produces the effect of a greater coldness. Properly speaking, the cold in high situations arises from the want of air, rather than from the air itself.

In the warmest regions of the globe, the air is cold at the tops of high mountains, merely because the air is there thin, and incapable of forming a medium for the retention of the sun's rays. In every country there is a point of altitude at which water freezes on all occasions, whether summer or winter. In Europe, this point—called by some the snow line, or point of eternal snow—is from five to six thousand feet above the level of the sea; in the hot regions of Africa and America, it is fourteen thousand feet high. At these points of altitude respectively, snow lies constantly unmelted on the mountain sides and summits. In the warm regions of Hindostan, the atmosphere is as cool and pleasant at a certain height on the Himalaya mountains as it is in the northern part of Europe. The plains of Mexico, under a burning sun, would not be endurable by man, if they were not at such an elevation as to possess an atmosphere so thin as to be incapable of being heated to excess.

Although the heat of the atmosphere thus depends on the density of the fluid, it is proper to state that it is likewise influenced by other circumstances. Certain bodies have the power of heating the atmosphere in a greater degree than would otherwise be the case. For example, in valleys the heat is thrown off from the sides of adjacent hills, from forests of trees, or other objects; and in these situations the air is hotter than if there were no such radiation. If the spot be sheltered from the cooling effect of winds, there is another cause of increase to the temperature.

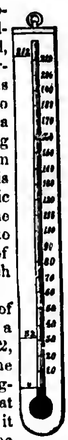

Fig. 2

The degrees of heat and cold in the atmosphere are called its temperature; and for finding this correctly, with reference to a standard, an instrument has been invented, called the *thermometer*, a word signifying heat-measurer. It is a glass tube with a bulb at the bottom, into which mercury or quicksilver is put, with a scale of figures along the tube to mark the rising of the quicksilver. This instrument differs from the barometer, inasmuch as the quicksilver is sealed up close from the air. The atmospheric heat, however, affects the metallic fluid in the bulb, and, according to its warmth, causes it to expand and rise in the tube. The degree of temperature is indicated by the figures to which it ascends.

Our common thermometer (Fahrenheit), of which a representation is given in fig. 2, has a graduation from No. 1, near the bulb, to 212, the degree of heat of boiling water. In the scale of figures, 32 is marked as the freezing-point—that is to say, when the mercury is at the height of 32, *water* freezes; and the more it is below that point, the more intense is the frost: 55 is reckoned moderate heat, and 76 summer heat, in Great Britain: 98 is the heat of the blood in the average of living men.

Different nations adopt different graduations in the scale of thermometers, which is a fertile source of error and confusion in estimating and comparing the statements of temperature made by scientific men in different countries. Wherever the English language prevails, the graduation of a person called Fahrenheit is generally preferred. By the Germans, Reaumur's is used; and the French now adopt what they term a centigrade thermometer. In the French centigrade thermometer, 0 is the freezing-point, and 100 the boiling-point; in Reaumur's thermometer, 0 is the freezing-point, and 80 the boiling-point. Each degree of Reaumur is equal to two and one-fourth of Fahrenheit. It was at one time imagined that the greatest cold could make the fluid in the thermometer fall only 32 degrees below the freezing-point, the place to which it then fell being zero, and therefore the notation has been commenced by Fahren heit at that place. But much greater degrees of cold exist at different parts of our globe in winter, and may be produced artificially, so that the fluid in the stem of the thermometer often descends below that point, and is then said to be at so many degrees below zero.

Water, as above mentioned, boils at 212 degrees, but this is only under the common pressure of the atmosphere near the sea's level. By removing a portion of the pressure either by an air-pump or by ascending a height, the vaporic or boiling point will be reached correspondingly sooner. On this account we might ascertain with tolerable accuracy the height of mountains, by noticing at what degree of heat by the thermometer water boiled. A writer in the *Encyclopædia Britannica*, has given the following instructions on this subject:—

"Boil pure water in an open vessel at the bottom of the elevation, and observe on the thermometer the point at which it boils. Boil it again at the top of the mountain, and observe with the thermometer the point at which it now boils; the difference of temperature, multiplied by 530 feet, will give a close approximation to the height of the upper above the lower station. This will give an approximation; but if greater accufacy be required, it will further be necessary to correct for the difference of the temperature of the air at the two stations, in the following manner:—Add the temperatures of the air at the stations, and subtract sixty-four from their sum; multiply the remainder by one-thousandth part of the height found, and this will be the correction to be added to the height formerly found. The result thus found will still require a slight correction for the figure of the earth and latitude of the place; but this does not amount to more in our latitude than an addition of about two feet in a thousand, which forms a second correction.

"To illustrate the mode of deducing heights from the boiling-point, as we have given it, we take the following example:—Water boils on the top of Ben Nevia at 203·8 degrees, while at the side of the Caledonian Canal it boils at 212 degrees, the temperature being 30 degrees on the summit of the mountain, and 35 degrees below.

In order to determine the height,

4358, true measured height—the difference being less than 1 foot.

"This method, however, is seldom susceptible of so high a degree of accuracy, even with the most carefully conducted experiments."

The Hygrometer.—One of the principal meteorological phenomena of the atmosphere is its capacity for receiving and holding moisture. Evaporation, to a lesser or greater extent, is in constant exercise over the whole earth. The ocean, lakes, rivers, fields, are ever yielding up water to the atmosphere, and plants and animals are also at all times giving forth exhalations. The atmosphere is thus a great receptacle for the moisture of the earth, and its capacity in this respect is increased by an increase of temperature. In a hot day, much more evaporation is produced than in one which is cold, but it is not on that account more perceptible by the senses. The more warm and free the air, so is the moisture less observable in its mass; and it is only when the atmosphere sinks to a certain pitch of cold, that we begin to see the suspended moisture in the form of mists and clouds. Thus, in a hot day, we do not see the breath issuing from our mouth, it being conducted away in an ethereal state, but in a cold damp day in winter, we see it proceeding in puffs at every expiration.

The state of the atmosphere as respects its moistness, is called its *hygrometric condition*, from the hygrometer, an instrument for measuring the degree of dryness or moistness of the air. There are various kinds of hygrometers, depending on the principle of the shrinking and expanding of bodies in relation to the degree of humidity with which they are affected. Fibrous vegetable substances, such as ropes, contract by imbibing moisture, while, on the contrary, hairs and catgut (strings of violins), contract by drought. Hair has been found to be the most delicate in hygrometrical motions. The celebrated Saussure, a French philosopher, accomplished the construction of a hygrometer from a single long hair, previously cleaned in a soda ley. Various philosophical toys, as ornaments for mantelpieces, have also been constructed to indicate the dryness or moistness of the atmosphere, all on the similar principle of contraction and expansion of a hair, piece of catgut, or part of the beard of the wild-oat. One of the most useful instruments of this class is a small object resembling a watch in external appearance, designed to prove the dampness or dryness of beds: a movable hand on the dial-plate points out very speedily the hygrometrical condition of the bed-clothes on which the instrument is laid.

Hygrometers of the kind just mentioned, however ingenious, fail as instruments of science or comparison, chiefly from the circumstance of their liability to lose their contractile and expansive energy, as well as the difficulty of making many of them possessing similar powers. To supply the required instrument of comparison, Professor Daniel contrived a very elegant hygrometer, which is now universally in use. It consists of a glass tube, bent nearly in the form of ∩, supported on a stand, with a ball at each extremity, and containing only some ether. Within one of the depending limbs a thermometer is placed. The instrument operates on a little ether being dropped on one of the balls; evaporation immediately takes place, heat is abstracted, and the ball containing the thermometer is so cooled, that a dew perceptibly gathers on its surface. The degree of temperature at which the dew is seen to collect, marks the exact hygrometric condition of the atmosphere. The principle is precisely that on which a bottle of cold liquor, on being brought into a warm apartment, collects dew on its surface. If no dew appears on a bottle in such circumstances, the atmosphere of the room is certainly very dry.

CLOUDS.

