Charcoal is the substance which remains when wood or any vegetable substance is exposed to red heat in close vessels. The properties of this substance are various and remarkable, and it affords a most striking proof of the extraordinary differences of appearance which the same body may assume, and also of the intrinsic worthlessness of some of those objects upon which we set so high a value. We are all aware of the enormous price which is paid for a good diamond, and yet chemical investigation has proved it to be, beyond all question, only a bit of carbon! The diamond burns in oxygen with a brilliant flame, and, like charcoal, forms carbonic acid; like charcoal, it also forms steel, in combination with iron. The difference between the two bodies seems to be chiefly in their state of aggregation, the diamond being harder, and crystallised. Charcoal is destitute of taste and smell. When new made, dry, and warm, it absorbs gases in very large quantities. It is probably on account of this property that it acts so powerfully as an antiseptic, and removes the tainted odour given out by bodies during the process of putrifaction. No effect is produced upon carbon by the most intense ordinary heats, except that it is rendered harder, denser, and more sonorous. Carbon combines with all the supporters of combustion, and also with hydrogen and azote. When it is burned in oxygen, intense light and heat are produced, and a compound is formed, entitled

Carbonic Acid Gas.—This gas possesses very remarkable properties; its specific gravity is 1.5277. It is colourless, has an acrid taste, and, when applied to the nose, excites a pungent sensation. No combustible will burn it; and its effect upon animal life, when inhaled into the lungs, is evinced by the fate of persons who incautiously expose themselves to the vapours of charcoal burning in ill-ventilated apartments, or who venture into large vessels in which fermentation had been conducted, as in breweries, distilleries, &c. Animals give out this gas during expiration; and it is also generated by the combustion of wood and coal; so that it is not surprising that a portion of it should always exist in the atmosphere. This gas combines with bases, and forms a genus of salts called *Carbonates*. Like all weak acids, it unites in various proportions with most of the bases. With one half the quantity by volume of oxygen gas, carbon forms what is called *carbonic oxide*. This gas, if inspired, acts as a poison. Those who breathe it become immediately deprived of sense and volition. Carbonic oxide cannot be condensed by pressure into a fluid. It possesses no acid properties, and is not absorbable by water. It unites with chlorine, but the compounds are unimportant. There is another combination of carbon with oxygen, called

Oxalic Acid.—This substance is derivable from digesting sugar along with nitric acid. The acid is deposited in small crystals, which have an intensely acid taste, and, when taken internally even in small quantities, destroys life. It combines with bases, and forms a genus of salts called *oxalates*. Carbon and chlorine are capable of uniting in three different proportions, with bromine in one or two, and with iodine in two. But we must pass from these compounds to those of far greater moment, which it forms with hydrogen.

There are many combinations of carbon with hydrogen, and much uncertainty prevails, both with regard to their number and nature; they are all designated by the name hydrocarbons, or more properly hydrocarburets. Marsh gas, fire damp, or carburetted hydrogen, is that which bubbles from the bottom of stagnant pools, and issues from the fissures of coal mines. It is transparent, colourless, elastic like common air, and has a disagreeable smell, if not well purified, when it is nearly inodorous. If it be mixed with twice its volume of oxygen gas, and a lighted taper applied, or an electric spark passed through, an explosion takes place with a loud report, and carbonic acid and water are the results. Carburetted hydrogen consists of one volume of carbon vapour and two volumes of hydrogen gas. Its specific gravity is 0.5555. It is fatal to animal life if breathed. Olefiant gas or bicarburetted hydrogen is similar to the former, but contains double the quantity of carbon vapour. It burns with great splendour, producing a dense white flame.

COAL GAS.

Carburetted and bicarburetted hydrogen bear very different relations to the wellbeing of man: the former, when a spontaneous production of nature in mines, is one of the most terrific instruments of destruction, and a great obstacle to human industry; for, by mixing with a certain quantity of common air, it acquires the property of exploding when accidentally kindled, and thousands of human lives have fallen sacrifices to its violence, until the splendid invention of the safety-lamp divested it of its terrors. Bicarburetted hydrogen is the chief, although not the most abundant ingredient in *coal gas*, now so generally used for illumination; the other ingredients are carburetted hydrogen, hydrogen, and carbonic oxide. Coal gas is made by introducing a quantity of bituminous coal into a large iron cylinder called a retort, close at one end, and furnished with a mouth-piece at the other, for closing or opening it; there is also a tube for carrying off the gas and other products as they form. A quick strong heat is applied round the cylinder, and a vast quantity of gas, composed of the four ingredients just mentioned, is thus extricated, with tar and an ammoniacal liquor, both of which are condensed by passing through pipes immersed in cold water. There is a great difference in the relative proportions of the gases in the mixture, as also in the quantity of tar, according to the quality of the coal, and the mode of applying the heat. The more tar the gas holds dissolved, the more dense will be the flame when the gas is made to burn, and the more disagreeable will be the smell when it is not burning. A slow heat gives much tar and little gas, and that little of a poor quality; a quick heat gives much gas, of good quality, and less tar. Owing to these and other causes, the illuminating power of coal gas varies much. Before it is let through the conducting tubes for public consumption, it is well agitated in contact with a mixture of lime and water, or passed through strata of loosely strewed hydrate of lime; it is thus deprived of much of its smell, and also of some of its illuminating power. On an average, a chaldron of good Newcastle coal, weighing 25 cwt., will afford 12,000 cubic feet of gas, provided that the retorts are new. After being used a few months, the product will not exceed 11,000 feet, or even 10,000. On the whole year, the average may be about 11,000. The quality of this gas is such, that half a cubic foot per hour is equivalent, in burning, to the light of a mould candle of six to the pound, during the same space of time; hence, one pound weight of coal will afford light equal to such a candle for four hours and a half. An illuminating gas of this kind is sometimes presented ready formed by nature. A village of Fredonia, in the western part of the state of New York, is lighted with this gas as it naturally issues from a rock; the flame is large, but not quite so brilliant as that of coal gas.* *Oil gas* being of a similar nature, it need not be particularly described. There are other less important compounds of carbon and hydrogen, and the whole correspond with the law of multiple combination already described. *Naphtha* and *naphthaline* are hydrocarburets; the former is a transparent volatile fluid, the other is a transparent volatile solid, which assumes the form of crystalline plates; both are obtained from coal tar by distillation.

Cyanogen.—This substance is a gaseous compound of azote and carbon. It burns with a purple flame, but it destroys life on being breathed. Cyanogen unites with a variety of bodies, and forms many important compounds.

BORON.

The borax of commerce is a compound of boracic acid and the alkali called soda. Boracic acid is a compound of oxygen and boron, in the proportion, it is supposed, of one atom of the latter to two of the former. Pure boron is an opaque brownish olive powder, infusible, and not volatile at any temperature to which it has as yet been subjected. It neither dissolves in nor acts upon water. At about 600°, it takes fire, and combines with oxygen, forming

Boracic Acid.—This substance evinces the usual properties of an acid, but it is not a powerful one. When it is detached from borax, by vitriol being poured upon that compound, it exhibits itself in scaly crystals. It dissolves in rectified spirits, and, if the solution be set on fire, it burns with a green flame. Borax itself, when heated, melts into a perfectly clear glass, which is the basis of some artificial gems of considerable beauty. Borax communicates its own fusible nature to other bodies, and hence is used as a flux. Flux is a general term made use of to denote any substance or mixture employed to assist the fusion of minerals. There are a considerable number of such bodies; the alkalis are those most generally used. Boracic acid is the only known compound of boron with oxygen. There has been no compound yet discovered of boron with either bromine or iodine, but it combines with chlorine, forming a gaseous acid, to which the name of *borochloric acid* has been given; and also with fluorine, forming

Fluoboric Acid, which exists in the gaseous state. It is colourless, has an exceedingly acid taste, and a smell similar to muriatic acid. It contains no water, but possesses a powerful affinity for that fluid, and is on that account sometimes used as a test of the presence of moisture in gases. Its specific gravity is 2.362; and it seems to consist of one atom of fluorine and two of boron. The combinations of boron with hydrogen, azote, and carbon, are still unknown.

SILICON.

Quartz, or *rock crystal*, which constitutes so considerable a portion of the crust of the earth, consists essentially of a peculiar acid substance, called *silica*, or *silicic acid*. It is a white tasteless powder, which combines with the different bases forming compounds, analogous to the salts. This substance is a compound of oxygen, with a base which has been entitled silicon. It is a powder of a deep brown colour, and very similar to boron in its appearance, and in its relations to other matter. It stains the fingers, and adheres to every thing that comes in contact with it. It can be exposed to a very high temperature without being fused; after ignition, the specific gravity of silicon is about 1.837. It dissolves in a mixture of fluoric and nitric acids with great facility, although it is not acted upon by them singly. When mixed with dry carbonate of potash or soda, and heated far below redness, it burns vividly at the expense of the carbonic acid; carbonic oxide is disengaged, and the residue is tinged black by carbon being deposited. By this process silicon is converted into silica, which is a compound of one atom of silicon and one atom of oxygen. Silicon combines with chlorine, forming a *chloride of silicon*. This is a colourless volatile liquid, having a suffocating smell, and probably acid properties. With fluorine, silicon unites and forms

Fluosilicic Acid.—This is a gaseous substance, transparent, colourless, and having a smell like muriatic acid. It smokes when mixed with moist air, and it is rapidly absorbed by water. Its specific gravity is 3.6. It combines with carbon, but no other compounds are known.

SULPHUR.

Sulphur, or brimstone, is a substance whose appearance is too familiarly known to require particular description. In many parts of the world it is found in a state of great purity. It occurs plentifully in volcanic countries, and is an abundant ingredient in various minerals. It is a non-conductor of electricity, and, when rubbed, becomes highly electric. It has a specific gravity of 2.0332. When heated to 170°, it is volatilised, and the result is a fine powder called *flowers of sulphur*. It melts at 218°, but at 340° it becomes thick, and from 482° to its boiling point, about 750°, it gets thinner. When suddenly cooled, it remains soft, in which state it is used for taking impressions. It is extensively used in the arts; for instance, in the manufacture of gunpowder. With oxygen it combines in five proportions, forming five compounds, all of which possess acid properties.

Sulphurous Acid.—When sulphur is heated to 300° in the open air, it takes fire, and burns with a pale blue flame, at the same time emitting abundance of fumes of a suffocating nature, which are sulphurous acid. It is colourless, extinguishes flame, is not inflammable, converts vegetable blues to red, forms a class of salts called *Sulphites*, and has a specific gravity of 2.2222. This gas bleaches various textures, as those of silk, wood, and straw; the liquid acid bleaches sponge. Sulphurous acid is supposed to consist of equal bulks of oxygen and sulphur.

Sulphuric Acid, or *Oil of Vitriol*.—This acid is made in great quantities for the use of bleachers, and other manufacturers, by burning sulphur in leaden chambers. At the same time, a quantity of nitric acid from the decomposition of saltpetre is admitted into the chamber. The sulphur is converted into sulphurous acid. Five atoms of this acid unite with one atom of nitric acid, and two atoms of water, and form a white solid salt, which falls to the bottom of the chamber into a quantity of water placed to receive it. As soon as it comes in contact with the water, a strong effervescence takes place; the nitric acid is decomposed, and converts the sulphurous into sulphuric acid, while at the same time a quantity of deutoxide

* Donovan's Chemistry, p. 117.

of azote is disengaged. This gas, coming in contact with the oxygen of the air, is converted into nitric acid, which combines with an additional dose of sulphurous acid, and is decomposed as before. Thus the process goes on as long as sulphurous acid and oxygen gas exist in the leaden chamber.* Sulphuric acid thus obtained is a colourless liquid, possessing some viscidity; and when as much concentrated as possible, its specific gravity is 1.837. A stronger acid, however, can be obtained by another process, in which state it is entirely destitute of water. Sulphuric acid is one of the most powerfully corrosive bodies known to us. The following are some of its principal properties. When mixed with water, to which it has a very powerful attraction, a decrease of volume occurs, and a considerable degree of heat is generated. It freezes when sufficiently cooled, and the crystals are sometimes large, distinct, and hard. When exposed to the air, this acid discharges whitish-grey vapours, which are sulphuric acid in a dry state. Acid of specific gravity 1.896, contains about one-tenth of water, and is so volatile that it boils at 120°. The constitution of sulphuric acid is, sulphur two parts, and oxygen three parts. It forms a very numerous and important class of salts called *Sulphates*. The other compounds of sulphur and oxygen it is unnecessary to notice. Sulphur unites with chlorine in two proportions. It also combines with bromine, iodine, and fluorine, but its next most important combinations are those with hydrogen.

Sulphuretted Hydrogen.—This is a colourless gas, having a strong fœtid smell, something like rotten eggs, and a sweetish taste. It is a non-supporter of combustion, and, when breathed, destroys animal life. Its specific gravity is 1.1805. It is combustible, and burns with a bluish-red flame. Water absorbs 3.66 times its bulk of this gas; and if it be passed through water tinged with a vegetable blue, it will change the colour to red. A few drops of nitric acid let fall into a vessel filled with sulphuretted hydrogen, sets fire to it. This gas blackens silver, and darkens the wood-work of rooms painted with white lead, from human exhalations containing a portion of it. Its atomic constituents are said to be one atom of sulphur and one atom of hydrogen. Double the quantity of sulphur to the same proportion of hydrogen forms what is called the *bisulphuret of hydrogen*. No compound of sulphur and azote is known, but with carbon there is more than one. With boron and silicon, sulphur forms sulphurets.

SELENIUM.

This is a substance nearly allied to sulphur in its nature, although it in some respects partakes also of the character of a metal. It melts at about 212°, and on cooling becomes solid, in which state it has a metallic lustre, and a deep brown colour. It is soft and easily reduced to powder, which is of a deep red. Its specific gravity is 4.3. It is a bad conductor of heat, a non-conductor of electricity, and is also non-electric. Like sulphur, it sublimes into flowers; such are its leading characteristics. It combines with oxygen in three proportions, forming *oxide of selenium*, a gaseous body, *selenous acid*, which has an acid and acrimonious taste, and, lastly, *selenic acid*, which resembles sulphuric acid in its consistence, and in many of its properties. It is to be remarked, that the compounds of selenium and oxygen bear a strong analogy to some of those of oxygen with sulphur. Selenium combines also with sulphur, chlorine and carbon.