The capacity of the atmosphere for moisture, even in the most favourable circumstances, is limited. The air cannot be loaded with water, in any form, beyond a certain point. Meteorologists mention, that if saturated with vapour even to its utmost extent, the whole would not form more than from six to seven inches of rain; in other words, not more than six or seven inches of water can be maintained in solution throughout the forty-five miles of atmosphere above, at any one time. The capacity for retaining moisture is greatest in the lower strata of the atmosphere, or where it is most dense and warm. At great elevations, such as eight or ten miles, the air is too thin to hold water in solution; and in all ordinary circumstances, the vapours of the earth do not ascend above four or five miles from its surface at the sea's level. Above these heights, whatever be the state of the weather beneath, all is clear and comparatively dry. In very many cases, clouds do not reach the mo derate height of three miles; and the field of their evolutions in temperate climes is more frequently not above a mile or a mile and a half high.

Clouds, it will be perceived, are in reality dependent on temperature, and temperature is often dependent on winds. In a warm and dry summer day, evaporation proceeds with great activity, and, in a manner invisible to the eye, the moisture rises to the higher regions of the air. If the sun be powerful, the moisture may thus ascend several miles, and be dispersed like a gas, leaving no cloud to indicate its existence. All, therefore, appears clear, serene and beautiful. Currents of cold air may now be supposed to intrude themselves on the scene—the gas-like vapour is condensed—and clouds consequently make their appearance. A similar occurrence will take place by the weakening of the sun's rays, and withdrawal of heat at the approach of night, when clouds, as is well known, are always most numerous.

Clouds are commonly formed by the ascending of the invisible vapour into the cold regions of the air, where they take shapes conformable to the degree of temperature and action of varying currents. These currents and other circumstances affecting them are so constantly changing, that seldom for a single minute do they remain of one form, but shift into all sorts of postures, rise, fleet away to a distance, congregate, sink, disperse, and vanish. While the aggregation of clouds is caused by their coming in contact with cold currents of air, their evanishing is attributable to their being acted on by the currents or strata of air warmer than those in which they have previously been sustained. The dispersal and the evanishment of clouds may occasionally be seen to advantage in the neighbourhood of ranges of hills terminating abruptly. The clouds resting on the hill-tops are seen to begin to move towards the precipitous declivity, in consequence of the springing up of a breeze in that direction; and when they arrive at the precipice, they seem to tumble over and vanish in the fall. Dr. Arnott speaks of the beauty of this phenomenon at Table Mountain, at the Cape of Good Hope; and we have observed it occurring at the termination of the range of Pentland Hills near Edinburgh. The explanation of the phenomenon is simple: the cloud, on rolling from the summit of the hill, falls into an atmosphere of a higher temperature, and its particles being diminished into the gaseous form, disappear. When, on the contrary, a cloud is seen to ascend a hill, it enters a region of cold, and being condensed, it is precipitated as a shower of rain. From these oft-observed facts, the old saying has been derived—

> "When the clouds go up the hill,
> They'll send down water to turn a mill."

Luke Howard, in his Essay on clouds, distributes them into four essentially different formations. These formations are—1. *Cirrus*, consisting of thready fibres diverging in all directions, or curled up at one end; 2. *Cumulus*, or roundish bank of cloud, increasing from a horizontal base upwards: 3. *Stratus*, layers vastly extended, connected, and horizontal: 4. *Nimbus*, the heavy black cloud dissolving in rain. There are subdivisions in this classification, as *cirro-cumulus*, *cirro-stratus*, &c.

By the same meteorologist, the clouds are generally assigned to three atmospherical regions—the upper, the middle, and the lower one, to which a fourth, the lowest, may be added. In the upper region, the atmosphere is in such a state, that it can receive and sustain only light and thin vapours; and to this district belongs the *cirrus*, a representation of which is given in fig. 3. Of all the various forms of cloud it has the least density, but the greatest height and variety of shape and direction. It is the first indication of serene and settled weather, and first shows itself in a few fibres, spreading through the

Fig. 3.—The Cirrus.

atmosphere. These fibres by degrees increase in length, and new fibres attach themselves to the sides. The duration of the cirrus is uncertain—from a few minutes to several hours. It lasts longer, if it appears alone and at a great height; a shorter time, if it forms in the neighbourhood of other clouds. From its usually curling appearance, the cirrus is called in England the *mare's tail* cloud.

The *cumulus* is a cloud of a much more massive character. It is vapour in the most compact form, and usually moves with the stream of air nearest to the earth. This region can receive much humidity, but not in perfect solution. The humidity becomes collected, and shows itself in masses rising conically and resting on a region of air capable of giving it support. The annexed engraving, fig. 4, represents the more usual forms of cu-

Fig. 4.—Various forms of Cumulus.

mulus, whether in separate or congregated masses. The appearance, increase, and evanishing of cumulus, in fine weather, are often periodical, and correspondent to the degree of heat. Generally, it forms a few hours after sunrise, attains its highest degree in the hottest hours of the afternoon, and decreases and vanishes at sunset. Great masses of cumulus, during high winds, in the quarter of the heavens towards which the wind blows, indicate approaching calm and rain. If the cumulus does not disappear, but rises, a thunder-storm is to be expected during the night. If the upper region, with its drying power, predominates, the upper parts of the cumulus become cirrus. But if the lower region predominates (into which the densest vapours are attracted and dissolved into drops), the basis of the cumulus sinks, and the cloud becomes stratus, which is of moderate density, and its lower surface rests generally upon the earth or the water.

The *cirro-cumulus*, of which a representation is given in fig. 5, consists of a collection of small white clouds,

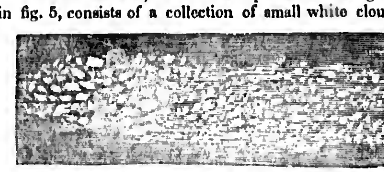

Fig. 5.—Cirro-Cumulus.

of a roundish form, which give to the sky the appearance called dappled, and are in summer considered a prognostic of settled weather, or at least of an increase of temperature. Occasionally the cirro-cumulus may be observed to change into another variety of clouds—the cirro-stratus.

The *cirro-stratus*, which we represent in its common forms in fig. 6, exists in a high region of the air, and is often the cirrus in an altered shape. It is generally in the form of long horizontal streaks, which are ever shifting their figure and position. Sometimes it is a long row of

Fig. 6.—Various forms of Cirro-stratus.

slanting streaks, and at other times an apparently drawn out and translucent cumulus. In the latter form, when shone upon, at the close of day, it is not unlike a long feathery streak of fire.

The *stratus* is the proper evening cloud, and is in reality the vapour which creeps along the ground or mounts into the lowest region of the air at sunset, after a fine summer day. All mists and fogs are of this species of cloud, which in its lightest state does not wet leaves or any objects with which it comes in contact. In calm evenings, the stratus may be seen ascending from the valleys to the higher grounds, and there, as shown in fig.

Fig. 7.—The Stratus.

7, it extends itself in masses like a fleecy mantle. It generally arrives at its point of greatest density about midnight, or between that time and daylight, and disappears at sunrise by the gradual elevation of temperature in the atmosphere. Sometimes it remains quiet and accumulates in layers, till the atmosphere is incapable of sustaining its weight, when it assumes the condition of the heavy and dark *nimbus*, and falls in a shower of rain. We have placed a representation of the nimbus, yielding its tribute of rain, as a frontispiece to the present article.

The various circumstances which concur to precipitate moisture in the atmosphere into the visible form of clouds, are summed up as follows by an intelligent meteorologist, Mr. Graham Hutchinson, in his Treatise on Meteorological Phenomena (Glasgow, 1835):—1. "When a diminution of the atmospheric temperature, unaccompanied by atmospheric rarefaction or transportation, takes place. 2. When a diminution of the atmospheric temperature, arising from atmospheric rarefaction, takes place. 3. When a diminution of the atmospheric temperature, arising from the transportation of air from a warm to a cold climate by the agency of winds, takes place. 4. When an intermixture, and consequent reduction to a mean temperature, of different portions of air, of previously different temperatures, takes place. If any one, or any combination of these circumstances happens to occur, when the atmosphere is previously saturated with humidity; or supposing the atmosphere previously somewhat under-saturated, if they take place to such an extent as to produce over-saturation, a precipitation of moisture, into the visible form of cloud or mist, is the necessary consequence."

Clouds of the cumulus form are frequently seen to rest or hover over the tops of mountains, and it has therefore been supposed that hills attract clouds. Undoubtedly, from electric causes, clouds are occasionally attracted by mountain-tops, where they discharge their contents in a thunder-storm; but, in common circumstances, attraction not the cause of cumulus on hills. The ordinary cause is a low temperature of the atmosphere at these altitudes—a temperature lower than that of the region of air at the same height away from the hills. The mode of cloud-formation on mountain ranges seems to be this: the warmer air of the valleys or of the sea, loaded with invisible particles of moisture, is blown in the direction of the hills, and being compelled to ascend, the particles become visible when they attain the summit. But the wind does not rest there: the particles are blown away beyond, and perhaps vanish in a warmer region of air but new particles are constantly coming up to supply their place; and thus a shifting appearance is given to the masses of clouds which we observe hovering on the tops of the hills. "Mountains of themselves," observes Mr. Hutchinson, "that is to say, without wind, can form no clouds; and winds of themselves, that is to say, without the aid of atmospheric rarefaction which accompanies their exaltation while passing over mountains, are, in this respect, equally inefficient. In short, mountains in all climates may be regarded as passive instruments in the formation of clouds only during windy weather. And whenever their height is such that the temperature of the lower atmospheric strata, while surmounting them, becomes so much reduced as to cause over-saturation, the formation of clouds must take place. Hence, the higher the mountains, the more certain they are, during windy weather, to cause the formation of clouds; and the nearer the hygrometric condition of the aërial strata, before beginning to ascend the mountain, is to the point of saturation, the less height will suffice for that purpose. Accidental coldness on the tops of mountains, beyond what results from their height, sometimes adds to their efficacy in causing the formation of clouds. Such may be occasioned by snow-falls during the cold season remaining unmelted, or only partially melted (as frequently happens on the northern exposure of mountains in the northern hemisphere), till long after the returning heat of spring and summer has rendered the falling of snow, at corresponding altitudes, extremely improbable."

Haze—Mist—Fog.—Mists or fogs, as has been noticed above, are a variety of clouds, and are scientifically described by the term *stratus*. A haze is that species of vapour in which the watery particles are only partially or imperfectly condensed, so as to produce an indefinite obscuration, which generally may be observed in the evening, when the temperature of the air becomes diminished by the decline of the sun towards the horizon. When viewed from a distance, the surface of the earth always appears enveloped in a haze of greater or lesser density; and although, when sailing on an open expanse of ocean, the atmosphere may appear very clear, yet, on being viewed from a high mountain, the water will appear obscured by a haze, which will be found to extend many feet above its surface. When the watery vapour in the surrounding air becomes more condensed, with a defined outline in the form of a cloud, either resting on the surface of the earth or a few feet above it, then it is termed a mist; and when the whole atmosphere around appears equally obscured, then we give it the name of a fog, which, however, is not to be confounded with that moist and obscured state of the air which often accompanies our easterly and westerly winds.

Mists, as well as fogs, consist of thin vesicles of water containing air. How these vesicles are formed, is not well understood; but the general opinion is, that mists and fogs arise from air of unequal temperatures, holding moisture in solution, mingling together. Accordingly, the mixture of the evening sea-breeze with the air above the land, often produces dense mists; for the air above the sea is warmer than that above the land, and when they intermix, a condensation of aqueous vapour into mist or fog takes place. Besides this, the contraction of the air, from its becoming colder after sunset, often produces a condensation of the watery particles floating in it. In addition to which, there can be no doubt that a certain quantity of vapour rises up, or evaporates, from the earth itself, which we may suppose to have been within a short period moistened by rain, and this, having become elevated to some distance above the ground, in like manner becomes condensed. During the night, therefore, the air above the surface of the earth is thus generally rendered hazy, and light mist are observed hanging in gauzy folds along the sides and around the summits of hills and mountains; hence Lord Byron, in noticing the approach of morning, gives us this beautiful passage:—

> "Night wanes; the vapours round the mountains curl'd
> Melt into morn, and light awakes the world."

Fogs are often, especially in large towns, remarkably dense; indeed, so much so as to occasion serious accidents from their interference with distinct vision. This frequently happens in London, and in other large cities, and arises from smoke, vapours, dust, &c., being stagnated in the thick fog. On certain calm winter days it may be observed, that the smoke, on leaving the chimneys, descends towards the ground, and downward currents often set through flues at the bottom of which there is no fire. Fogs seldom rise high in the atmosphere; hence Dr. Darwin, in giving an account of one which overspread a tract of ground through which he had occasion to ride, states, that on every rising of the ground he was quite above its level, though in descending again it was so thick that he could scarcely see a yard beyond his horse's head. In the northern regions, fogs are extremely dense, owing, doubtless, to the difference between the temperature of the air which sweeps over the immense tracts of ice extending through those desolate regions, and that of the air which passes over the warmer surface of the ocean. It is one of the greatest annoyances which the whalers and navigators in those dangerous seas have to encounter.

Colour of the Clouds, &c.—Clouds being composed of pure watery particles, cannot intrinsically possess the colour of any foreign body; nevertheless, by the peculiar action of the rays of light on different parts of their mass, they frequently assume a variety of tints, particularly red and orange, at and shortly after sunset. The sun and moon likewise, when shining through a dense vapoury medium, assume a deep red tinge. Superstition would ascribe these phenomena to supernatural causes; but, in truth, all is but a simple effect of the refrangibility of the rays of light. The white rays are decomposed in shining through the globules of vapour, and they shine as if coming from a prismatic spectrum. In our article OPTICS, as has been explained, each of the seven rays of which the white light is composed, has a different degree of refrangibility, and it is on this account that a variety of colours exist in nature. "Had it been otherwise—had the objects of the material world," says Sir David Brewster, "been illuminated with white light, all the particles of which possessed the same degree of refrangibility, and were equally acted upon by the bodies on which they fall, all nature would have shone with a leaden hue, and all the combinations of external objects, and all the features of the human countenance, would have exhibited no other variety than that which they possess in a pencil-sketch or china-ink drawing. But he who has exhibited such matchless skill in the organization of material bodies, and such exquisite taste in the forms upon which they are modelled, has superadded that ethereal beauty which enhances their more permanent qualities, and presented them to us in the ever-varying colours of the spectrum."*

In cold climates the sky has generally a dull blue or gray tinge, even in fine weather, a circumstance arising from the prevalence of moisture in the air, which forms a kind of gauze, through which our eye is unable to penetrate. In more warm and genial climes, such as that of Italy, the colour of the sky is a bright blue, and in hot weather slightly purplish. This brilliance arises from the comparative absence of vapoury particles; yet that vapour does exist in the clearest azure sky is indisputable, for it is by refraction of light that the colour appears. If moisture were entirely absent, there would be no refrangibility, and consequently no blue colour. The sky, as formerly mentioned, would be black. The reason assigned for the prevalence of a blue colour in the sky is, that the blue rays are reflected more copiously than any of the others.

DEW.

Dew is a result of an alteration of temperature after sunset. No sooner does the sun begin to decline towards the horizon, than its rays fall more slantingly on the earth, whereby their intensity is diminished, and a change of temperature immediately ensues; for the air soon feels chilly and damp, and the grass beneath our footsteps becomes moistened with a genial and refreshing dew.

It has been elsewhere explained, that all bodies receive a certain quantity of heat, which in particular circumstances they again emit; in doing which they necessarily become colder than they previously were, unless they receive in exchange another quantity of heat sufficient to compensate for the loss they have sustained. In this case, their temperature will remain stationary; but if they part with more than returns to them, their temperature necessarily must fall. When, then, the object so cooled is encompassed by a warm and moist medium, it condenses, by its cold contact, vapour on its surface, and thereby becomes moistened. Hence the origin of dew; for no sooner does the sun sink towards the horizon, than the blades of grass which clothe the surface of the earth give out the heat which they have been receiving during the day; the consequence of which is, that their temperature falls so much below that of the surrounding air, that they condense on their surfaces part of the moisture which immediately surrounds them. The temperature of the body, as indicated by the thermometer, at which this deposition takes place, is called the "dew point," which, for the formation of dew, must always be below the temperature of the surrounding atmosphere; indeed, the quantity of dew formed will always be in proportion to the [illegible] of the grass and to the quantity of moisture sus[illegible] the air. Besides this, after the sun has set, th[illegible] which the earth has imbibed during the day, [illegible] still rests below the grassy surface, rises up or [illegible] —in doing which, it rises up through [illegible] blades of grass, the cold contact of wh[illegible] denses it. Dew, therefore, on calm [illegible] more abundant shortly after rain than durin[illegible] son of dry weather. During westerly or south[illegible] which are generally impregnated with moisture, it [illegible] formed more copiously than during easterly and northerly winds. Besides the quantity of moisture existing in the air, the greater or lesser copiousness of the dew formed, depends, as we have premised, on the coldness of the objects on which it is about to be condensed. If the night be calm and clear, the grassy blades emit their heat freely, and it is dispersed through the atmosphere without any equivalent return, whereby the temperature of the grass soon sinks sufficiently low to condense the surrounding vapour; but if, instead of this, the night be cloudy, then the clouds reflect, like mirrors, the rays of heat back again to the grassy blades, and prevent this diminution, so that less dew is then deposited. If, in addition to the sky being overcast with clouds, the weather be windy, no dew will be formed; for the temperature of the grass is then prevented sinking by the

* Life of Sir Isaac Newton, p. 78

agitation of the air, by which a warmer current is continually brought to succeed the colder current by which it is surrounded. Hence, if, during the night, the weather, from having been calm and serene, become windy and cloudy, not only will dew cease to form, but that which has been already deposited will disappear, or diminish considerably. Every kind of covering or shelter which extends above any object, will interrupt the radiation or escape of its heat; for which reason gardeners, to prevent plants being chilled, cover them over, on the approach of evening, with a layer of straw or matting.