TELLURIUM.

This substance is a metal, having a silver-white colour, and considerable brilliancy. It has a laminated texture, is brittle, may easily be reduced to powder, and has a specific gravity of 6.1379. It fuses at a temperature rather higher than that which is necessary to melt lead. It combines with oxygen, and forms *oxide of tellurium*. This compound possesses at once acid and alkaline properties. When tellurium is heated before the blowpipe, it burns with a blue flame, emitting a white smoke, which is the oxide. Tellurium burns spontaneously in chlorine gas, and forms a *chloride of tellurium*. It also unites with iodine, hydrogen, and carbon. The other combinations of this metal are still unknown.

PHOSPHORUS.

This well-known substance is commonly prepared from the earth of bones, which consist chiefly of the phosphate of lime. This salt is decomposed by sulphuric acid, and after going through a difficult process, the phosphorus is distilled into a receiver in the shape of melted drops. It is an amber-coloured and semi-transparent solid. Its specific gravity is 1.748. It is so very combustible, that it takes fire in the air, emitting a white smoke having the smell of garlic, and appears luminous in the dark. At the temperature of 148°, it burns with a large resplendent flame, giving out a white smoke, which is

Phosphoric Acid.—This substance can be obtained by other processes, in which case it exhibits itself as a transparent solid body like glass, having an acid taste. It has no smell, but an exceedingly sour taste; it is not corrosive. Its atomic constituents are supposed to be one atom of phosphorus and two and a half atoms of oxygen. With oxygen, phosphorus forms a weaker acid, called *pyrophosphoric acid*, and also *phosphorous acid*, both feeble acids.

Phosphuretted Hydrogen.—This gas is colourless, has a smell like garlic, and a very bitter taste; its specific gravity is 1.7708. It burns spontaneously. When mixed with oxygen, *rarefaction* causes them to explode, as *condensation* produces explosion in other gases—a very remarkable property of this substance. This gas may be detonated, also, with protoxide and deutoxide of azote. When mixed with chlorine gas, it burns with a greenish-yellow flame. It is composed of equal volumes of hydrogen gas and phosphorous vapour. There are other compounds formed of these two substances; and phosphorus combines also with chlorine, bromine, and iodine, in two proportions each. It likewise unites with fluorine, carbon, sulphur, and selenium.

ARSENIC.

The *White Arsenic* of commerce is a combination of arsenic and oxygen. When mixed with *black flux* (which is cream of tartar exposed to a red heat in a covered crucible, till it ceases to smoke), and subjected to heat, it is reduced to the metallic state. It has a bluish-white colour, is soft, brittle, and easily reduced to fine powder. Its specific gravity is 5.672. When moderately heated, it evaporates, combining with oxygen, and forming the arsenic of commerce, so well known for its destructiveness to animal life. With oxygen, arsenic forms two acids, the *arsenous* and *arsenic*. *Arsenous acid* is a white, brittle, compact substance, having a weak, acrid taste, which at last leaves an impression of sweetness. It is one of the most virulent poisons known. *Arsenic acid* is quite similar in its constitution to phosphoric acid. Arsenic combines with chlorine, bromine, iodine, fluorine, hydrogen, sulphur, phosphorus, and selenium.

ANTIMONY.

This is a metal, which, when pure, possesses a silver-white colour. It is well known, being much used as a medicine. Its texture is fibrous, and it is easily reduced to powder by being pounded in a mortar. Its specific gravity is 6.4366. It melts when heated to redness, and at a higher heat it evaporates. It combines with oxygen in three proportions, and forms three compounds, two of which possess acid properties. The other is an oxide, which constitutes the base of all the active medicinal preparations of this metal. With chlorine it combines in two proportions, forming two chlorides, which are analogous to two of the compounds formed with oxygen. It also combines with bromine, iodine, fluorine, sulphur, selenium, phosphorus, and arsenic. Antimony is extensively used in the arts, particularly in typefounding and in stereotyping.

CHROMIUM.

This is a metal of a whitish colour and a brittle consistency. Its specific gravity is 5.9. It requires a very high degree of heat to melt it, and is only obtained pure in small grains. No acid readily dissolves it, except the fluoric. Chromium combines with two proportions of oxygen, forming two compounds, which have received the names of *green oxide* and *chromic acid*. Chromium unites with chlorine, sulphur, phosphorus, and probably fluorine. It is used in coloured glass making, and glass and porcelain painting. It is also used in enamelling, and as a rich, strong, and durable pigment. To glass and enamel it communicates a green colour, but to the painter it affords one of his prettiest yellows.

VANADIUM.

This is a metal which was only discovered four years ago. It is white, resembling silver, brittle, a good conductor of electricity, and is easily dissolved in nitric acid and aqua regia. When heated rather under redness, it takes fire, burns with a dull flame, and is converted into a black-coloured oxide. It combines with oxygen in three proportions, forming, first, *black oxide* or protoxide, *blue oxide* or binoxide, and *vanadic acid*. It combines also with chlorine, sulphur, and phosphorus, but its other compounds are unknown.

URANIUM, MOLYBDENUM, TUNGSTEN, COLUMBIUM, AND TITANIUM.

These substances are all metals, but on account of their scarcity, or on account of the difficulty of reducing them to the metallic state from their ores, are but imperfectly known, and have not been applied to any useful purpose. *Uranium* has an iron-grey colour of considerable lustre, and, when heated to redness, takes fire. Its specific gravity is 9. *Molybdenum* has a silvery-white colour, is brittle, and has a specific gravity of 8.636. *Tungsten* is of a greyish-white colour, is very hard and heavy, having a specific gravity of 17.4. *Columbium*, when burnished, assumes a yellowish-white colour and a metallic lustre. *Titanium* has a copper-red colour, and considerable brilliancy. It crystallises in cubes, is hard enough to scratch rock crystal, and has a specific gravity of 5.3. All these metals combine with oxygen and some of the other supporters, but the oxides and acids so formed are not deserving of particular mention.

We have now described the *simple acidifiable bases*; let us turn, therefore, to the *simple alkalifiable bases*, which, as far as at present known, are thirty-one in number. These Dr Thomson divides into five families; namely, alkaline, earthy, difficultly fusible and easily fusible bases, and the noble metals.

ALKALINE BASES.

This family consists of seven metallic bodies. Their oxides constitute the most powerful alkalis, and the latter readily combine with acids, forming *salts*. The chlorides, bromides, and iodides of these bodies, are also salts. We shall shortly notice them in detail.

Potassium is the base of that well-known and very useful article potash. The properties of potassium were first determined by Sir H. Davy, to whom we are indebted for the discovery of the composition of the alkaline bodies. It is a white metal, like silver. At 32° it is hard and brittle, at 50° is soft and malleable, at 132½° melts, and nearly at red heat evaporates. Its specific gravity at 60° is 0.8507, water being 1.000. When exposed to the air, it rapidly absorbs oxygen, and forms potash. This body in commerce is always combined with water, which cannot be expelled by heat. When thrown on the surface of water, which it swims upon, it decomposes that fluid with such rapidity that the metal takes fire, and burns with a red flame. Potassium combines with two proportions of oxygen; it also unites with chlorine, bromine, iodine, hydrogen, sulphur, and several other bodies.

Sodium is a metal so similar in most respects to the foregoing, as to stand in no need of particular description. It is the base of the alkali called soda, which is formed when the metal is brought into contact with water, or when it is heated in oxygen. It decomposes water, and in its relations to other bodies bears a strong resemblance to potassium.

Lithium.—This metal is the base of the alkali called lithia, which is of a white colour, and has a taste fully as caustic as that of potash itself. It is of course an oxide of lithium. Lithium likewise unites with chlorine, but its other combinations are unknown.

Barium.—This metal is the basis of barytes, an alkaline earth. It is of a white silvery appearance, absorbing oxygen rapidly by exposure to the air, thus forming barytes; and it also rapidly decomposes water. Barium combines also with sulphur and phosphorus, and forms salts with chlorine, bromine, and iodine.

Strontium.—This metal is the base of strontia, an earth very similar to the foregoing. Strontium and barium resemble each other very much in most of their properties, and their combinations with oxygen have also a very strong resemblance. Strontium also unites with chlorine, phosphorus, and sulphur.

Calcium.—This metal is the base of the well-known and indispensable commodity lime. *Lime* has been known from the remotest ages, and appears always in combination with an acid, most commonly with the carbonic, constituting *limestone*, *marble*, *calcareous spar*, *chalk*, and frequently, with sulphuric acid, constituting *gypsum*, *selenite*, and *sulphate of lime*. It combines also with various other acids. Calcium is white, like silver, solid, and much heavier than water. When heated in the open air, it burns brilliantly, and quicklime is produced. Calcium unites with oxygen in two proportions, forming lime and peroxide of calcium. Pure lime is tasteless, and insoluble in water. It, however, readily absorbs water poured upon it, and swells, producing at the same time a great heat. The fact is, that the water becomes solidified, and of course gives out a great quantity of heat, which accounts for the rise of the temperature. This process is called slacking lime. Lime combines with chlorine, and forms *chloride of lime*, a substance which has become an important article of commerce under the name of *bleaching powder*. It is a white powder, with a hot taste, having the power of destroying vegetable colours. Calcium combines with sulphur and phosphorus.

Magnesium.—This metal is the basis of magnesia, a substance universally known from its frequent employment in medicine. Magnesium is obtained in brown scales, which, when rubbed against agate, leave a metallic stain of a leaden colour. It burns with a red light, and, by thus combining with oxygen, becomes *magnesia*. This is a soft, elastic, tasteless powder, not sensibly soluble in water, and slowly changing vegetable blues to green. Magnesia forms salts with chlorine, bromine, and iodine.

EARTHY BASES.

This family comprehends six substances, the oxides of which are white tasteless powders, formerly distinguished by the name of *earths*.

Aluminum.—Alumina, which, when pure, is a fine light powder of brilliant whiteness, is an essential constituent in every kind of clay, and constitutes the base of *alum*, from which substance it may easily be obtained. It is a compound of oxygen and aluminum, consisting of eight parts of the former to one hundred of the latter. This metal, when burnished, assumes the metallic lustre and splendour of tin. It is not easily fused, but at a red heat it burns with great splendour, and is converted into alumina. This substance, so useful in the manufacture of every species of pottery, is the only compound known of oxygen with aluminum. Alumina possesses the remarkable property of shrinking into less bulk according to the intensity of the heat which is applied to it; hence, it has been employed as a kind of thermometer, or rather pyrometer, for measuring very high degrees of temperature, in furnaces for instance. A guage is used for measuring the amount of the contraction. Aluminum combines with chlorine, phosphorus, sulphur, and selenium.

Glucinum.—Glucina, which is the oxide of glucinum, exists to about fourteen per cent. in the beryl or emerald, from which it can be extracted. Glucinum

* Thomson.

is a dark-grey powder, which, when burnished, acquires the metallic lustre. It is very difficult of fusion. When heated in air or oxygen, it burns brilliantly, and affords the oxide glucina—the only compound which it forms with oxygen. Glucina, which consists of 100 metal and 44.44 oxygen, is a soft, tasteless, white powder, which, when wet, is somewhat plastic, like alumina. It neither dissolves in water, nor melts in the fire. Its salts have a sweetish taste, like those of alumina; and both of these earths are in this respect opposed to magnesia, which with acids affords salts of a bitterish taste. Glucinum combines with chlorine, phosphorus, sulphur, selenium, iodine, and bromine.

Yttrium.—Yttria, which constitutes the oxide of this metal, is obtained from a scarce mineral called gadolinite. Yttrium is procured from it in iron-grey scales. If heated in common air or oxygen, it burns brilliantly, forming the earth yttria; and as far as is known, this is the only compound formed by the union of oxygen and yttrium. The latter substance combines with chlorine and the combustibles.

Cerium.—This metal exists in a reddish-coloured mineral found in Sweden, called *cerite*. Cerium is a dark-grey powder, having a metallic lustre, but its properties have not yet been properly determined. It, however, combines with oxygen, chlorine, carbon, sulphur, and phosphorus.

Zirconium.—The earth called zirconia is a harsh, whitish powder, destitute of taste or smell. The base zirconium is composed of brilliant scales, which are probably metallic, although the substance has not as yet evinced the metallic lustre. When heated in common air, it takes fire, and is converted into zirconia, which is perfectly white. This is the only compound which it forms with oxygen. It unites with chlorine, carbon, and sulphur.

Thorium.—This is a newly discovered metal, of a leaden-grey colour, heavy, and under the burnisher shows metallic lustre. If it be heated in open air, it burns with much splendour, and the resulting snow-white oxide is the earth called thorina. This is the only compound of thorium with oxygen, and the resulting substance is distinguished from the other earths by various properties. Thorium, when heated in vapour of sulphur, burns, and it also unites with chlorine and phosphorus.

DIFFICULTLY FUSIBLE BASES.

This family comprises some of the most useful bodies in existence. The oxides of these bases, which are four in number, cannot be reduced to the metallic state by heat alone, but they readily dissolve in acids, and from this solution they cannot be precipitated in the metallic state by the introduction of zinc.

Iron.—This well-known substance is one of the seven metals with which the ancients were acquainted; these were gold, silver, copper, iron, tin, lead, and mercury. Iron is a metal of great utility, and it is fortunately found abundantly. Almost every mineral contains it. The ore from which the iron of Great Britain is obtained, is a *carbonate of iron*. Iron, after passing through a fiery ordeal, has a grayish colour, a metallic lustre, and, when burnished, a good deal of brilliancy. Its hardness exceeds that of most metals, and, when in the state of steel, it may be rendered harder than most bodies. Its specific gravity is 7.843 after hammering. It is attracted by the magnet and may itself be converted into a permanent magnet. It is malleable at every temperature, very ductile, and very combustible, for we see a thin wire burn in the flame of a common candle. It burns brilliantly in oxygen, with which it combines in two proportions, forming oxides. It combines also with chlorine, bromine, iodine, boron, sulphur, selenium, phosphorus, arsenic, chromium, and antimony; but the most important of its combinations with simple substances are those with charcoal, which form the important compounds *cast-iron* and *steel*. Iron forms with the acids a numerous and valuable class of salts.