For reasons similar to those now advanced, the grass which is situated beneath the boughs of large and spreading trees, becomes only sparingly moistened with dew; for the shelter above interrupts the progress of radiation from the substances underneath, and so preserves their temperature. Accordingly, it is an established axiom, that whatever diminishes the view of the sky, as seen from the exposed body, will occasion the quantity of dew to be less than would have been deposited if the exposure to the sky had been complete. Dew is formed, therefore, more sparingly and irregularly in cities than in the country, where the most open grassy plains are always the most abundantly bedewed. In England it begins to appear in shady places as soon as the heat of the atmosphere has declined; but though the grass on clear still evenings often becomes moist several hours before sunset, dew is seldom present in such quantities as to exhibit visible drops until the sun reaches the horizon; nor does it become copious until some time after sunset. It continues to form also in shaded places some time after sunrise; and it is remarkable, that more dew forms a little before, and in shaded places a little after sunrise, than at any other period. It has also been observed, that more dew is formed between midnight and sunrise than between sunset and midnight—a circumstance which is owing to the cold of the atmosphere being greater in the latter than in the former part of the night. As the quantity of dew deposited thus depends so much on the degree of coldness which the body about to be bedewed attains, its quantity must be materially modified by the greater or the lesser facility with which substances part with their heat. Grass, being a filamentous substance, parts more readily with its heat than garden mould or gravel; wherefore dew is more plentifully deposited on meadow grounds than on ploughed lands. Thus, cultivated soils are refreshed with abundance of dew, while barren rocks and sandy deserts do not receive this congenial moisture. Indeed, every shrub and herb, every leaf and blade of grass, possesses, according to its kind, a different power of radiation, so that each condenses as much dew as is necessary for its own individual and peculiar exigencies. Thus, not even a single dew-drop seems to have been formed by the rude hand of chance, but is adjusted by the balance of infinite wisdom to accomplish a definite and benevolent end.

THE WINDS.

A change in the temperature, a diminution of the vapour, or any other cause that may occasion a portion of the surrounding atmosphere to contract or expand, will give rise to the aërial currents denominated winds, which, indeed, bear a strong analogy to the currents which occur in the ocean. When the air by which we are surrounded becomes heated, it expands, and becomes specifically lighter, in consequence of which it mounts upwards; and the colder and denser air which surrounds the mass thus rarefied, rushes in to supply its place. When the door of a heated apartment is thrown open, a current of air is thereby immediately produced; the warm air from the apartment passing out, and the cold air from the passage rushing in. So, also, in those buildings where the manufacture of glass is carried on, the heat of the furnace in the centre being intense, a violent current of air may be observed to force its way in through the doors or crevices on the opposite sides of the house. On applying these principles to account for the origin of the wind, we find that, when the rays from the sun, by their reflection from the earth's surface, have heated or rarefied a portion of the surrounding air, the air so rarefied ascends into the higher regions of the atmosphere and the colder air by which it was surrounded moves forward in a sensible current to fill the vacuity. When, also, a condensation of vapour in the atmosphere suddenly takes place, giving rise to clouds which speedily dissolve in rain, the temperature of the surrounding air is sensibly altered, and the colder rushing in upon the warmer, gives rise to a sudden gust of wind. For this reason, a cold heavy shower passing overhead, with a hasty fall of snow or hail, is often attended with a violent and sudden gust of wind, such as sailors call "a squall," which ceases when the cloud disappears, but is renewed when another cloud, sweeping along in the same direction, brings with it a fresh blast.

The general nature of the winds in this and in other countries depends very much on the character of the region whence they may have swept; and, accordingly, it is necessary to remember that the globe is divided into five zones or belts—the torrid, which is exposed to the direct rays of the sun; the two temperate zones, which, meeting the rays of the sun obliquely, enjoy a moderate degree of heat; and the two frigid zones, which, deprived of the heat of the sun for a great part of the year, and during the other part receiving his rays still more obliquely, are regions of ice and snow which, it would appear, are destined ever to remain uninhabitable solitudes. Generally, in the British islands, a westerly wind is moist, because it comes from the Atlantic, where a great quantity of vapours arise. When mingled with that of the south, which comes from the torrid zone, it is rendered particularly warm. The east wind is the driest, because it comes from the continent of Asia, where there are few seas. The north wind, however, is the coldest, because it sweeps from the immense tracts of ice and snow in the frigid zone. The north-easterly winds, therefore, being so dry and cold, are in this country proverbially the most chilly and bitter.

While the south-west is the most predominant wind in Europe, the north-east winds in spring may be regarded as periodical in the climate of Britain; it is to be remembered, however, that the succession of the seasons of the year, with their characteristic changes of temperature, depend principally on the relative position of the earth to the sun. The more vertically or directly the sun's rays reach the surface of the earth, descending in a more concentrated manner, the greater is the degree of heat which they produce; but the more obliquely they fall, being thereby more scattered, and consequently falling with less power, the smaller is the degree of heat they impart. Accordingly, in the winter season, the sun's ray's reach the surface of the globe in our latitude more obliquely than they do in the summer season; consequently, that season is characterized by the coldness which then prevails; therefore, the winds, powerful as their agency certainly is, exercise only a subsidiary influence in modifying the temperature of the seasons. Besides this, the physical aspect of a country, its mountains and table lands, its chains of hills and its valleys, its rocky elevations and its level plains, its protected or exposed coasts, all influence very materially the direction of the wind, which must, as it sweeps along, coincide with the elevations and depressions of the country over which it passes. Hence it has been shown by physicians, that the climate in certain districts of England, owing to the protection of surrounding elevations, rivals in salubrity, even in the most trying seasons, many of the most favourite and fashionable resorts for invalids in the south of France.

Besides the division of the winds founded on their direction from the cardinal points—as into north, north-east; south, south-east; west, south-west; east, &c.—they are divided by meteorologists into four classes, namely, regular, irregular, periodical, and hot winds; the causes of which, with the phenomena by which they are attended, will now be considered.

Regular Winds—Trade-Winds.—In order that we may distinctly understand the cause and nature of the trade-winds, it is necessary to bear in mind that the earth, in the centre of its circumference, at an equal distance from the poles, is divided by a line called the equator into two hemispheres—the northern and southern. Across the equator, cutting it obliquely, there passes another great circle called the ecliptic, which describes the path the sun traverses. It extends 23½ degrees north and 23½ degrees south of the equator, which is the utmost limit the sun traverses; for, when arrived at either of these boundaries, he again seems to return towards the equator. It must be very evident that the region of the earth included within a circle drawn 23½ degrees north and 23½ south of the equator—which will comprehend the greatest portion of Africa, a considerable part of Asia and America, and many large, fertile, and populous islands in the East and West Indies—will receive constantly the solar rays in a direction so little oblique, that the most intolerable heat might there be anticipated. It was therefore called the torrid zone; and the limits at which the sun stops, and appears to retrace his course, have received the name of tropics, or circles of return. This being premised, and it being also remembered that the earth revolves daily, "her silent course advancing," round the sun from west to east, the cause of the trade-winds will be readily understood. The rays of the sun, in its apparent motion from east to west, obviously rarefy, by the heat they impart, the air beneath, and the air so rarefied rises into the higher regions of the atmosphere. While this takes place, the colder air from the adjoining temperate zones rushes in to supply its place. But it is from the polar regions, north and south, that these colder currents originally come; and did the earth remain at rest, such would be their obvious direction. Instead of this, however, north of the equator the direction of the trade-winds is from the north-east; south of the equator, from the south-east; the cause of which is thus explained:—The velocity with which the earth revolves, is inconsiderable, if appreciable, at the poles, but increases as we advance, and is at its maximum at the equator; the winds, in sweeping from the poles, do not acquire a corresponding velocity with the motion of the earth, as they advance towards the equator; therefore, moving more slowly than the earth, they are left behind, striking bodies with the excess of the earth's velocity; so that, to the observer who imagines himself at rest, the air appears to move in a direction contrary to the rotation of the earth, namely, from east to west. While the trade-wind thus blows upon the surface of the earth, there is no doubt that an opposite current, probably that of the rarefied air which has ascended, flows in the contrary direction, at a great elevation in the atmosphere.