Manganese.—When this substance is pure, which is rarely the case, it is rather whiter than cast-iron, of a granular texture, and may be reduced to powder by pounding. Its specific gravity is 8.013. It is not attracted by the magnet. It gradually absorbs oxygen from the atmosphere, and decomposes water, a property which it loses when alloyed with iron. It is much in use. Glass-makers use it for two purposes; first, for communicating a purple or violet colour, or for destroying all colour, and rendering the glass colourless. Manganese has a strong affinity for oxygen, with which it combines in four proportions, forming oxides. It unites also with chlorine, fluorine, carbon, and sulphur.

Nickel.—This metal, when pure, has a white colour, like silver; is rather softer than iron; is malleable both hot and cold; is attracted by the magnet; and, like iron, can be converted into one. Its specific gravity is 8.380 after fusion. The preparations of this metal contain poisonous qualities. Nickel combines readily with oxygen, forming two oxides. It also unites with chlorine, carbon, sulphur, phosphorus, and arsenic.

Cobalt.—This metal has a grey colour with a shade of red, and is not brilliant. Its texture is granular; it is rather soft and brittle; its specific gravity is 8.7. It is used for giving a blue colour to glass and porcelain; the tint is beautiful; and hence the metal bears a high price. It unites with oxygen, and forms two oxides; these are the preparations of cobalt used in the arts. It also combines with chlorine, sulphur, selenium, and phosphorus.

EASILY FUSIBLE BASES.

Of the eight metals composing this family, all are malleable except bismuth, which is not very brittle. They melt at a comparatively low heat. A rod of zinc throws down these metals from their acid solutions in the metallic state.

Zinc.—This metal is of a bluish-white colour, and is composed of plates adhering together. It is rather soft, and, after fusion, its specific gravity is 6.896. It becomes malleable at 212°, and melts at 680°, or before it is quite red. When heated red-hot with access of air, it takes fire, burns with an exceedingly beautiful greenish or bluish-white flame, and is at the same time converted into the only oxide of zinc with which we are acquainted. It is of a snow-white colour, is tasteless, and insoluble in water. With an alloy of copper, zinc forms that well-known and useful substance *brass*. Zinc combines with, and is set on fire by, chlorine; it enters into union with phosphorus, sulphur, selenium, iodine, and various metals.

Cadmium.—This metal, which is commonly associated with the ores of zinc, has a white colour with a shade of bluish-grey, and resembles tin in its appearance. It is very malleable, and has a specific gravity after fusion of 8.6040. It unites with oxygen, chlorine, and some other supporters, but the compounds are unimportant.

Lead.—This is one of the most abundant of all the metals, and one of the softest and most fusible. Lead has a bluish-white colour, and a good deal of lustre, but it soon tarnishes. Its specific gravity after fusion, which takes place at 606°, is 11.351. Lead is very malleable; it is also ductile, but its wire possesses little tenacity. By exposure to a very strong heat, it is volatilised, and at the heat of burning hydrogen, urged by oxygen, it burns with a bluish flame. While exposed to the atmosphere during fusion, it imbibes oxygen, and is converted into an oxide. There are three oxides of lead—the protoxide, which is known in commerce and the arts as a yellow paint, under the name *massicot*, or, if it be semi-vitrified, *litharge*; the deutoxide is also a paint of a brilliant red colour, inclining to orange; it obtains the name of *minium*, or *red lead*; and the peroxide, which is of a deep puce *brown* colour. When triturated with sulphur, spontaneous combustion takes place. Lead also combines with chlorine, bromine, iodine, sulphur, selenium, arsenic, &c. It is rendered hard by antimony, and the alloy, mixed with a little tin, constitutes the material from which printers' types are elaborated. The salts of lead are numerous and very important. *White lead* or *cerure*, the only white used in all oil paintings, is made by subjecting thin plates of lead, rolled up spirally, to the fumes of vinegar. The lead soon becomes corroded, and assumes a white appearance and a brittle consistency. If this substance be dissolved in acetic acid or vinegar, it becomes *sugar of lead*. Lead is never found native; by far the most common state in which it occurs in nature, is mineralised by sulphur. The common name for sulphuret of lead is *galena*. It is abundant in all quarters of the globe.

Tin.—This metal resembles lead in many of its properties. It possesses a fine white colour, with a slight shade of blue, and has a good deal of brilliancy. Its specific gravity after fusion is 7.285. It is very malleable. Tin leaf or *tinfoil*, as it is called, is about the one-thousandth part of an inch thick, and it might be made much thinner, if requisite. It is ductile, but of inferior tenacity. It is very flexible, and produces a remarkable crackling noise when bended. It melts at 442°, but a very violent heat is required before it will evaporate. It soon tarnishes with the air, and, when intensely heated, oxygen being supplied, it burns with great brilliancy. Tin combines with oxygen in two proportions, forming the protoxide, which is *black*, and the peroxide, which is *yellow*. It also unites with chlorine, bromine, iodine, sulphur, selenium, phosphorus, and fluorine. It alloys with various metals. The coat of tinning which is given to the inside of copper vessels, is a mixture of lead and tin; for although lead be a poisonous metal, the presence of tin renders it innoxious. Pewter is composed of lead and tin; the latter rendering the former safe, as in the preceding instance. English tin is the best of all, and it is affirmed that it was exported from this island 2200 years ago.

Copper.—This metal, in point of general utility, ranks next to iron. It possesses a rose-red colour, and a great degree of brilliancy. Its specific gravity, after being rolled out into plates, is 8.953. It has great malleability, and very considerable ductility. A bar of cast copper, one quarter of an inch thick, requires 1192 lbs. to break it, whilst hammered copper requires nearly 1000 lbs. more to break it. It melts at 2548°; and if the heat be increased, it evaporates in fumes, which are visible. When rubbed, it emits a smell. When heated in a hydrogen flame urged by oxygen, it burns brilliantly, emitting a dazzling green light; a piece of copper in a coal fire tinges the blaze green. When exposed to air, it rusts into *verdigris*, but slowly, without moisture. With oxygen it combines in three proportions, forming three oxides, two of which occur native; the other is not a permanent compound. Copper combines also with chlorine, iodine, sulphur, phosphorus, arsenic, and tin. Its alloys with the latter metal are very important. From eight to twelve parts of tin, combined with one hundred parts of copper, compose *bronze*, and the *metal of cannons*. Three parts of copper and one of tin compose *bell-metal*. The alloy used for the mirrors of telescopes was employed by the ancients for the composition of their mirrors. It consists of about two parts of copper united to one part of tin.

Bismuth.—This metal has a reddish-white colour, and is composed of broad plates adhering to each other. It is one of the most fusible of the metals, and communicates its fusibility to other metals. Its specific gravity is 9.833. Although not very brittle, it is not malleable, nor can it be drawn into wire. A mixture of tin, lead, and bismuth, is so fusible, that it melts when thrown into boiling water. A toy of this kind is well known; it is a spoon, which, when immersed in a very hot liquid, immediately melts. Bismuth combines with oxygen, chlorine, bromine, iodine, sulphur, and selenium. What is called Newton's fusible metal, is a compound of eight parts by weight of bismuth, five of lead, and three of tin. It melts at 212°.

Mercury or Quicksilver.—This metal has a silver-white colour, possesses great brilliancy, and remains fluid at the common temperature of the atmosphere. Its specific gravity, at 60°, is 13.56846; at 38°66, when it assumes the solid form, it is 14.465. When solid, it may be beaten out with a hammer, or cut with a knife. When heated to 656°, it boils; and when heated in the open air, or when agitated for a long time in the open air, it oxydises. The oxides and chlorides of mercury afford an admirable proof of the truth of the atomic theory. It combines, also, with bromine, iodine, sulphur, selenium, and phosphorus. The compounds which mercury forms with the other metals are usually termed amalgams. This metal occurs in South America and in Spain, in great abundance. But the mine of Idria, in Carniola, an Austrian province, is perhaps the greatest in the world, and has been wrought for more than three centuries.

Silver.—This metal is of a fine white colour, with a slight shade of yellow. When polished, it displays a great deal of brilliancy and beauty. It is very malleable, and may be beaten out into leaves so thin as one 100,000th of an inch. It is softer than copper, and harder than gold; but its tenacity is inferior to the former metal. When melted and cooled slowly, its specific gravity is 10.3946; when hammered and rolled, it is a little higher. Its melting point is 1830°; and if it be kept melted for a long time, it absorbs oxygen, and forms a brown oxide; but it possesses the very singular property of parting with the oxygen on solidifying. Gay Lussac, a great French chemist, says that the presence of a little copper deprives it of this property. Silver combines with oxygen in three proportions, forming three oxides. It also unites with chlorine, bromine, iodine, sulphur, selenium, phosphorus, and arsenic. There are numerous alloys of silver, but few of much consequence. One pound of standard silver is coined into sixty-six shillings; the mint price of silver, therefore, is 5s. 6d. per ounce at present. Silver is found in all parts of the world, sometimes alloyed with a variety of other metals and substances, and sometimes in the native state.

NOBLE METALS.

This family comprehends six metals, which all require a violent heat to fuse them. The name noble metals has been given to the family, because it contains gold and platinum, the most esteemed of all the metals; and because the other four metals belonging to it are usually associated with native platinum. They are insoluble in nitric acid, and their oxides are reducible to the metallic state by the application of heat alone.

Gold.—This is the most valuable of all the metals. It always occurs in the metallic state, although seldom pure. It has a beautiful yellow colour, and considerable lustre, which it retains, not being liable to tarnish by exposure to the air. It is rather softer than silver, and after fusion, it has a specific gravity of 19.2. It is the most malleable of metals, and may be beaten out into leaves no thicker than one 282,000th of an inch, and the gold leaf with which silver wire is covered is only 1-12th of that thickness. Its tenacity is considerable, but inferior to that of silver. It melts at 2590°. It is insoluble in sulphuric, nitric, and muriatic acid; but it readily dissolves in aqua regia, which is a compound of the two latter. It is difficult to oxydise gold, and still more to burn it; but both can be accomplished. Oxygen combines with gold in two proportions, forming two oxides. Gold also unites with chlorine, bromine, iodine, sulphur, phosphorus, and arsenic. There are a number of alloys of gold; the standard gold coin of the realm is an alloy of twelve parts of gold to one of copper or silver, or sometimes both. Gold occurs in almost all parts of the world; but Africa and America supply the chief European consumption.

Platinum.—This metal is white, like silver; its specific gravity is 21.47, so that it is heavier than gold. Its hardness is intermediate between copper and iron. It is very ductile and malleable, though much less so than gold. Its tenacity is considerable. It will not melt in the heat of our most powerful furnaces, but it may be fused by the oxyhydrogen blowpipe. Its property of resisting high temperatures without fusion, is a most important one, and on this account it has been employed in the formation of vessels which it is necessary to subject to an extraordinary degree of heat. Like gold, it resists the action of all the single acids, but dissolves in aqua regia. It combines with oxygen in probably four proportions, forming oxides. It unites, also, with chlorine, bromine, iodine, silicon, sulphur, selenium, and phosphorus. There are numerous alloys of platinum, but they are not of much importance. There is a form of this metal which possesses extraordinary properties; it is called *spongy platinum*. It is prepared by dissolving platinum in a mixture of nitric and muriatic acids by heat; muriate of ammonia is added, when a precipitate falls, which must be filtered and dried. If a small quantity of this powder be heated by a candle, it will become incandescent, as if it took fire. It is, when cold, fit for use. If a jet of hydrogen, from a tube of a very slender bore, be directed on it from a little distance, the metal immediately becomes red-hot, and it sets fire to the hydrogen. This may be repeated a great number of times, but the sponge at last loses its power; the smaller the quantity, the sooner its power is lost.

Palladium, Rhodium, Iridium, and Osmium.—These four metals occur in the platinum of commerce. They are procurable in very small quantities; they have not been applied to any use of moment; they possess no very remarkable qualities, and therefore do not require to be minutely described. They all unite with oxygen and chlorine, and some of them with the other supporters.

Such is a brief sketch of the fifty-four simple substances, whose numerous combinations give rise to the infinite variety of objects which are found ready formed in the laboratory of nature, or have been discovered in that of the philosopher.

GENERAL OBSERVATIONS ON ACIDS, BASES, & SALTS.

Of these various compounds, a general account was given in the early part of this article, and, as we have gone along, we have endeavoured to point out the most important, and to describe them as far as our limits would permit. We have attempted to give a view of the constitution of the various classes of bodies entitled *acids*, *alkalis*, *oxides*, and *salts*. We have shown the affinity which acids manifest for metallic oxides, including alkalis and earths, and the resulting compound formed, which is called a salt. The oxygen acids are by far the most numerous and best known. They are of two kinds: those which are united to a single base or a single supporter, as sulphuric acid and carbonic acid (they amount at present to thirty-six in number); and those in which the oxygen is united at once with two and sometimes with three bases (they amount at present to above sixty in number). Thus, *acetic acid* is a compound of *oxygen*, *carbon*, and *hydrogen*, while *uric acid* is a compound of *oxygen*, *carbon*, *hydrogen*, and *azote*. The second set of acids are very numerous, and they either exist ready formed in the vegetable or animal kingdom, or they are formed from vegetable or animal bodies by chemical processes. A number of the most common acids belonging to the first division, we have already described; and some of those which belong to vegetables, we shall allude to shortly. To those who are desirous of obtaining complete information upon the subject, we recommend Dr Thomson's System of Inorganic Chemistry. The *salts* which are formed by these various acids are so immensely numerous as entirely to preclude the possibility of giving even the shortest description of them here. Besides the salts formed by the acids of the five supporters, there are those formed by cyanogen acid, sulphur acid, &c. Let us now advert to a most important branch of chemistry, namely, that of

ORGANISED STRUCTURES.

The substances constituting the subjects of this branch of chemistry are the principles of which vegetables and animals are composed. In the former, for example, we have sugar, starch, gums, resin, &c.; and in the latter, albumen, muscle, bone, &c.

Vegetables.—Notwithstanding the infinite diversity of form which vegetable substances assume, it has been proved that they are all composed of the same ultimate elements, and these are only *four* in number; namely, oxygen, hydrogen, carbon, and azote. These, again, by uniting amongst themselves, form various compounds, each form of combination producing a substance of a different kind. These substances associated with each, more or less numerously, compose the vegetable structure; and being the more immediate objects of sense, in the investigation of any organisation, they are called their proximate principles. Existing ready formed in woods, roots, &c., we find a considerable number of *proximate principles*, as acids, alkalis, sweet principles, bitter principles, oils, exudations; some poisonous, others wholesome; some spontaneously separating, others remaining obstinately combined. We shall give a brief outline of these:—

Citric Acid.—This acid exists in the juice of lemons, and, when crystallised, one hundred grains consist of water $23\frac{2}{3}$, and pure acid $76\frac{1}{3}$, which is a compound of 42.1 oxygen, 31.58 carbon, and 2.63 of hydrogen. *Sorbic acid* is the sour principle of apples, sorbus berries, and other fruits. It consists of the same ingredients as the former. *Tartaric acid* is the sour principle of grapes, when a large quantity of them are left to ferment; the result it is well known is wine. On the side of the vessel containing this liquor, crystals of the acid form, which, when purified, are *cream of tartar*. Twelve parts in the 100 are water; and the remaining 88 consist of oxygen, 52.97; carbon, 32.39; and hydrogen, 2.64 parts. *Oxalic acid.*—The plant called sorrel is valued for its acidulous taste, which is conferred upon it by this acid. It has no hydrogen in its composition, consisting merely of oxygen and carbon. It is an active poison, and from resembling Epsom salts in appearance, many persons have fallen victims to its virulence. The antidote is powdered chalk. *Gallic acid* is obtained from nut-galls. Its most remarkable property is that of changing the colour of solutions containing iron to an intense blue-black colour, as in the case of common writing ink. 100 grains consist of 56.25 carbon, 37.5 oxygen, and 6.25 hydrogen. There are a number of other acids, which, being of little use, are not worth naming. Those just described exist ready formed in fruits, &c.; they are simple *educts*. But there are others formed by chemical changes produced on certain elements contained in vegetables, which afford the base of the acid; these are acid *products*; some are produced by the agency of fire, others by the action of nitric acid. Several acids, when distilled at a high temperature, undergo decomposition, and new acids are formed. Their names remain the same, with the word *pyro* as a prefix. Thus we have *pyrocitric acid*, &c. There are other acids generated by similar means, but they have simple names without any prefix.

Vegetable Alkalis.—It has been ascertained that alkalis, as well as acids, exist ready formed in plants as one of their constituent parts. Those which evince alkaline properties of a weak character are entitled *alkaloids*. The alkalis are *quinina* and *cinchonia*, which resemble each other, have a bitter taste, and neutralise acids. *Morphia*, which is obtained from opium, is a white crystalline powder; *strychnia*, one of the most powerful bitters and poisons, which has of late been much used in medicine; *brucia*, also a violent poison; *digitalia*, which is procured from the leaves of foxglove; *hyoscyama*, *atropia*, *veratria*, *emetina*, &c., which are derived from henbane, deadly nightshade, &c. Of the other proximate vegetable principles, the first deserving of notice is the woody fibre which constitutes the solid bases of all vegetable structures. It is called *lignin*, from *lignum*, wood; and consists of 52 carbon, and 48 of oxygen and hydrogen, in the ratio which forms water. With lignin are associated various other bodies, such as *resins*, which are various and abundant. In the different species of the pine-tree we discover that peculiar liquid resin called *turpentine*. From resins are obtained what are called *essential oils*; because, after the resin has been heated in a distilling apparatus, an odoriferous oil distils over, and leaves the resin hard, dark, and odourless. The *essence* of the substance is supposed to have passed away in the aëriform state, hence the name. From its speedily evaporating on being exposed to the air, it is also called *volatile oil*. The seeds of plants yield another oil, which, not evaporating, is called *fixed oil*. To these two oils there are two substances bear some analogy, *wax* and *camphor*. The former, when melted, possesses the properties of a fixed oil, and the latter seems to possess the properties of a concrete volatile oil, although it possesses qualities distinct from those of all other bodies. *Gum*, for instance gum arabic, possesses the following properties: They are—transparency, tastelessness, perfect solubility in water, viscidity of the solution, capability of cementing fragments, and of affording a varnish, and total insolubility in spirit of wine. There is a class of bodies called *gum resins*, whose properties are intermediate between those of gum and resin; and somewhat allied to resins, although essentially different in most of its properties, is the substance called *caoutchouc*, or *Indian rubber*. It is the exuded juice of a peculiar tree, and is composed of carbon and hydrogen. From wheaten flour a substance is obtained, called *gluten*, from its glutinous nature. There are two principles in this substance—the one is called *gliadin*, and the other *zimomin*. There is a substance called *vegetable albumen*, distinct from animal albumen. It constitutes, according to some chemists, no less than one quarter of the whole weight of sweet almonds, and seems to be the basis of all emulsive grains in place of starch. *Starch* is a fine white sediment, precipitated from the white and brittle parts of vegetables, particularly the tuberous roots, and the seeds of the gramineous plants. One of the most remarkable properties of starch, or, as it is called, *fecula*, is that of being convertible into sugar by the action of diluted sulphuric acid. Starch is not only afforded from various grains, but from potatoes; and, as extracted from this vegetable, it is much in demand as an article of food. *Arrow root*, which is obtained from the roots of a West India plant, is the same kind of substance.

Sugar.—Every one, we suppose, should know what sugar is; being in particular a sweetener of the kindly beverages tea and coffee. It is derived from many sources—from the sugar cane, maple tree, beet root, and grapes. Nothing is easier than its formation from grapes. Grape juice is to be saturated with chalk, clarified with white of eggs, or blood, and evaporated; after a few days it assumes the form of a crystalline mass. From oak bark, or nut galls, a peculiar substance is obtained, called *tannin*; so named from being the material employed in tanning leather. It is inodorous, colourless, and possesses a rough astringent bitter taste.

THE ANIMAL COMPOUNDS.

The materials of which animals are composed, are nearly similar to those which we have described as belonging to plants. The difference is in the relative quantity, and in the mode of combination. The combustible substances phosphorus and lime, exist in the bones of animals in considerable quantities. They have also been detected in some plants, as in the onion, but in very minute proportions. The chief substances, then, which enter largely into the composition of animal matter, are oxygen, hydrogen, azote, carbon, phosphorus, and lime. We also find some other kinds of matter, as certain acids and metals, but in quantity so small, as not to affect the truth of the above statement, that the foregoing six ingredients constitute the great bulk of the animal fabric.

Bone consists of phosphate and carbonate of lime, and two other ingredients, *cartilage* and *gelatine*. The latter is the coagulating, or rather elastic, principle in all *animal jellies*. When bones are burned in a close vessel, they form *ivory black*. *Fibrin* is obtained from the vessels; when recently obtained, it is elastic; but when perfectly dry, it is somewhat horny and transparent. There is an important substance, called *osmazome*, which communicates to soups and broths their peculiar taste and smell, and the greater the quantity present, the better is the soup. The *tendons*, *ligaments*, and *membranes*, are nearly allied to gelatin in their nature.

Albumen is a substance very abundant in animal matter. It occurs nearly pure in the white of eggs. Of this substance in the coagulated state, along with gelatin, are *horns*, *nails*, and *hoofs* composed.

The *brain*, the thinking organ of man, consists of water 80, white fat 4.53, red fat 0.7, osmazome 1.12, albumen 7, phosphorus 1.5, sulphur and various salts 5.15, parts in the hundred. *Blood*, when left to rest a few hours after being drawn, separates into two parts; one quite liquid, of a greenish whey-like appearance, and hence called *serum*; the other is an elastic firm jelly, of a crimson-red colour, and is called the *crassamentum*. If evaporated to dryness, a very dark-red substance remains, which is the *colouring matter* of the blood. In animal structures there are numerous fats and oils of a peculiar character, and also some acids, &c.; which, however, we have not space to describe.

FERMENTATION.

The spontaneous decomposition which animal and vegetable matter undergoes when placed under proper circumstances, is called fermentation. The most remarkable result of this process is either alcohol, acetic acid, or a putrid smell. The production of these different results gives origin to three distinct stages of the process, each characterised by different phenomena. If grape-juice be exposed to a moderate temperature, it soon begins to effervesce, and loses its transparency; a viscid scum rises to the surface; the taste changes from sweet to viscous; and under proper management, the liquor is concocted into wine. Solutions of sugar and all sweet liquids are capable of undergoing similar changes, and of being converted into a kind of wines. The process by which these changes are effected, is, on account of the nature of the product, called the *vinous fermentation*, and the result of it is the formation of *alcohol*, or spirit of wine. This is the principle which confers ardency upon brandy, whisky, gin, rum, &c. By the action of acids upon alcohol, a peculiar class of volatile liquids, called *ethers*, are formed. When equal parts of sulphuric acid and alcohol are distilled, a light, odorous, colourless, highly volatile fluid, of a penetrating taste and smell, comes over. This is called *sulphuric ether* for distinction, because there are various other *ethers*.

If the liquor which has undergone the *vinous fermentation* be exposed to the temperature of about 75°, it, from being transparent, again appears somewhat muddy; the taste changes to sour, for the alcohol is now changed into vinegar; and from *acetum*, the Latin for vinegar, this stage is called the *acetous fermentation*. Vinegar, when long kept, loses its acidity and its transparency; it exhales a putrid smell, and has now undergone its last stage, or the *putrifactive fermentation*.

These processes, as well as the other parts of practical chemistry, we shall not describe in detail at present, as it is our intention to devote a number of the Information to the subject of Chemical Science applied to the Arts and Manufactures.

Note.—Specific gravity is the relative gravity or weight of any body or substance, compared with that of some other body which has been fixed upon as a standard. By universal consent, pure distilled water has been assumed as the standard; and it fortunately happens that a cubic foot of pure water weighs exactly 1000 ounces avoirdupois. Water is indicated by unity—thus, 1. When, therefore, it is expressed that any body has a specific gravity of 2, then, bulk for bulk, it is just twice the weight of water. If there be more figures than one, and there be a dot or point between them—thus, 2.5—the unit is here divided into ten parts, and the body is twice and five-tenth times, or two and a half times, heavier than water. If two figures occur—thus, 10.40—the unit is supposed to be divided into an hundred parts, and the body is ten and forty-hundredth part times heavier than water. If there are three figures, the unit is supposed to be divided into a thousand parts; if four, into ten thousand parts, and so on; the number and value of the figures always indicating the exact specific gravity of the body according to the above principle. Common air is sometimes taken as a standard with which to compare gases, as in the instances mentioned in the text. It is a simpler and more intelligible way of comparing the relative weights or densities of aerial substances. But all the solids and fluids are estimated with regard to water.

MANUFACTURES AND COMMERCE OF THE WORLD.

The most important art pursued by human beings is that of manufacturing, producing, or preparing commodities for their subsistence or bodily comfort and convenience. Strictly speaking, the term Manufactures applies only to those articles which have been converted from raw materials into all sorts of useful and ornamental articles, promoting the comforts and luxuries of society; but by a wider signification, when treating of the principles which guide the production, preparation, and sale of commodities, the term Manufactures may be applied to all articles whatsoever, suitable to human wants, and upon which a greater or lesser degree of skill and labour has been bestowed in making them ready for use. Thus, agricultural produce, from not being prepared or fashioned like commodities which have passed through the fingers of the artificer, has not usually been classed under the general head of national manufactures; inasmuch, however, as corn and other agricultural produce neither spring into existence nor are made fit for market till certain processes by hand and by machinery have been performed by the producers, it is obvious that, in the above wide definition of the term, agricultural produce may correctly be stated as manufactures. By adopting this simple and comprehensive idea of what constitutes manufactures, the political economist has his way wonderfully cleared in his endeavours to seek out and make manifest the principles which ought on all occasions to govern the commercial policy of a country. Including the producers of raw or partly prepared commodities, the manufacturing class is not only the most numerous, but the most useful in communities. Still, by their efforts alone, society would be but to a small extent benefited. Their uses would be confined to only the scene of their labours, were their operations not encouraged by the large and respectable body of individuals who practise the business of merchants and dealers, and whose functions consist in purchasing the commodities from the manufacturers after they are prepared, and transferring them to countries or localities where they are required for use by the consumers. By the interference of merchants in this traffic, they lend immense assistance to the manufacturers, whom they relieve of their commodities without any trouble, and by that means allow them to devote the whole of their time to their peculiar pursuits; wherefore, by this division of labour, they indirectly increase the quantity, and facilitate the processes of manufactures. Unless, therefore, for the operations of the mercantile classes, the manufacturing energies of a nation would soon decline, and the inhabitants degenerate into a very rude condition. The operations of the mercantile classes of men with the manufacturing and consuming classes, are indicated by the term Commerce, which applies equally to traffic carried on at home or with foreign countries.