The external limits of the trade-winds are 30 degrees north and 30 degrees south of the equator; but each limit diminishes as the sun advances to the opposite tropic. The larger the expanse of ocean over which they sweep, the more steadily do they blow; accordingly, they are more steady in the Pacific than in the Atlantic, and in the South than in the North Atlantic Ocean. Within the region of the constant trade-winds, rain seldom occurs, but it falls abundantly in the adjoining latitudes. The reason is, that rain is produced by the sudden mixture of air of different temperatures charged with moisture; but the constant circulation and intermixture of the air from the upper strata of the atmosphere, or ground current, maintains so equal a temperature in these latitudes, as not to occasion the condensation of vapour which is necessary for the production of rain. Besides which, it is plausibly enough alleged by Daniel, that the aqueous vapour constantly flows off in the current of the equatorial wind into the adjoining temperate zones. Within the limits of the trade-winds, contrary to what might have been anticipated from the latitude, the atmosphere is peculiarly cool and refreshing.

The agency of the winds in clearing the atmosphere from noxious effluvia, and keeping it from stagnating, is so apparent, that it scarcely requires to be noticed. In the case of the regular winds to and from the equator, an interchange of atmosphere is effected, beneficial to both torrid and temperate zones. On this interesting point in natural science, the following observations are made by Liebig in his work on Organic Chemistry (1840).—"The proper, constant, and inexhaustible sources of oxygen gas are the tropics and warm climates, where a sky seldom clouded permits the glowing rays of the sun to shine upon an immeasurably luxuriant vegetation. The temperate and cold zones, where artificial warmth must replace deficient heat of the sun, produce, on the contrary, carbonic acid in superabundance, which is expended in the nutrition of the tropical plants. The same stream of air which moves by the revolution of the earth from the equator to the poles, brings to us, in its passage from the equator, the oxygen generated there, and carries away the carbonic acid formed during our winter. The experiments of De Saussure have proved that the upper strata of the air contain more carbonic acid than the lower, which are in contact with plants; and that the quantity is greater by night than by day, when it undergoes decomposition. Plants thus improve the air, by the removal of carbonic acid, and by the renewal of oxygen, which is immediately applied to the use of man and animals. The horizontal currents of the atmosphere bring with them as much as they carry away; and the interchange of air between the upper and lower strata, which their difference of temperature causes, is extremely trifling when compared with the horizontal movements of the winds. Vegetable culture heightens the healthy state of a country, and a previously healthy country would be rendered quite inhabitable by the cessation of all cultivation." How grand the theory in these passages respecting the influence of winds on vegetation! Those streams of air, which superstition would ascribe to demons, are among the most beneficent means arranged to preserve atmospheric salubrity, and afford materials for man's subsistence.

The Monsoon.—In India, a very remarkable periodical or half-yearly wind prevails, which is called the Monsoon, from a Malay word *moussin*, which signifies season. It blows one half the year from the south-west to the north-east, and the other half from north-east to south-west. The former is accompanied by rain and tempest, and constitutes in India the "rainy season;" the latter, although in this respect admitting of some modifications, constitutes the "dry season" of the year. The south-west monsoon, in the southern parts of India, commences about the beginning of June; but in proceeding northwards, it does not commence until later. It is ushered in by vast masses of clouds, which arise from the Indian Ocean; and as they advance towards the north-east, gather and thicken as they approach the land. In a few days afterwards, the sky assumes a more troubled aspect towards the evening, and it is in the night that the monsoon generally sets in. It begins with violent blasts of wind, which are succeeded by floods of rain, during which the lightning flashes without intermission; at first illuminating the sky, showing the clouds near the horizon; then discovering the distant hills, and leaving them again shrouded in darkness; then, in an instant, reappearing in vivid and successive flashes, which exhibit even the nearest objects in all the clearness and distinctness of noon-day light. The thunder, in the mean time, continues in loud peals, and when it ceases, the rain pours in large volumes. This lasts for several days; the sky then clears, the air becomes soft and pure, the rivers are full and tranquil, and the whole face of the earth, as if by enchantment, appears clothed with thick and luxuriant verdure. The rain, after this, falls at intervals for about a month; then it increases in violence, and attains its height in the month of July, when it descends thickly and heavily *en masse* from the heavens. Then this monsoon, in August, somewhat diminishes; in September it abates, or is entirely suspended until the end of the month, when it again re-appears; and departs, as it came, amidst thunder and lightning, and all the turmoil of tempest.

Such is the south-west monsoon, as it appears in the greater part of India; but it is liable to considerable variations, caused by the influence of the sea and the mountainous regions along which it may sweep. Near the sea, the rain falls more plentifully; because, from the more abundant evaporation, the air is there more charged with moisture. The mountains also affect its course, by interrupting and diverting the progress of the winds and the clouds they bear. Thus, the wind which brings the rain to the north-eastern part of the Indian continent, originally blows from the south-west over the Bay of Bengal, until it reaches the Himalaya Mountains, and those which join them from the south; these check its current, and compel it to follow their range towards the north-west; but when it has continued so far towards the north-west as to meet that chain of mountains called the Hindoo Coosh, then it is by them turned off towards the west, and sweeps along until interrupted by the range of the Solimaun, which prevents its proceeding farther in that direction, or compels it to part with the clouds with which it was laden. If the reader will for a moment trace on the map the course here described, he will at once perceive the influence these mountains must have in modifying the direction and general character of the monsoon.

Hitherto we have principally noticed the south-west monsoon, which constitutes the "rainy season" in India; to this succeeds the north-east monsoon, which, with the exception of the eastern side of the Coromandel coast—to which it brings the periodical rains that begin about the middle of October, and end generally in the middle of December—is attended with dry weather throughout the peninsula. After setting in, during the month of September, with considerable variations in its commencement, the north-east monsoon establishes a milder though not less absolute dominion, which lasts until the end of February or the beginning of March. From that period to the month of June, the winds are irregular, and the heat very great all over the peninsula. In respect to the cause of the monsoons, they are, on the authority of the celebrated philosopher Halley, to be explained on the same principles as the trade-winds; the action of the sun's rays inducing a rarefaction of the air, and consequent rushing in of a colder current from the sea and land; and the physical aspect of the country, its elevations or plains, modifying the reflection and influence of the solar rays: which causes, taken conjointly, sufficiently account for the periodical occurrence and local peculiarities of the monsoon.