Commerce is of great antiquity, and, both in the earliest times and in our own day, has been one of the principal engines of civilisation. Among the industrious nations which at a remote period of history were planted on the borders of the Mediterranean Sea, it became a means of spreading knowledge in the interior of Asia, and many parts of Africa and Europe. Unfortunately, the intelligence which was so disseminated was afterwards obliterated by the overruling powers of barbarous and warlike nations; but the efficacy of commerce in modern times is likely to be permanent wherever its influence is extended, seeing that the greatest manufacturing and mercantile people are at the same time the most powerful and most capable of offering protection to those who sustain a commercial intercourse with them. It is exceedingly pleasing thus to reflect on what commerce is capable of effecting, independent of the actual comfort which it produces, wherever it is fairly introduced. By its appeals to the selfishness, the vanity, and other passions, good and bad, of mankind, it appears to be the best of all forerunners to the inroads of the schoolmaster and the missionary. Its influence in this respect has been remarkably exemplified in the boundless regions of Hindostan, which, by the efforts of a company of merchants, have been laid open to the settlement of cultivated men from Europe, who, though by slow degrees, will ultimately spread the blessings of education, and the decencies of social life, among many millions of human beings. In the remote islands in the Pacific Ocean, the influence of commerce has been recently of marked utility. The introduction of articles of a fanciful nature, both for the ornamenting and covering of the person, has induced a desire of following European manners and customs; and as these commodities cannot be procured but by the exchange of native commodities, a spirit of industry has consequently been produced, which cannot fail to be of both moral and physical advantage to the natives. It is always thus with the intercourse which commerce necessarily involves. New tastes are created, and, to be gratified, industry must be exerted. But to witness the extraordinary influence of commerce in producing civilised and refined habits, we need not look beyond our own country. Commerce, in this its chosen seat, has caused roads every where to be cut, canals to be opened, railways to be formed, expeditious modes of travelling by sea and land to be effected; all of which great accessaries to our comfort have tended in the most wonderful manner to introduce not only useful commodities and personal luxuries, but highly cultivated sentiments, literature, and the arts, into districts which at no distant period lay in a comparatively primitive condition. The intercourse which commerce in this manner requires, is the grand lever which, it is apparent, must in the first place be employed to lift the load of ignorance from off the natives of Africa; and when this lever is properly insinuated, the way will soon be prepared for the introduction of those measures of melioration which philanthropists so anxiously design.

QUALITIES OF A COMMERCIAL PEOPLE.

The establishment of systems of manufactures and commerce in particular countries, seems to be dependent on certain moral qualities, as well as on various geographical properties. A country possessing materials for manufacture and commerce, may neither be a manufacturing nor a commercial country, perhaps because the climate is fine, and wants so easily supplied, that few think of exerting themselves. The abundance which nature provides, furnishes an excuse for sloth, which it would be needless to stop here to condemn; but no such apology can be allowed in cases where nature is less bountiful, and where poverty and misery predominate from the conjunct influence of pride, bigotry, and indolence. It would appear that, without a due share of common sense, no people can be successful either as manufacturers or merchants, certainly not as the latter. This principle is very observable in the present condition of commerce in the different quarters of the world. In proportion as steadiness of exertion is practised by individuals, and, what is more, *left at liberty* to act, so is commerce successful, and national prosperity established. It has unfortunately happened that singularly few nations have possessed this species of industry, and this independence. Europe generally has long taken a lead in universal traffic; but among about thirty principal nations into which Europe is divided, only two have hitherto demonstrated a well-regulated aptitude in commercial operations. These nations are the Dutch and the English, both of whom have set an example to the rest, and shown how the people of countries of very limited dimensions—spots hardly recognisable on the map of the world—may, by their industry, their economy, their probity, and their enjoyment of free institutions, attain a pitch of opulence and comfort which nations of ten times their size, and fully as fertile in resources, have, by their mismanagement or their laziness, failed to accomplish. As will hereafter be seen, the commerce of the Dutch, from national misfortunes and other circumstances, has declined in favour of that of Great Britain, which, both as regards the operations of the manufacturer and the merchant, has, for a considerable period, stood at the head of all nations in the two hemispheres. The British are hence a remarkable people. They seem to be endowed, above all other tribes of men, with a spirit of industry and commercial enterprise—a spirit which renders them actually unhappy, unless when busily engaged in some pursuit calculated to enrich them, or at least to produce for their families the means of a respectable subsistence. The Americans, who are but a branch of the same British stock, are equally, if not more, remarkable for this fervent spirit of industry, and, though only set up as a separate nation within a period of fifty years, have already distanced many of those dignified European principalities and powers which first discovered and colonised their country. The French, the Germans, the Spaniards, the Portuguese, the Italians, and others, though each possessing a larger or smaller extent of manufactures and commerce, are obviously deficient, in a national sense, of the eager spirit of industry which is so characteristic of the people of Great Britain. Taken in the gross, they are too apt to addict themselves to amusement in preference to business. They delight in holidays, and will at any time leave their work to mingle in a dance or some kind of buffoonery, in which an Englishman would be ashamed to appear. Scarcely one of the continental nations, moreover, has yet settled down under a well-conducted government appointed by the people. There indeed seems to be little which is settled amongst them. Some of the principal are yet at that stage of social life which was common in England about the reign of Henry VII.; others are not farther advanced than a period considerably earlier; and all have yet a great deal to suffer and to learn before they attain that state of quietude and security to life and property, that condition of domestic comfort and national prosperity, which Great Britain, with all its faults, so amply enjoys.

REGULATING PRINCIPLES OF COMMERCE.

The nature of the principles which should regulate the manufacturing and commercial industry of a nation, has been discussed by many writers at great length, and with much warmth, though in few instances either soundly or with that clearness which can render them intelligible to the people. The subject, however simple, has been so effectually and strangely mystified, that many yet labour under an idea that it would require to be studied as a science before it could be thoroughly understood. There could hardly, however, be a greater mistake; for the principles which regulate manufactures and commerce are so intelligible, that a child might comprehend them.

The beneficent Creator has bestowed upon each particular country certain peculiar properties and commodities, which the others want, but which, by a mutual process of exchanging, or commercial intercourse, may be made common to all. Some countries are totally destitute, by nature, of articles of luxurious consumption, as wines, teas, and spices; but by possessing coal and iron ore, they are enabled to manufacture cutlery, which they can give in exchange for the wines, teas, and spices of the countries possessing these commodities, and which have no coal nor iron ore of their own. It is obvious that this scheme of mutual interchange among nations, of the commodities which they respectively produce, is agreeable to every rational principle, and must have been designed by a wise Providence for the universal benefit of his creatures. In order that manufactures may be produced, and commerce brought in to disseminate them both at home and abroad where they are wanted, no species of legislative enactment is requisite either to encourage or direct. The law which governs production and consumption is a law of nature—it is the overruling principle of *self-interest*, by which only that quantity of manufactures are produced which can be advantageously disposed of, and only those commodities purchased and consumed which the wants of individuals require. And, curiously enough, this principle of self-interest, if allowed free scope, is uniformly and sufficiently competent to regulate both the production and consumption of commodities to a degree more nice and satisfactory than could be attained by the best-devised statutes which the wisest legislators could enact. The grand principle, therefore, which can alone regulate commerce and manufactures, is found in the natural passion for gain; and the sole essential requisite for the successful advancement of mercantile and manufacturing industry and wealth among the people, is for the people to be let alone.

DUTIES AND RESTRICTIONS.

Evident as these principles must be to all who have any knowledge of social life, they have either from ignorance, or some other cause, been generally lost sight of by governments in all ages of the world, and plans have been contrived to regulate that which, if left alone, would have much better regulated itself. To such an extent have regulating and restrictive laws been carried in some countries, that they have nearly annihilated both manufactures and legitimate commerce, and reduced masses of the people to the condition of paupers, besides encouraging the pernicious and demoralising pursuits of the smuggler. The restrictions and regulations which governments usually impose upon commerce, do not perhaps originate so much in the plea that manufacturers and merchants stand in the condition of children, and require to be taken care of lest they should hurt themselves, as from the unfortunate exigencies under which the governments happen to be placed. They have all less or more engaged in wars which have been conducted at an enormous expense to their respective countries. In order to liquidate these expenses, all kinds of taxes are levied directly and indirectly; but as the levying of these taxes breeds discontent, large bodies of military have usually to be kept up, to act as an armed national police. Thus, the people of these countries have for ages to go on paying not only the price of the wars, or the interest of the sums borrowed and laid out upon the wars, but as much more for the military force afterwards imposed upon them. What is more distressing, the people have probably to give a deal of money, in order that their respective governments may be the more able to secure the attachment of men of consequence to assist in allaying the general clamours for a redress of grievances. This is a very rough view of the matter, but it is enough to show the dreadful exigencies into which nations fall, by their engaging in wars or other expensive follies. In whatever manner, however, national exigencies originate, the plan pursued for relief consists chiefly in the imposition of duties on certain commodities much in demand, and at various stages of their manufacture, transmission, and sale. The mechanism which produces them is taxed; the food which the manufacturers eat, the clothes they wear, and the houses they live in, are taxed; the goods are taxed if they be sent out of the country, and they are taxed if brought into it; they are taken to market by taxed horses fed on taxed corn; they are sold in taxed shops by taxed shopmen; and when transferred at last to the consumer, the bit of paper certifying their payment is also an object of taxation. It is easy to perceive that this illimitable process of taxation on commodities must tend not only to raise the value, but decrease the amount, of manufactured produce, to the manifest injury of the manufacturer, the merchant, and the consumer.

FREE TRADE.

Were duties imposed only for the honestly confessed purpose of furnishing the necessary means of support to government, it would be of little comparative consequence; they are fully as frequently exacted for the specious purpose of preventing foreign manufacturers injuring those of the country to which the government which imposes them belongs. Some nations are more enlightened than others on this point; yet each separate country has still a terror of being overreached by others. They all strive to be sellers without being buyers. They are all anxious to send their goods to their neighbours, but will take nothing but money in return. In other words, each nation gives a facility to exportation, but lays heavy duties on the importation of commodities. We shall endeavour to explain how this illiberality originates. The advocates for restrictions on the importation of foreign goods, into Britain for instance, give two reasons for the necessity of the imposition. The first reason is, that the importation would injure the native manufacturer; and the second is, that unless the exporting country takes our goods free of duty, we should not take theirs free of duty—or, that there must either be reciprocity of trade, or no trade at all. With regard to the first, we shall take the very obvious case of Prussia and Great Britain. Prussia, we shall say, could furnish this country with corn at half the price it can be manufactured for here—a circumstance arising from superiority of soil, cheapness of labour, &c. Nevertheless, Great Britain will not buy Prussian corn for fear of hurting the English and Scotch corn manufacturers. These persons have in all directions cultivated lands, good and bad, at a dear rate, and therefore cannot sell their commodity so cheap as to compete with the *foreigner*. If you admit foreign corn, say they, we are ruined, and the country is ruined also. But the country would not be ruined. If the cheap Prussian corn were admitted free of duty, all the bad lands, which should never have been cultivated, would go out of cultivation, and be devoted to that purpose for which nature intended them. As for those who farmed or wrought upon these lands, they would take up some other trade as a matter of course. By this means, a competition would take place betwixt British and foreign farmers, and the superior skill of the farmer would compensate for many disadvantages in circumstances. The free importation of cheap corn might do a little injury for a time to a *few*—to a class—but it would wonderfully benefit the *many*. It would lower the price of provisions to the working classes, and at the same time encourage manufactures. This may seem a paradox; for it is alleged that foreigners who would sell us corn would not take our British goods in return; and as our present farmers take these goods, we should therefore lose customers for our manufactures. But if the Prussians, or others, would not take goods, they would at least take money. This brings us to the matter of reciprocity. It would at all times be advantageous to deal with countries which admitted our goods free of duty; but seeing that some countries will not do this, we must not on that account refuse to buy from them in any shape. If they will sell cheap, we should buy, even though solid gold were paid for the commodities. Suppose that we were to receive cheap corn from Prussia without duties, and that the Prussians were resolute in excluding British merchandise from their country, and would take payment only in money, the importer consequently sends his payment in money; but this money is only goods under a convenient form. The money was not got for nothing; it did not come into England for nothing; it was paid for in some way or other in goods, and is only the representative of goods. The merchant who originally imported it in the shape of bullion from South America, either paid for it in British commodities, or, what is more probable, sent a draught on London to the exporter, and he sent it back to England to pay for goods which he had previously purchased. In short, in whatever manner we examine the matter, it always turns out that the money which pays the foreigner for his corn was originally got in exchange for goods; and, therefore, it comes to the same thing whether the Prussians take goods in barter, or take gold for which goods have already been bartered. The manufacturers of goods are equally well employed in either case; although there can be no doubt, that, if Prussia would buy our goods freely, another would be added to the list of our customers. If this definition of the value of free buying be not sufficiently explicit, it may be made still more so by an example nearer home. The publishers of this sheet send their goods to the Shetland islands, and at intervals receive sums amounting to twenty pounds sterling, in payment. The staple commodity of these remote islands is fish; but it would never enter the mind of our agent there to oblige us to take that commodity in return for our goods—for the obvious reason, that money is a more convenient form in which to effect a transfer. Besides, the twenty pounds which we from time to time receive are only the representatives of fish. The twenty pounds were previously got by the industrious Shetlanders for their fish; *where* they got the money is of no consequence to the argument; it might be got from the Portuguese for fish to eat during Lent, or from merchants for fish to send to the West India slaves; it is all the same, for it is clear the money must have been got somewhere and for something, otherwise it could not have been given. The Shetlanders thus lose nothing by our not taking their native produce, and no more would the British nation lose by paying foreigners in money on similar commercial principles. It is as ridiculous for nations to refuse buying at the cheapest market, as it would be for the butcher not to buy from the wine-merchant, because he did not buy his meat from him. In the large congregation of tradesmen in a city, each buys where he chooses, and at the cheapest and best shop. When we wish to purchase a hat, we seek out the best hatter, and buy from him, even although he does not deal with us "on principles of reciprocity." The money we give him we got from some one else for our commodities, and that is sufficient. Thus it is with the inhabitants of large communities, and in a wider sphere it ought always to be thus with nations, which are but communities on a more extended scale.*

An able writer on this topic has well remarked: "As the same country is rendered the richer by the trade of one province with another; as its labour becomes thus infinitely more divided and more productive than it could otherwise have been; and as the mutual supply to each other of all the accommodations which one province has, and another wants, multiplies the accommodations of the whole, and the country becomes thus in a wonderful degree more opulent and happy; the same beautiful train of consequences is observable in the world at large—that great empire, of which the different kingdoms and tribes of men may be regarded as the provinces. In this magnificent empire, too, one province is favourable to the production of one species of accommodation, and another province to another; by their mutual intercourse they are enabled to sort and distribute their labour as most peculiarly suits the genius of each particular spot. The labour of the human race thus becomes much more productive, and every species of accommodation is afforded, in much greater abundance. The same number of labourers, whose efforts might have been expended in producing a very insignificant quantity of home-made luxuries, may thus, in Great Britain, produce a quantity of articles for exportation, accommodated to the wants of other places, and peculiarly suited to the genius of Britain to furnish, which will purchase for her an accumulation of the luxuries of every quarter of the globe. There is not a greater proportion of her population employed in administering to her luxuries, in consequence of her commerce; there is probably a good deal less: but their labour is infinitely more productive: the portion of commodities which the people of Great Britain acquire by means of the same labour, is vastly greater."*

There can be no doubt that the full developement of the universal principle of free trade, which we have now explained, would have a tendency to granulate all the nations of the earth down to a uniform level; but it remains to be proved that the Creator of the world has intended that one or more nations should for ever by force or fraud maintain a superiority over the rest. Nature has no preferences. There cannot be a code of commercial principles for one country, and another code for another country, any more than there can be two different codes of morals, or two kinds of truth. The interests of the human race are the same in all regions, whatever be the arrangements or exigencies of governments. It is not, therefore, by force that any nation can remain permanently prosperous. Armies may be raised and fleets manned to maintain national monopolies; but inasmuch as it is an eternal law of Providence that the hand of the diligent can alone make rich, so the only true way of gaining as well as retaining a true national supremacy, is by the general and individual exercise of superior skill, industry, and just dealing.

GREAT BRITAIN.

England at an early period began to manifest a fitness for manufactures and commerce; but the industrious habits of the people were, for centuries after the Norman conquest, depressed by all kinds of restrictions, corporate and baronial privileges, and engrossing monopolies. Even in the reign of Henry VII., in which the middle classes may be said to have arisen, and assumed a respectable station in the community, commerce was restrained by regulations, which, however well meant, were destructive to national industry. The reigns of Henry VIII. and Elizabeth were still more distinguished for the encouragement of injurious monopolies in trade; and till this period, the country produced no manufacture of any description which was not surpassed in quality by the same commodity in one or other of the continental nations. It is in the reign of James I. that we have to look for the origin of the commercial prosperity of England. In the year 1624, a law was passed, declaring "all monopolies, grants, letters-patent, and licences, for the sale, buying, selling, and making of goods and manufactures, not given by an act of the legislature, to be altogether contrary to the laws of this realm, void, and of non-effect." This well-devised statute, as might be expected, immediately excited national industry. The hands and the genius of the people were let loose; and as it was also about this period that trade began to be carried on with the American colonies, we may correctly state that the energies of the nation were not fairly demonstrated, in a manufacturing or commercial point of view, till the end of the first quarter of the seventeenth century, or about two hundred years ago. These energies were, however, dreadfully checked by the subsequent disasters of the nation; although it ought to be allowed that commerce was in the interim considerably indebted to the establishment of the British power in the West Indies, during the protectorate of Cromwell, and to the destruction of much of the Dutch influence in the East. The Revolution of 1688, by defining public and private rights, and giving security to property, very much accelerated the progress of the useful arts in Britain; still we have to attribute, to a period of comparatively recent date, the final establishment of England's commercial greatness. Up till the middle of last century, the nation could boast of none of the great interior works useful to commerce for which it is now so celebrated. Till 1756, it had not a single line of artificial navigation, and possessed, for inland traffic, only a small number of roads injudiciously cut and ill kept up. The cutting of the Duke of Bridgewater's canal, to convey coal to Manchester, gave a sudden impulse towards improved modes of communication, which very soon intersected the country in all directions with canals and turnpike roads, and otherwise produced immense improvements, both in the interior and in the various seaports. The successful institution of various railroads, in latter times, and the introduction of vehicles of all kinds for conveyance, on improved principles, may be said to have, along with what was previously accomplished, given quite a new character and appearance to every portion of the United Kingdom. More has thus been done for commerce in Great Britain within the last eighty years, than had been done for eighteen hundred years previously. Dupin, an intel-

* See our article "Political Economy," for further illustrations of the value of free trade.

* Mill's Commerce Defended.

ligent French writer, in speaking of the unexampled commercial power of the British empire, has fallen into an error with regard to the cause of this greatness. While very properly eulogising the English for their industry, their economy, and their general probity, as sources of national wealth, he states that the great public works of Britain have arisen, in a great measure, from the fostering care of the government, "which," he says, "has allowed commerce a free course, and has thought that it served it sufficiently in securing to it protection without, liberty within, and justice every where." This is decidedly a fallacy, though one which a foreigner might very excusably commit. The British people have owed almost nothing to the state, besides mere legislative protection of life and property. They have, in reality, become a great people in spite of the various administrations which have managed their affairs. The fundamental charter of commerce was wrung from James I. only by the greatest exertions on the part of the Parliament, and by the prospect of subsidies being granted to him. Since that period, the monopoly of the East India trade has been uniformly supported by government at the expense of the public interests; and it can never be forgotten that the imposition of restrictions and taxes on the North American trade lost to this country, by violence, by far the most valuable of its exterior provinces. It would be tiresome to recapitulate the extent of recent and existing restrictions on the British import, export, and home trade; and it would also be needless to mention the number of cases in which great internal improvements, projected by the people, have been prevented from being executed, by the withholding of the consent of the legislature.

British Manufactures.

England has been properly called "the workshop of the world." It supplies manufactured commodities to all nations, even to those from which it has imported the raw materials for manufacture. The greatness of England in this respect is derived from those elementary principles of society already noticed, and from the extraordinary division of labour and employment of machinery, which have created capital ready to be applied to any useful line of industry. A singularly striking instance of the advance of British manufactures from the employment of machinery, is found in the case of the cotton manufacture. The entire value of this manufacture, in 1760, did not amount to L.200,000. It now (1834) may be estimated at about L.40,000,000, employing 850,000 weavers, spinners, bleachers, &c., and 111,000 engineers, masons, smiths, joiners, machine-makers; whose joint wages amount to L.5,330,000 annually. The capital invested in this manufacture is calculated at upwards of L.75,000,000. British manufactured cotton goods are exported to all parts of the world, and in the East Indies, from whence a portion of the raw cotton is procured, undersell the native manufacture. Such are the results of the combination of capital, the division of labour, and the wonderful powers of machinery. The goods which are produced are equal to the work of eighty millions of men.

The manufacture of silk goods has also made extraordinary progress, especially since 1823. Since 1825, the consumption of silks in Great Britain has increased 60 per cent., and the value of the exports has augmented from L.160,000 to L.500,000. The British are fast approaching the French in this branch of manufacture; and nothing can prove this more decidedly, than the fact that the value of our exports of silks to France increased from 119,570 francs in 1826, to 643,720 francs in 1830. The consumption of French silks in this country is correspondingly decreasing. The annual value of the British silk manufacture is estimated at L.8,000,000; 700,000 workmen are employed, and 1,500,000 persons directly or indirectly concerned in the trade. The woollen manufacture is another of the great staples of industry: its annual produce is estimated at L.22,300,000, and gives employment to above half a million of men, women, and children. To supply this manufacture, above 22,000,000 lbs. of wool are annually imported from Germany, independent of what is produced at home. The linen manufacture, which comes next in point of national importance, employs 300,000 persons, and the gross produce annually is valued at L.11,000,000. The manufacture of leather, including the making of saddlery, gloves, boots, shoes, and other articles, is also very extensive. It is computed that it employs 254,000 persons, which, we think, must be below the mark, and that the annual produce amounts to L.15,000,000. No country produces such excellent and cheap hardware as Britain: here the division of labour has been carried to an exquisite pitch of perfection. The annual value of the goods manufactured from iron, steel, copper, brass, tin, pewter, &c., may be estimated at about L.18,000,000, and the number of persons employed at 370,000. The earthenware, china, and porcelain manufacture, has been greatly improved, and now excels that of any other country. Its annual produce is estimated at L.3,500,000, and that of the glass manufacture at L.2,500,000. The restrictions and duties on the glass manufacture oblige nearly all classes to use the coarsest kinds, and as small a quantity of the article as possible. A considerable manufacture is carried on in jewellery, gold and silver plated articles, and gold and silver lace. The annual produce of this elegant branch of manufacture now far exceeds that of France, and was estimated at L.2,500,000 in 1811, since which period the consumption of the various articles must have greatly increased. The annual produce of the following manufactures—paper, pasteboards, hangings; book and printing apparatus; fine arts and engravings; paints, colours; household furniture; coaches, waggons, and carriages—is estimated at L.9,000,000. The miscellaneous manufactures of Britain are almost endless; as salt, alum, soap, tobacco, beer, porter, spirits, gunpowder, candles, cooperage, straw, hair, oil-cloths, tinnery, musical instruments, toys, corks, ships, houses, bricks, tiles, &c. The annual produce of the miscellaneous manufactures is estimated at L.31,200,000. Reckoning all branches of these manufactures in Great Britain, in which raw materials are converted into all sorts of useful and ornamental articles, the amount of the annual produce is estimated at L.148,050,000.

Immense as the amount of the foregoing manufactures appears to be, the value of the commodities raised by cropping the ground, and generally included in the term farm and dairy produce, is much greater. It is computed that the enormous sum of L.1,901,000,000 is invested in the business of farming in Great Britain, and that the total annual produce amounts to L.246,000,000. The quantity of grain raised amounts to about 52,000,000 of quarters, and the average quantity of corn imported may be taken at 900,000 quarters, which is less than two weeks' consumption. The annual value of the produce of the mines, including those of coal, amounts to L.21,400,000. In the year 1830, the total number of vessels employed in commerce belonging to Great Britain, was 23,723, having a burden of 2,531,819 tons, and employing 154,809 men. Calculating profits of all kinds derived from the commercial marine, the total produce amounts to L.34,398,059. Having in our article "The British Empire and its Resources" given a list of the value of the inland trade, fisheries, and other sources of national wealth, we may briefly mention, that the total amount of public and private property in the United Kingdom is estimated at L.3,679,500,000, and that the produce and property annually created is L.514,823,059.

The vast sum of happiness and comfort which might be supposed to flow from the possession of such enormous capital, is reduced to a comparatively inconsiderable amount from the incessant paralysing action of the national taxation. The sum of forty-one millions is levied annually upon consumption—upon the necessaries of life, food, coals, malt, sugar, tea, dress, household articles, raw produce, and the materials of manufactures. The exaction of this prodigious sum, and the restrictions it naturally creates, deprives British manufacturing and commercial industry of innumerable advantages, and prevents the enjoyment of the full benefits of our extraordinary mechanical inventions. "Those (says the accurate Pablo Pebrer, in his excellent work on the Resources of the British Empire) who cannot resolve the perplexing problem, that, in Great Britain, with an immense increase of maritime power, with equally increasing improvements in agriculture, with unbounded commerce and industry, and with immense wealth, individual happiness does not accompany these transcendant advantages, but, on the contrary, marches rapidly in the contrary road, may here find the key to its solution!" The extent to which the commercial greatness and moral elevation of England would be carried, were the national industry relieved of its burdens and restrictions, no human being could calculate.

British Commerce.

The chief exports of Great Britain are, to the north of Europe, cotton and woollen cloth, glass, hardware, pottery, lead, tin, coal, East India and colonial wares, dyestuffs, salt, and refined sugar. In return, Great Britain receives from the north, corn, flax, hemp, iron, turpentine, tar, tallow, timber, linen, pearl and pot ashes, cordage, and hogs' bristles. To Germany, Holland, France, Italy, Spain, and Portugal, it exports cotton and woollen fabrics, cutlery, dried and salt fish, pottery and glassware, colonial and East India goods, and all kinds of the finer manufactures. From Germany it imports corn, flax, hemp, linen cloth and thread, rags, hides, timber, and wine. From Holland, flax, hemp, madder, gin, cheese, butter, rags, and seeds. From France, wine, brandy, lace, cambric, silk ornaments, and fancy goods and fruit. From Italy, Spain, and Portugal, silk, wool, barilla, sulphur, salt, oil, fruit, wine, brandy, and cork. To Turkey it sends cotton and woollen goods, hardware, colonial and East India goods, lead, tin, iron, clocks, and watches; receiving in return, coffee, silk, fruits, fine oil, dyestuffs, carpets, &c. To North America it sends woollen and cotton manufactures, hardware to a large extent, linen, glass, and other wares: the imports from thence are, flour, cotton, rice, tar, pitch, pot and pearl ashes, provisions, ship timber, &c. The export trade to North America has been greatly injured by the duties imposed by the American tariff. The chief imports from South America are cotton, hides, skins, tallow, cochineal, dyewood, sugar, indigo, cocoa, gums, &c.; and the exports from England are the same as above mentioned. The same exports are likewise sent to the West Indies; and, in return, Great Britain receives rum, coffee, tobacco, sugar, ginger, pimento, pepper, indigo, dyestuffs, drugs, gums, cotton, mahogany, Campeachy wood, &c. To the East Indies, China, and Persia, it sends woollen goods, iron, copper, lead, tin, foreign silver money, gold and silver in bars, hardware, and a variety of manufactures; for which it obtains muslins, calicoes, silks, nankeens, tea, spices, arrack, sugar, coffee, rice, saltpetre, indigo, opium, drugs, gums, quicksilver, precious stones, pearls, &c. To the colony of New South Wales, the common English manufactures and colonial goods are exported, and exchanged for train-oil, seal-skins, wool, &c.