Sea and Land Breezes.—The sea and land breezes, occurring in warm climates, may also be classified under the head of periodical winds; they occur in the following manner:—During the day, the wind blows for a certain number of hours from the sea to the land; but when evening arrives, it changes its direction, and blows as many hours from the land to the sea. In this country the sea-breeze sets in about seven or eight in the morning, and is strongest at noon, but continues very sensible until three o'clock, when the surface of the sea will be observed to exhibit ripples of a deep blue colour. After this, at six in the evening, the land-breeze commences. The sea now assumes a greenish hue; and this breeze continues until eight the next morning. The cause of this alternation may be readily explained. During the day, the air over the surface of the earth is more heated by the rays of the sun than that over the surface of the sea; because the earth, from its greater density, comparative state of rest, and numerous elevations, reflects the sun's rays sooner, and with more power then they are reflected from the sea, which, from its state of constant motion and transparency, imbibes the warmth very intimately, though more slowly. Accordingly, when the sun, having arisen above the horizon, has, by the reflection of its rays, thus imparted a sufficient degree of warmth to rarefy the body of air over the land, the air so rarefied ascends into the higher regions of the atmosphere, while that over the surface of the sea, being scarcely at all rarefied, rushes in to supply its place. Hence, a sea-breeze, or current of air from the sea to the land, at this time prevails; but when the sun again begins to sink below the horizon, the body of air over the surface of the land becomes rapidly cold, and the earth itself, by radiation, parts very quickly with the warmth it had absorbed. Then the land air, being below the temperature of the sea air, rushes in to supply its place, and thus during the night, a land-breeze, or a current of air from the land to the sea, is produced. When the sea-breeze first sets in, it commences very near the shore, and gradually extends itself farther out to sea, and, as the day advances, becomes more or less hot. Hence, the sails of ships have been observed quite becalmed six or eight miles out at sea, while at the same time a fresh sea-breeze has been blowing upon the shore. The cause of this is obvious: for it is natural to suppose that the mass of air nearest the land will be the first to rush in, for the purpose of supplying the place of the air which is rarefied immediately above it. On this account the effect of the sea-breeze is said not to be perceptible at a distance of more than five or six leagues from the shore, and for the most part becomes fainter in proportion to its distance from the land. The distance, on the other hand, to which the land-breeze extends in blowing across the sea, depends on the more or less exposed aspect of the coast from which it proceeds.

Hot Winds—The Simoom.—Hot winds of a very dreadful character occur, in Arabia, Egypt, Syria, and adjacent countries, the moving air having acquired a prodigious degree of heat and aridity in passing over the hot desert continents. One of the most appalling of these winds has been called by the Arabs the *simoom*, from a word meaning poison; and it is also known by the name of the *kamsin*, which signifies fifty days. When the simoom begins to blow in Arabia, the atmosphere assumes an alarming aspect. The sky, at other times so clear, becomes dark and heavy; the sun loses its splendour, and appears of a violet colour. The air is not cloudy, but thick from the subtle dust with which it is loaded. Sometimes the sky appears yellow from the refraction of light on the minute pieces of quartz which are floating in the air. Sometimes it has a peculiar and frightful blue colour; which variety of this wind comes from those districts where the soil is composed of a great deal of blue-coloured marl and limestone. At first, the wind is light and rapid, and not remarkably hot; its temperature, however, soon increases, until it ranges at upwards of 128 degrees Fahrenheit. The danger, however, is most imminent when it blows in sudden squalls, as then the rapidity of the wind increases the heat to such a degree as to be altogether intolerable. "When this wind occurs," says Volney, "all animated bodies discover it by the change it produces in them. The lungs, which a too rarefied air no longer expands, are contracted and become painful. Respiration is short and difficult, the skin parched and dry, and the body consumed by an internal heat. In vain is recourse had to large draughts of water; nothing can restore respiration: in vain is coolness sought for; all bodies in which it is usual to find it deceive the hand that touches them. Marble, iron, water—notwithstanding the sun no longer appears—are hot. The streets are deserted, and the dead silence of night reigns everywhere. The inhabitants of towns and villages shut themselves up in their houses, and those of the desert in their tents, or in wells dug in the earth, where they wait the termination of this destructive heat." All travellers bear testimony to the destructive effects of this wind; and it is stated that camels are so conscious of their danger from its influence, that they instinctively bury their nostrils in the sand, and keep them there until the squall is over.

The Sirocco—the Solano.—The sirocco is the name given to the hot wind which occasionally blows in Sicily, and which is supposed to derive its origin from the excessively heated deserts of Africa. The solano is a term applied to a modification of this wind which is met with in Spain and Portugal. The heat of the sirocco wind is described to be excessive. Brydone observes, that, when he experienced its first blast, he felt as if his face had been exposed to the burning steam from the mouth of an oven. When this wind occurs, the inhabitants of every town close their doors and windows against the admission of the external air, and sprinkle their apartments with water. Not a person ventures into the open air. It lasts from six or seven to thirty-six or forty hours. During this period the air is thick and heavy, and the sun does not appear. The thermometer, from 70 or 72 degrees, suddenly rises to 110 or 112 degrees, or even higher. When this sirocco wind, which always blows from the south, shifts, the north wind, which is called the *tramontane*, succeeds, and the country is again relieved from this distressing visitation. The most remarkable effect of the sirocco is the extreme depression of animal spirits which it produces. It gives a degree of lassitude both to the body and mind, which renders both alike unfit for performing their functions in an efficient manner. "The natives themselves," says Brydone, "do not suffer less than strangers; and all nature seems to languish during this abominable wind."

Velocity of the Wind.—The velocity of the wind is from an imperceptible movement to 100 miles in an hour. When it moves at the rate of 1 mile per hour, it is said to be hardly perceptible; at 2 or 3 miles, just perceptible; at 10 to 15 miles, pleasant or brisk; at 20 miles, bracing; at 20 to 25 miles, very brisk; at 30 to 35 miles, high; at 35 to 45 miles, very high; at 50 miles, storm or tempest; at 60 miles, great storm; at 80 miles, hurricane; at 100 miles, hurricane, tearing up trees, and throwing down houses, &c.

The Anemometer.—Many years ago, an instrument called the *anemometer* was contrived, for the purpose of measuring the force of the wind; and latterly an apparatus with the same name has been invented, to measure not only the force, but to indicate the direction of the wind at every minute of the day. From an exterior vane, a connection is established to a pointed index in the form of a pencil, which, according as the vane moves, travels on a sheet of paper spread on a table in a room beneath, and marks the paper in certain waving lines as it proceeds. The pencil being influenced by the movements of a clock, and the paper being squared into divisions for every hour in the day, a most effectual record is produced. Anemometers of this kind are now established at all the principal observatories.

RAIN.

It has been explained in the preceding paragraphs, that the waters of the earth yield up a certain quantity of moisture into the air, which, being condensed, assumes the form of clouds of greater or lesser density and magnitude, floating at a variable distance above us in the regions of the atmosphere. It has also been shown that clouds consist of an assemblage of small vesicles, or globules of moisture, which, on being affected by a diminution of temperature, lose their suspensory property, and gathering into larger globules, they drop to the ground in the form of water drops or a shower of rain. The fall of rain, therefore, is the result of so simple and obvious a cause as to require no lengthened explanation; and the only circumstances demanding our attention are the lesser or greater size of the drops, the closer or more distant arrangement of the showers, and the quantity which falls in reference to peculiar localities and different regions of the globe.

Within the tropics, and also in Great Britain, when the air has been charged with electricity, as often happens during the dry summer or autumnal months, the rain-drops are very large, but during the wet and chilly season which attends the fall of the year, they are often very small, and, as it is technically termed, *drizzling*. It is a remarkable fact, and worthy of our notice, that drops of rain have always been found larger in the lower regions of the atmosphere. Thus, Dr. Walker observed, in going down a high mountain, that the drops gradually increased in size as he descended. At a little way below the summit of the mountain, the precipitation appeared only a gentle mist; but this gradually became denser as he descended, until, on reaching the valley, it increased to a heavy rain. In the year 1776, Dr. Heberden proved this curious fact. He placed one instrument for measuring the quantity of rain which falls, called the *rain-gauge*, on the square part of the roof of Westminster Abbey; another on the top of a neighbouring house considerably lower than the first; and another on the ground in the adjoining garden. The rain collected on each was as follows:—Top of Westminster Abbey, 12 inches; top of the house, 18 inches; and on the ground, 22 inches: so that much more rain was collected in the lower than in the upper rain-gauge. It has been observed, that this difference may in some measure be owing to the action of the wind, which might drift the rain from the higher and more exposed vessel; but let the greatest pains be taken to avoid this difficulty—which may be done by placing all the vessels in positions equally exposed to the wind—still the fact will hold good, that the quantity of rain increases as we descend in the atmosphere.

It has been conjectured that the increased size of the drops, as we descend mountains into valleys, depends on their uniting together as they fall. But the truth seems to be, that the increased quantity of moisture precipitated is owing to the continued evaporation going on at the earth's surface. When the sun has withdrawn his rays, or is overcast by a dense cloud in the higher regions of the heavens, and when the air is loaded with excess of vapour, should an additional quantity arise from the earth's surface, it must be obstructed in its ascent, and, meeting with a colder current, be condensed, and converted into rain. In traversing a mountainous country during a storm, we have had occasion to observe this fact; for often the rain by which we have been wet through has seemed not so much to descend from above, as to be formed immediately around us. The garments about the knees of the pedestrian will, under such circumstances, be wet through, while his shoulders remain comparatively dry. Hence, marshy and maritime situations which emit much vapour are observed to be remarkably rainy. Mountainous regions are generally visited also with much rain, in consequence of the condensation of clouds on the summits of the hills. When the hills are in the neighbourhood of the ocean, their tendency to excite rain is greatly increased; and in proportion as we leave hills so situated, and pass into inland and more level districts, the less rain will be found to fall.

Winds, however, exert the chief influence over the atmospheric condition which produces rain. Thus, if winds blow from instead of to a hilly country, the clouds will be carried elsewhere, and be precipitated in lower regions at a distance. But, if these low-lying regions be warm, the clouds will be radiated, and their particles, in a refined state, will be carried onwards by the winds, till they come over a cold, high-lying country, where they will drop in heavy showers. In this manner the vapours from the Mediterranean are carried over Egypt, and do not collapse into rain till intercepted by the higher regions of Abyssinia. In consequence of certain winds blowing within the tropics, most countries near the equator have their *rainy seasons*—periods during which much greater quantities of rain fall than we are accustomed to in temperate climes. The rains in India, which are often so desolating in their effects, as already noticed, generally occur during the shifting of the monsoons, and also during what is termed the south-west monsoon.

In that part of Peru called Valles, which lies on the north and south side of Lima, and is bounded on the east by the Andes, and on the west by the Pacific Ocean, it never rains at all; but during winter, the earth is covered with a fog so thick and dense as to intercept the rays of the sun. These fogs supply sufficient moisture to render the most arid and barren soil fertile, and to convert the disagreeable dust in the streets of Lima into mud. The reason why it never rains in this country, is, that the wind always blows from the south, that is, from a colder to a warmer region of the world.

Speculations on the chance falling of rain in such countries as Britain are exceedingly hazardous, in consequence of the variability of the winds, and the conditions of the atmosphere at points far beyond our knowledge. With respect to the likelihood of rain, we can attain only a few general principles, all beyond which is doubt and difficulty. For example, if the weather be steady and dry, the winds, if not distracted by any foreign circumstance, will continue blowing and carrying away the evaporated moisture to distant regions, thus averting rain; but if, in the meanwhile, the temperature suddenly falls, or the winds shift, clouds immediately make their appearance, and showers of rain are the consequence. Yet there are exceptions to these general rules, as we will immediately mention.

In all countries, particular winds are noted for being accompanied either by wet or by dry weather: thus, the south and the south-west winds bring much moisture into Britain, while those from the north and north-east are cold, dry, and penetrating; hence the old proverb—

> "When the wind's in the south,
> It's in the rain's mouth."

Not only does this arise from the immense surface of ocean over which these winds sweep south of the equator, the evaporation from which must be prodigious, but from these southerly winds being of a higher temperature, whereby they hold a greater quantity of vapour in suspension or solution, the condensation of which must be proportionally greater on arriving in this colder climate. Accordingly, it has been observed that the wind will turn from the north to the south quietly and without rain, but, on returning from the south to the north, will blow hard and bring much rain. Again, if it begin to rain from the south, with a high wind, for two or three hours, and the wind falls, but the rain continues, it is likely to rain for twelve hours or more, and does usually rain until a strong north wind clears the air. For the same reason, winds from the west and south-west are considered to bring with them wet weather; hence the old saying—

> "A rainbow in the morning is the shepherd's warning;
> But a rainbow at night is the shepherd's delight."

In the morning, the sun rising in the east shines directly upon the rain falling in the west, and thereby warning the watchful shepherd of the approach of wet weather with this humid wind; but at night, when the sun sinks in the west, its rays fall on the rain in the east, and the shepherd then sees the storm departing; hence this is one of the many popular sayings founded on observation of nature.

Men of science have made very careful inquiries to ascertain the quantity of rain which falls in certain places during a given time, and the instrument devised for that purpose is the *rain-gauge*. Its construction is very simple, consisting merely of a circular or square vessel, to which is affixed a pipe, funnel-shaped, for conducting the rain into it, where its quantity is estimated by a scale marking the number of square inches which enter. The annual quantity of rain is greatest in tropical countries, and diminishes as we approach the poles; a circumstance explicable by the greater evaporative qualities of the atmosphere in warm than in cold countries. The following table illustrates the progressive diminution of rain as we reach higher latitudes:—

	North Latitude.				Inches of Rain.
Uleaberg. - -	65 degrees,	30 minutes.			13·5
Petersburg, - -	59	—	56	—	17·5
Edinburgh, - -	55	—	58	—	24·5
London, -	51	—	31	—	22·2
Paris, - -	48	—	50	—	19·9
Rome, - - -	41	—	54	—	39·0
Calcutta, - -	22	—	25	—	81·0
Vera Cruz, -	19	—	5	—	83·8
Bombay, - -	18	--	57	—	82·0

The mean quantity falling annually in England is reckoned to be 32 inches, or, according to Dalton, 31·3; but this is unequally distributed. At Keswick, in Cumberland, the depth, on an average of seven years, was found to be 67 inches; and at Plymouth, in Devonshire, 46 inches. In the western parts of Scotland, the depth is from 30 to 35 inches, which is from 6 to 10 inches more than that on the east coast.

Although the quantity of rain which falls in tropical countries is usually greater than what is precipitated in colder regions, it is dispersed over less time, and chiefly falls in heavy showers during a limited season of the year. In our temperate climates, therefore, we have more rainy and drizzling days throughout the year than are experienced in warm countries; and it is this which gives the character of moistness and personal discomfort to our climate.

The seasons of the year, while they contribute, by their variety, to our pleasure and happiness, are characterized by such weather as is best adapted to the necessities of the vegetable and animal creation; wherefore the proportions of rain vary in different months of the year. In summer we have not so many rainy days as in winter; but the showers are then heavier, the streams of rain closer together, and the quantity which falls is greater than during any other season. Dr. Dalton has ascertained that the first six months of the year may be regarded as dry, and the last six as wet months. Another ingenious author has inferred, from long observation, that in spring it rains oftener in the evening than in the morning, but that towards the end of summer, oftener in the morning than in the evening, and storms at this time are apt to occur a little after sunrise.

The reason that in winter less rain falls, though we have more rainy days than in summer, is, that the temperature of the air is less variable in winter, and the condensation of moisture not so forcible; therefore, the rain continues falling in small drizzling drops, which, accompanied or followed by chilly north-east winds gives rise to colds and coughs, and many distressing maladies. It is also to be observed, that, while a clouded and damp atmosphere favours the increase of vegetable foliage, it is not so favourable to its fructification. In such seasons, while the blades of grass grow broader, the nutritious principle which they should contain is not well developed; so that animals feeding on this poorer grass are obliged to take a larger portion to satisfy their appetites. Cattle and sheep which feed on such pasturage, may be observed to be almost continually eating; whereas, in moderately dry seasons, when the occasional rains have been heavier, every blade of grass grows more healthily, its nutritious principle is better evolved, and less sufficing, the same animals may be seen lying down and ruminating in the shade. In the progression of the seasons, rain falls at all times during the twenty-four hours; but it has been ascertained that much less falls by day than by night.

Rain has occasionally been known to fall of a peculiar colour or substance; but this, like other atmospheric phenomena, admits of an explanation on natural grounds. In the year 1810, a shower of red rain fell in Hungary. It lasted a quarter of an hour, and the water was like blood. This was ascertained to be owing to the rain-water being loaded with the red pollen of certain kinds of trees from a neighbouring forest. Red rain, however, is more frequently caused by an incorporation with the atmosphere of a minute fungous vegetation or of animalcules, both too small to be seen by the naked eye. Viscid or a kind of *glutinous rain* has likewise fallen. In the Transactions of the Royal Society of London, an account is given of a shower of viscid rain which happened in Ireland. On examination, it was found to be owing to the presence of extraneous matter, partly vegetable and partly animal. In 1828, a substance was shown to the French Academy, which fell in the plains of Persia. It was edible, and afforded nourishment to cattle and many other animals. This nutritious matter was found to be a vegetable production—the *Lichen esculentis* of botanists—which had been transported thither by the wind.