Internally, Great Britain trades in the following commodities. England receives from Scotland, corn, cattle, woollen, linen, and cotton goods, canvass, and iron manufactures; the Scottish fisheries also furnish an important article of commerce. For these things, Scotland receives the productions of Ireland, and articles of luxury, of all kinds, from England. Ireland buys of England and Scotland, woollen, cotton, and silk goods, East and West India goods, pottery, hardware, and salt; and, in exchange, gives its linen, hides, potatoes, and other provisions, &c. Ireland exports its productions and manufactures to France, Spain, Portugal, the West Indies, and North America, for wine, fruit, sugar, rum, &c. The commercial intercourse between Ireland and the north of Europe is mainly through England, and its trade with the East passes exclusively through the same channel. The chief articles of export from Ireland are linen, potatoes, and other provisions, corn, whisky, herrings, and salmon.

Within a recent period, the manufactures and commerce of Scotland have wonderfully increased. The iron manufactures of Carron, and the cotton and silk manufactures of Glasgow and Paisley, are known all over the world. The sail-cloth and coarse linen manufactures of Dundee, now one of the most flourishing ports in the empire, have greatly tended to the advancement of the Scottish export trade. The annual value of the Scotch manufactures was recently calculated to exceed L.14,000,000. The tonnage of vessels on the Clyde is nearly as great as that of all Ireland, the tonnage of which, in 1828, only amounted to 97,370 tons—not one-third of the total tonnage of Scotland; the tonnage of Aberdeen is as great as that of Dublin and Belfast, the two principal Irish ports put together.

The foreign possessions, settlements, and colonies of Great Britain, of which it possessed twenty-six prior to the French revolution, and has gained seventeen more by conquest, are Heligoland, Gibraltar, and Malta, with Gozo, and the Ionian Isles, in Europe; its possessions in India, under the administration of the East India Company, and Ceylon, in Asia; the Isle de France, or Mauritius, with the Sechelles and Amirante Isles, the Cape of Good Hope, Sierra Leone, Cape Coast, and Annabon, the islands of Ascension and St Helena, in Africa; Canada, New Brunswick, Nova Scotia, Cape Breton, St John's, Prince Edward's Island, Newfoundland, Hudson's Bay, and the Bay of Honduras, in North America; Berbice, Essequibo, and Demerara, in South America; Jamaica, Barbadoes, Antigua, St Vincent, St Christopher, Nevis, Montserrat, the Virgin Islands, Grenada, Tobago, Dominica, Trinidad, and the Bahamas, in the West Indies; also the Bermudas; in Australia, New South Wales, Van Diemen's Land, and the colony of New Zealand, and Melville's Island.

The most important commercial cities of England, besides London, are Liverpool, Bristol, and Hull; the most important manufacturing towns are Manchester, Birmingham, Leeds, Nottingham, Halifax, Rochdale, &c. In Scotland, the principal commercial places are Glasgow, Greenock, Leith, Dundee, and Aberdeen. The foreign trade of Glasgow and Greenock extends to the West Indies, the United States, the British American colonies, Brazil, and the whole continent of Europe. The foreign trade of Leith, Dundee, and Aberdeen, extends to the West Indies, America, the Mediterranean, and the Baltic. The greatest commercial cities of Ireland are Dublin, Cork, Wexford, Waterford, and Belfast.

Nearly two-thirds of the traffic of Great Britain is carried on in London, and about one-sixth of the whole shipping of the empire belongs to that port. London is likewise the centre point for the negociation of all the great commercial and pecuniary transactions in the United Kingdom. Through it proceed nearly the whole of the foreign bills of exchange, and upon it drafts are made payable from all quarters of the globe. The amount of accounts balanced every day by bankers in London is eight millions sterling!

Both the export and import trade of the United Kingdom have been steadily increasing for a number of years, in proportion as restrictions have become less harassing, as duties have been remitted, and as population has advanced. Not counting odd thousands, the following presents a view of this increase:—In 1800, the official value of the exports from Great Britain, of British manufactures and Irish produce, was twenty-two millions; in 1810, thirty millions; in 1821, thirty-seven millions; in 1828, fifty-one millions; and in 1830, fifty-five millions. This is not estimating the export of foreign and colonial produce, or exports from Ireland. The value of imports into Great Britain has risen in a similar manner, from twenty-four millions in 1800, to forty-two millions in 1830. The following tables will exhibit in the clearest manner the exact extent of the commerce of Great Britain with its colonies and with other foreign countries:—

TABLE I.

An Account of the OFFICIAL and DECLARED VALUE of the IMPORTS to and EXPORTS from the UNITED KINGDOM, from and to each of the BRITISH COLONIES and POSSESSIONS, for the Year ending 5th January 1831; being the last account laid before the House of Commons; distinguishing British and Colonial and Foreign Produce.

Names of the British Colonies, &c.	Official Value of Imports into the United Kingdom.			Official Value of Exports from the United Kingdom. British and Irish Produce and Manufactures.			Official Value of Exports from the United Kingdom. Foreign and Colonial Merchandise.			Declared Value of British and Irish Produce and Manufactures exported from the United Kingdom.

In the year ending January 5, 1832, Great Britain exported of British and Irish produce and manufactures, official value, L.60,090,123—exported of colonial and foreign produce, L.10,729,943; and imported to the value of L.48,161,661. The Irish exports for the same year amounted to L.608,939, and the imports to L.1,[illegible].

FRANCE.

This large and fine country, which ranks after Great Britain in political power, and from whence many of the refinements of social life have been imported into this country, has never been conspicuous as a manufacturing or commercial nation. It wants the iron ore and coal which England so abundantly possesses; and the industry of the people has taken a direction towards the producing of articles of a light fabric, more for ornament than use. Though possessing an extensive seacoast, France has very few good harbours; and this has powerfully tended to restrict its commercial greatness. Moreover, the attention of its various governments has for a very long period been directed more to military conquest than the arts of peace; consequently, internal improvements have not advanced, the division of labour has not yet been exercised on a great scale, machinery has hardly been brought into use, and spare capital has not been created to foster skill and labour. Besides these causes for the backwardness of manufactures and commerce in France, the existing government, from a mistaken, though common policy, and following the footsteps of Napoleon, has placed the most vexatious restrictions on the foreign and home trade. "Notwithstanding the vast importance to a country like France of supplies of iron and hardware at a cheap rate, that which is produced by foreigners is excluded, though it might be obtained for half the price of that which is manufactured at home. A similar line of policy has been followed as to cotton-yarn, earthenware, &c. And in order to force the manufacture of sugar from the beet-root, oppressive duties have been laid, not only on foreign sugar, but even on that imported from the French colonies. The operation of this system on the commerce and industry of the country has been most mischievous. By forcing France to raise at home articles for the production of which she has no natural or acquired capabilities, the exportation, and consequently the growth, of those articles, in the production of which she is superior to every other country, has been very greatly narrowed."—*M'Culloch's Com. Dic.*

The chief branch of industry in France is that connected with the producing and preparation of wines. It is calculated that 3,000,000 of individuals, or a tenth part of the population, are employed in this great trade, and that the value of the produce of the wine is about L.40,000,000. But the traffic in this valuable commodity is exceedingly hampered by restrictions; and both this and the silk trade have declined in late years.

The commerce of France may thus be summed up. The exports are wine, brandy, oil, corn, meal, liqueurs, snuff, silks, woollens, fancy goods of all kinds, watches, porcelain, crystals, carpets, bronze, linen, lace, cambric, tapestry, hemp, flax, fruits, capers, salt, jewellery, paper, &c.; and France receives the raw produce of all countries, but very few manufactured goods. In the year 1824, the value of all the exports of France amounted to 440,542,000 francs, of which 163,056,000 were in natural products, and 277,486,000 in manufactured goods. In the same year, goods imported into France to the amount of 189,635,000 francs in 3387 French vessels, to the amount of 108,307,000 francs in 4183 foreign vessels, and to the amount of 150,929,000 by land; the whole importation amounted to 454,861,000 francs. The principal ports are Bordeaux, Marseilles, Nantes, Havre de Grace, St Malo, L'Orient, and Dunkirk. The commerce of Marseilles is mostly with the Levant and the West Indies; that of Bordeaux with Asia, the West Indies, and the north of Europe. Calais and Dunkirk carry on a very lucrative contraband trade with England. Havre de Grace is the seaport of Paris, which has a very extensive indirect trade and dealings in bills of exchange with foreign countries. Amiens exports great quantities of velvet; Abbeville, Elbeuf, Louvier, and Sedan, trade mainly in cloths; Cambray, Valenciennes, and Alençon, in cambrics and fine laces. Cette, the port of Montpellier, has an extensive trade in Spanish and colonial goods. The commerce of Bayonne is chiefly with Spain. Silks form a principal article of the commerce of Lyons, which is situated in the centre of the roads leading to Switzerland, Spain, Italy, and Germany, and has annually four fairs. For Strasburg, its excellent turpentine is an important article of trade. Lisle has a direct intercourse not only with all the commercial states of Europe, but also with the French and Spanish colonies, and with the Levant. The other commercial towns of importance are Rheims, Troyes, Grenoble, Nismes, Angouleme, Cognac, Nantes, Rouen, Rochelle, and Caen. Grenoble supplies France, Italy, Spain, and even Great Britain, with fine gloves. Beaucaire has an important fair. The French colonies are Martinique, Guadaloupe, St Lucia, and Mariegalante, in the West Indies; Cayenne, in South America; Pondicherry, Chandernagore, and some other possessions in the East Indies; with several factories on the western coast of Africa, and on both sides of Cape Verde.

HOLLAND.

The Dutch, by their industry and enterprise, their free institutions, which gave perfect security to life and property, and other causes, were at one period the greatest commercial nation in Europe. They were at the height of their commercial glory at the middle of the seventeenth century, and by the greater number of their ships, and their superior skill in navigation, they at this time engrossed nearly the whole of the trade of carrying goods. But they soon after this period began to decline as a commercial people. Their republican freedom merged in corruption and abuse; the most burdensome taxes, or excise duties, were imposed; and their power, which was hence paralysed at its very root, was gradually subverted abroad by the enterprise and perseverance of the British. Holland at length sunk into the character of a second or third-rate commercial nation; though the trade which it still possesses is very considerable. Its chief exports are butter, cheese, linen, cloth, drugs, and paints, fish, wheat, linseed, clover-seed, genera (gin), dye-stuffs, paper, &c. The principal commercial cities in Holland are Amsterdam, Rotterdam, and Groningen. Before the decline of Dutch commerce, Amsterdam was one of the greatest commercial cities of the world, the mart of goods from the East and the West, and from the principal states of Europe. To the exchange and banking business, of which the channel was Amsterdam, the Dutch were also, in part, indebted for their great prosperity. With Hamburg, Amsterdam is yet the centre of the exchange business between the north and the south of Europe, although from the time that the credit of the bank of Amsterdam diminished, this branch of business has declined, a great portion of it being transferred to Hamburg and London. The imports are grain, wood, coal, tallow, wax, rags, &c. For the colonial trade of Holland, the possession of Batavia, Amboyna, Banda, Ternate, and Macassar, in the East Indies, is of importance, as are also the commercial settlements on the Coromandel and Malabar coasts, and those at Bantam, Padang, Japan, &c. In Africa, Holland has some forts in Guinea; in America it possesses Surinam, and the West India islands of Curaçao, St Eustatie, and St Martin.

The commerce of Belgium, which lies adjacent to, and was recently politically joined with Holland, has never been of any great importance. Belgium has few manufactures, the principal being lace and carpets; it has no colonies, and little foreign trade; what is worse, it has no vigorous industry, and no capital. Its chief towns are Brussels, Antwerp, Ostend, and Ghent. Corn, tapestry, lace, fine linen, and flax, are its principal articles of export.

GERMANY.

On account of its navigable rivers, the commerce of this country is considerable. The chief articles of export are linen, linen yarn, raw wool, rags, quicksilver, corn, timber, flax, hemp, wax, lard, salt, wine, and metals. Its imports are woollens, cottons, and silks, hardware, watches, tanned leather, leather goods, tea, cocoa, dyewoods, hides, colonial and East India goods. The principal ports of Germany are Hamburgh, Lubeck, Bremen, Trieste, and Dantzic. In the interior its chief commercial cities are Vienna, Magdeburg, Leipsic, Frankfort on the Maine, Frankfort on the Oder, Augsburg, Berlin, Breslau, Cologne, Nuremberg, Brunswick, Mentz, Bautzen, and Prague. Hamburg, in particular, is the channel through which flows, for the most part, the extensive trade between Great Britain and the German States. By means of the rivers running into the Elbe, the navigation of which has now become free, the numerous and valuable productions of Upper and Lower Saxony, of Austria, and Bohemia, go to Hamburg. By the Havel, the Spree, and the Oder, its commercial operations are extended to Brandenburg, Silesia, Moravia, and Poland. The business of Hamburg consists, in part, of the consignments of foreign merchants, and, to a great extent, of the purchase and sale of domestic and foreign goods. Its money transactions are very considerable. Bremen has important articles of export in the products of Westphalia and Lower Saxony, which it sends to England, Spain, and Portugal; and with America it has more intercourse than any other seaport of Germany. The trade in linens which foreign countries carry on with Germany, passes wholly through the hands of the Hamburg and Bremen merchants, to whom all foreign orders are directed. The importation of tobacco from America into Germany is almost wholly through Bremen. Leipsic, the centre of European trade with the interior of Germany, and the place of deposit for foreign and Saxon goods, has, besides other mercantile privileges, three fairs (Easter, Michaelmas, and the New Year), to which merchants resort from all parts of Europe, and from Asia, and each of which lasts three weeks: there is, besides, at this place, a considerable market for Saxon wool. The chief articles of traffic are Bohemian, Silesian, and Saxon linen; leather, hides, wax, and wool, from Poland; woollen goods and pigments, from Prussia; silks, velvets, and corals from Italy; leather, various manufactures, and dyestuffs, from Austria and Hungary; laces, silk goods of all kinds, ribbons, porcelain, watches, bronze and other manufactures, including fancy articles, from France; leather, hemp, and flax, from Russia; colonial commodities and manufactures, from England and Holland; and literary productions from all Europe. There is also in Leipsic an important horse-market. Augsburg, by means of its agents and bankers, is the medium of mercantile communication between Germany and the south of Europe. The exchange business of Vienna is commonly transacted by drafts on Augsburg. It also derives considerable advantage from the forwarding of goods to and from Italy. Frankfort on the Maine, a place of great commercial activity, especially at the time of its two great fairs, in the spring and autumn, has, besides, a very important business, owing to the opulence of its old and new banking-houses.