We are not, in these various instances, to forget the powerful agency of the wind, which often has been proved to carry to a prodigious distance, sand and dust, and the ashes and scoriæ which have been thrown up during the eruption of volcanoes. Not very many years ago, during a strong gale, herrings and other fish were carried from the Firth of Forth to Lochleven, a distance of upwards of ten miles.

Signs of Rain.—We conclude our observations on rain by enumerating a few of those prognostications of approaching rain, which, admitting of explanation, are most interesting. When the moon is of a pure silvery colour, good weather is indicated; but when it has a brown or chestnut-coloured tint, rain may be expected. This is owing to the effect of the vapour in the atmosphere in refracting the moon's light. For the same reason, when stars are surrounded by coloured halos, the approach of rain is indicated.

When mountain ranges or distant objects appear nearer to us than usual—when sounds are heard more clearly from a distance—when the odour of plants is more than usually powerful, rain may be prognosticated. The first of these signs arises from the effect of an excess of moisture in reflecting and refracting the rays of light—the two last from sounds as well as odours being conveyed better through a damp than through a dry air. The low flight of swallows indicates approaching rain. The cause of this is, that they pursue flies, which delight in warm air; and these flies, escaping from the excess of moisture above, descend nearer to the surface of the earth, and are there pursued by these birds.

Ducks, geese, and other waterfowls, before the approach of rain, may be seen to throw water with their bills over their backs, and dive frequently; the cause of which is, that, although so much in the water, they do not like being wet to the skin; to avoid which, when warned by the peculiar sensation preceding rain, they close their plumage together, by throwing a sudden weight of water on their bodies, in the direction of the growth of their feathers.*

Before the fall of rain, cattle may sometimes be observed stretching out their necks, and snuffing in the air with distended nostrils, which, doubtless, is occasioned by the odours of plants being more powerful than usual, when the air is saturated with an excess of moisture.

Man in strong and robust health does not feel his constitution affected by that change in the state of the atmosphere which precedes rain; but persons who are in delicate health are often much affected. Pain of the head, toothache, irritability of temper, pains in old sores which have healed, the aching of corns, and excessive nervousness, are all, in certain habits of body, signs of approaching wet weather.

Dogs closely confined in a room become drowsy and stupid before rain; the same, in a less degree, is observed in cats; horses neigh much; cattle low; the fallow-deer becomes restless; and many other animals, from the uneasiness they feel owing to the altered condition, prognosticate the approach of rain. Insects, being very sensible of every change in the state of the atmosphere, are good weather-guides; hence, fine weather may be predicted when many spiders' webs are seen in the open air; also when bees are found far beyond their hives. On the contrary, when spiders remain hidden, and bees do not range abroad as usual, rain may be expected. Many flowers and plants are excellent prognosticators of the weather. When the flower of the chickweed expands freely, and remains open, no rain will fall for many hours; but when it closes, showery weather or continued rain may be expected. The trefoil, the convolvulus, and many other plants, contract their leaves before the approach of rain.

FROST—SNOW.

When the temperature of the atmosphere falls to a certain degree of cold (indicated by 32 degrees in our thermometers), which it does principally from the weakness of the sun's rays in winter, the phenomenon of frost or freezing ensues. Freezing is a process of congelation, or properly, crystallization, produced by the withdrawal or absence of heat, and by which water assumes the form of ice.

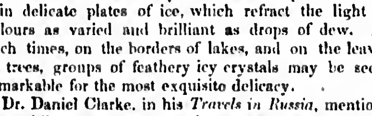
When the temperature of the atmosphere arrives at that low pitch which effects freezing, the watery particles which are upheld in the clouds are frozen in their descent, and coalescing, reach the earth in the form of flakes of snow; and these accumulating on the ground, constitute the appropriate characteristic of the winter season. An intensely cold current of air, mixing with the vapour suspended in a warmer current, occasions, as in the case of hail, this precipitation. Snow, however, is formed in the lower regions of the atmosphere, or might, if commencing in small nucleus, in higher regions, be converted in its descent into hail. That snow is formed in this manner, there can be no doubt; for a very cold stream of air, admitted into a room in which the contained air is warmer, and loaded with watery particles, will occasion its formation. In the huts of the people in the desolate arctic regions, snow is often so formed; they stop the chink, yet still the walls are often covered with a thick icy crust; and whenever a cold current from the external air is ad-

* Luke Howard's Climate of London, notes to vol. i.

mitted, snowy flakes are precipitated. Dr. Robertson states, that, in a crowded assembly-room at St. Petersburg, a stream of cold air was accidently admitted into the room by a gentleman breaking a pane of glass, on which the vapour in the air was immediately congealed, and fell in the form of snow-flakes. In Siberia, Pallas, Chappe, and others, have seen it formed under similar circumstances; and by the narrative of the Dutchman who wintered in Nova Zembla, we are informed that a shower of snow fell, from the vapour of expiration, every time there was any communication with the external air. The peculiarities of snow consist in its extreme lightness, and also in its being purely white. Its lightness is occasioned by the excess of its surface exceeding so much in comparison the matter it contains, and its whiteness is owing to the minute particles into which it is divided; hence, when ice is pounded, it is equally white. When snow, however, accumulates in large quantities, its weight becomes very considerable. Snow occurs in all regions of the globe at a certain height above the level of the sea, but falls more abundantly on plains as we proceed from the equator to the poles. In the arctic regions, snow falls nine days out of ten during the months of April, May, and June, and often a depth of two or three inches is deposited in an hour. In these regions, the thickest precipitations are observed to precede the occurrence of storms.

The forms of snow-flakes present an almost endless variety; they are often very regular and beautiful, and reflect with exceeding splendour the rays of the sun. When they are very large, they are said to indicate the approach of thunder. After a copious fall of snow, when the temperature is too low to produce any moisture, its level surface may often be seen sprinkled with thin delicate plates of ice, which refract the light in colours as varied and brilliant as drops of dew. At such times, on the borders of lakes, and on the leaves of trees, groups of feathery icy crystals may be seen, remarkable for the most exquisite delicacy.

Dr. Daniel Clarke, in his *Travels in Russia*, mentions that, while at St. Petersburg, he observed flakes of snow falling in regular and beautiful forms. "The season," he says, "began to change before we left Petersburg. The cold became daily less intense; and the inhabitants were busied in moving from the Neva large blocks of ice into their cellars. A most interesting and remarkable phenomenon took place the day before our departure: the thermometer of Celsius stood at that time only 5 degrees below the freezing-point, and there was no wind. Snow, in the most regular and beautiful crystals, fell gently on our clothes and on the sledge, as we were driving in the streets. All of them possessed exactly the same figure and the same dimension. Every particle consisted of a wheel or star, with six equal rays, bounded by circumferences of equal diameters: they had all of them the same number of rays branching from a common centre. The size of each of these little stars was equal to the circle presented by dividing a pea into two equal parts. This appearance continued during three hours; in which time no other snow fell, and there was sufficient leisure to examine them with the strictest attention, and to make the representation given in the first figure.



"As water, in its crystallization, seems to consist of radii diverging from a common centre, by the usual appearances on the surface of ice it might be possible to obtain the theory, and to ascertain the laws, from which this stellar structure results. An equiangular and equilateral plane hexagon is divisible into three equal and similar rhombs; and if the engraved figure A be attentively observed it will appear that each linear ray of the star is a diagonal (see fig. B) joining the acute angles of a rhomb, whose sides are the loci of the extreme points of the lines of ramification from these diagonals. The rhomb may therefore be the primitive form of water crystallized. This seems the more manifest, because, if equal and similar rhombs be applied between all the rays of the star A, in the spaces 1, 2, 3, 4, 5, and 6, an equilateral and equiangular hexagon will be the result, as represented by the dotted line in fig. C." The same star-like shape of snow flakes has been seen in Britain. According to a notice in an Edinburgh newspaper, the phenomenon occurred in Lanarkshire in the winter of 1838.

Snow is occasionally seen of a brown colour, which arises from its being impregnated with earthy substances, brought from the mountains by those streams of water which are derived from the thawing of ice or snow. Much oftener has snow been observed of a red colour, which appears generally to have arisen from its intermixture with some vegetable substance. Captain Scoresby informs us, that, in the arctic regions, the redness of the snow may occasionally be attributed to the little auk (*Alca alle*), which feeds on shrimps, and accumulates in immense numbers.