AUSTRIA

is entirely separated from Germany by its system of imposts and its commercial regulations. Its trade is mostly carried on by land, or on the rivers. Vienna, the storehouse of the inland trade of all Austria, has a very extensive commerce with England, the Netherlands, and France, and important dealings with Italy, Hungary, Poland, and Turkey. By the way of Vienna, Germany receives great quantities of raw cotton from Turkey. The commerce of Trieste, in the Littorale, consists chiefly in the exportation of German productions and of colonial goods, which go from thence to the Levant, and the coasts of the Black Sea. Trieste may be regarded as the depôt of the productions of the Levant. It is also actively engaged in the importation of British wares, and of the produce of the fisheries of Newfoundland. Except this city, the commerce of Austria is confined to Venice and Fiume. The most considerable places of inland trade in the monarchy, besides Vienna, are Lemberg, Prague, Brunn, Brody, Botzen, Pest, and Cronstadt. The allowed imports consist mainly of raw produce, cotton and wool, silk, rice, oil, spices, colonial articles, leather, cattle, &c. The articles of export are woollen cloths, linens, cordage, mineral productions, grain, and glass. Great profit is derived from the transportation of goods, especially of those of the Levant. In Bohemia, far the greater portion of the trade is in the hands of the Jews, who are numerous in the country. The trade is chiefly in exports: linens, woollens, silks, dyewood, leather, and glass. The glass is superior in polish and cheapness to that of other countries, and the exportation of it is very considerable. It is thought that the goods exported to Spain, Russia, the Levant, and America, amount to 2,500,000 guilders annually. The countries with which Bohemia has the most commercial intercourse, are Austria, Holland, Spain, Portugal, Italy, and Turkey. The exports are rated at from 5,000,000 to 6,000,000 dollars, and the imports (colonial goods, articles of luxury, &c.) at from 4,000,000 to 5,000,000 dollars. Prague is the first commercial city of the country; Reichenberg the second.

PRUSSIA.

The commerce of this monarchy is promoted by the Baltic, by many navigable rivers, and by canals. The commerce in domestic productions is more important than the transportation and commission trade, which flourishes mainly in Cologne, Magdeburg, Stettin, Minden, Dantzic, Königsberg, Breslau, &c. The exports by sea are grain, wax, tallow, wool, linseed, flax, hemp, wood, linen, yarn, woollen and cotton goods, fine works of art, including articles made of amber. The chief port is Dantzic, which is situated on the Vistula, and, after Petersburgh, is the most important centre of commerce in the northern part of Europe. This city is the great warehousing depôt for receiving corn from the interior, and exporting it to other European countries. Of the different commercial places, Frankfort on the Oder has three considerable fairs. Magdeburg sends corn, linen, cotton goods, cloths, leather, salt, and copper, to Hamburg, and to the fairs of Leipsic and Brunswick. It has, besides, a transit trade in colonial goods, wine, grain, &c. Timber is exported from Elbingen, Stettin, Königsberg, Anclam, and Berlin; staves and ashes from Dantzic, Memel, and Stettin; hemp, flax and linseed, tallow, wax, and hogs' bristles, from Memel and Königsberg. Tilsit carries on a brisk trade in corn, linseed, hemp, and flax. The exports of Brunsberg are woollen yarn, corn, and flax. Colberg exports corn, and the other produce of Poland. The trade of Stralsund, likewise, consists chiefly in the exportation of corn. Of all the articles of Prussian commerce, the Silesian linen holds the first rank, and for the manufacturing of it, the Silesian towns Hirschberg, Landshut, Schmiedeberg, Friedland, Waldenburg, Schweidnitz, and the Prussian section of Upper Lusatia, are celebrated. This linen is particularly in demand among the Hamburg, English, Dutch, Italian, and South American merchants. The imports which have the readiest sale in Prussia are colonial goods, dyewood, salt, Buenos Ayres hides, indigo, groceries, wine, silk, cotton goods, hardware, &c.

HANOVER

is not distinguished for its mercantile activity. The exports consist of horses, horned cattle, lead, wax, linen, leather, salt, oats, barley, timber, boards, and the ferruginous copper of the Hartz mountains. The linens are ordinary; the tablecloths and Osnabruck damask are inferior in quality to those of Prussia and Friesland. The surplus of the domestic consumption is exported to South America through the medium of the Hanseatic cities. The principal imports are English manufactures, especially woollen cloths and calicoes, colonial goods, Prussian and Friesland linen, fine French cloths, silks, jewellery, and French wines, with all kinds of small articles of luxury, which the Hanoverian merchant brings with him from the fairs of Brunswick, Leipsic, and Frankfort on the Maine. The chief commercial towns are Emden, Hanover, and Münden.

DENMARK AND HOLSTEIN.

Although the Danish merchants have formed connections with all the commercial states of Europe, and act an important part in the commerce both of the

Mediterranean and the Baltic, their own country possesses but few productions important as articles of export. Most of what they export are the productions of their East and West India possessions. To the ports of Petersburgh, Riga, Stockholm, and Memel, Denmark carries the woollen goods of Iceland and the Faroe Islands; salt from Spain, France, and Portugal; and the productions of the East and West Indies, and of China. To Germany it sends its horses, its cattle, colonial and West India goods, and woollen stockings, receiving, in return, linen, wool, brandy, and wine. To Holland it exports rape-seed, fish, &c., in exchange for groceries. To France, Spain, and Portugal, it carries horses, fish, and other articles from Russia, in exchange for salt, wine, fruits, sweet-oil, brandy, silk, &c. Its trade with England consists, mainly, in exchanging timber, &c. for English manufactures. To Iceland it exports rye-meal, rye, barley, brandy, and other spirituous liquors, together with the common articles of consumption; receiving, in return, fresh, dry, and salt fish, train-oil, tallow, eider down, wool and woollen stockings. It supplies Greenland with flour, spirituous liquors, &c., in return for train and seal-oil, seal-skins, eider down, and peltry.

The largest commercial towns of Denmark are Copenhagen and Elsinor in Zealand, Aalborg in Jutland, Flensborg and Tonningen in Sleswic, Altona and Kiel in Holstein. The West India colonies of Denmark are St Croix, St Thomas, and St John's. On the coast of Coromandel, it possesses Tranquebar; on the coast of Guinea, Christianborg and other small places. It has also small factories on the Nicobar Islands. In Europe it possesses Iceland. The chief commercial companies in Denmark are, the Asiatic or East India Company, the Iceland Company, the Maritime Insurance Company, the African, or Danish West India, and the General Commercial Society.

ITALY.

Although Italy possesses the most excellent harbours on the Mediterranean and Adriatic Seas, and has a geographical situation uncommonly favourable for commerce, its trade, both domestic and foreign, is very limited. The cause is to be sought in the impolitic restrictions, heavy taxes, and imposts, to which the commercial cities are subjected in this most fruitful, but, for the most part, badly governed country. The chief articles of export from Italy are corn, olive-oil, wine, brandy, silk, cotton, wool, hemp, flax, velvet, damask, barilla (soda), sulphur, sumach, gall-nuts, madder, velani or velonia, and other dyestuffs; senna leaves, liquorice juice and root, juniper berries, and other drugs; anchovies, almonds, figs, nuts, olives, currants, raisins, and other fruits; rags, chip and straw hats, the skins of sheep and kids, and marble. The principal commercial cities are Florence, Genoa, Leghorn, Naples, Venice, and Ancona. Leghorn is the main channel of the trade of Italy with the Levant and the Barbary States, and the central point of the commerce of England in the Mediterranean. A great part of its trade is in the hands of the Jews. Silks, taffeta, satins, brocades, light woollen goods, velvets, &c., are the main articles of export from Florence. These pass through Leghorn, and sell readily in the Levant. Milan and Turin carry on a very extensive trade in their silk, which is celebrated throughout Europe for its admirable fineness and lightness. Ancona has intercourse with the first commercial cities of Europe. Its business is chiefly agency and commission business. Some silk is exported from Nice. The exports of Lucca are olive-oil, silk, damasks, fruit, &c. Much olive-oil is exported from Gallipoli. The trade of Genoa continues considerable. Its exports are velvet, damask (which, next to the Venetian, is the most esteemed in Europe), raw silk, fruit, olive-oil, alum, marble, corals, coarse paper, &c. Venice, once the greatest mart of the world, notwithstanding the disappearance of its ancient splendour, is still an important place for commerce, a great part of the trade of Europe with the Levant being yet in its hands. The Venetian velvets, damasks, mirrors, and manufactured silks, in great quantities, form the most considerable constituents of the foreign trade of Venice. The exports of Naples are olive-oil, wool, silk, tartar, wines, raw and manufactured silk, fruit, sulphur, and staves.

THE ISLANDS OF THE MEDITERRANEAN SEA.

The exports of Sicily, a country on which nature, with profuse generosity, has lavished in abundance all her gifts (the benefit of which, however, is almost destroyed by the weakness of the government), consist of silk, grain, barilla, sulphur, olive-oil, wine, cantharides, sumach, manna, coral, rags, almonds, figs, raisins, nuts, anchovies, amber, goat, buck, and sheep skins, pomegranates, oranges, lemons, &c., and pine apples of remarkable size and exquisite flavour. The chief port is Messina; next to this comes Palermo.

The exports of Sardinia are, chiefly, grain of uncommon excellence, tunny-fish, hides, barilla, and salt. Cagliari is the most considerable commercial city.

Corsica exports silk, olive-oil, and black, white, and red corals. The silk goes mostly to Genoa and Lyons, and the corals are sold at Marseilles, where they are manufactured and polished, to be sent to Africa, to be sold to the Moors and Negroes. The Corsican ports are, Ajaccio, Bastia, and Porto Vecchio.

Malta, which is, like Gibraltar, a depôt for British and colonial goods that are to be disposed of in the Mediterranean, exports cotton, oranges, and other fruits.

The Ionian Islands (Cephalonia, Zante, Corfu, Santa Maura, &c.) export wine, brandy, olive-oil, raisins, currants, citrons, melons, pomegranates, honey, cotton, and salt. The raisins and currants are superior to those of the Morea in quality. The wine is Muscadel.

The commerce of the island of Cyprus is inconsiderable. It exports cotton, wool, silk, wine, salt, turpentine, Turkish leather, &c. Its largest commercial cities are Larnica and Rhodes.

The exports of the island of Candia, which, by its situation, is designed for the mart of the European, Asiatic, and African trade, consist of oil, soap, wax, wine, linseed, rasiins, almonds, laudanum, &c.

RUSSIA.

This large empire has greatly increased its commerce in modern times, but its merchants engaged in foreign traffic are mostly foreigners, who are placed under various restrictions injurious to trade. The main element of the Russian commerce lies in the immensity of the raw produce of the country, as tallow, hides, and flax; and unless these commodities found a vent in foreign countries, among which Great Britain takes most, the greatness of Russia, which is founded on no proper principle, would speedily crumble in pieces. The principal commercial city of Russia is Petersburgh, at the confluence of the Neva with the Gulf of Finland: Riga is second in importance, and commands the Baltic trade. The chief exports from these and other ports are tallow, hemp, flax, iron, copper, grain, deals, ship masts, potashes, bristles, linseed, hempseed, oils, furs, leather, hides, and skins of various kinds; canvass, cordage, wax, isinglass, tar, and other raw and partially manufactured articles. The principal imports are cloths, cotton goods, silks, salt, wines, and all foreign articles of luxury. By the Black Sea, and the Sea of Azoph, Russia carries on a tolerable trade with various Turkish ports. It likewise carries on trade to some extent with Persia, and other countries in the East. by means of land carriage.

SWEDEN AND NORWAY.

The articles exported from the twenty-eight Swedish ports are iron, steel, copper, pitch, tar, fir, alum, and fish. The chief commercial cities are Stockholm, Gottenburg, and Gefle. Carlscrona carries on considerable trade in iron, timber, pitch, tar, tallow, potash, linseed, &c., which articles are sent mainly to the French, Spanish, and Italian ports, commonly in exchange for salt. The exports of Gottenburg are fish, iron, steel, and boards. The institutions of Sweden for the promotion of commerce are, the Bank, the East India Company, the West India Company, the Levant Commercial Company, the Association of Industry, &c. From Norway are imported fish, oak and fir timber, deal boards, masts, alum, vitriol, fish, and seal-oil, pitch, hides, woollen stockings, iron, copper, and tar. The chief commercial cities are Christiania, Bergen, Drontheim, Christiansand, Drammer, and Stavanger.

SWITZERLAND.

Switzerland has a considerable foreign trade. Its exports consist chiefly of fine linen, silks, velvets, imitations of East India goods, and shawls, fine calicoes, clocks, watches, ribbons, wine, cheese, honey, &c. The most important articles of importation are colonial and East India goods, from Holland; salt, grain, wool, and cloths, from Germany; raw cotton, silk, &c. from Italy; manufactures of various kinds, from England; wine and brandy from France. The principal commercial cities of Switzerland are Basle, Berne, Zurich, Geneva, and Neufchatel.

SPAIN.

For three centuries, with the decrease of the industry of Spain, its trade has been on the decline. This country might have monopolised the commerce of the world, if it had understood and improved its situation. The natural wealth of the soil is, nevertheless, still the prop of its trade. The most important productions are wool, silk, salt, iron, copper, coal, quicksilver, barilla, rice, saltpetre, sugar, almonds, olives, oranges, lemons, figs, wines, brandy, and fruit. In Segovia and Leon, about 1,000,000 arobas of fine wool are annually collected, of which about four-fifths are disposed of to the French, Dutch, and English. The excellent Spanish wines, brandy, fruit, barilla, &c. are profitable articles for the country. From the port of Barcelona, excellent silks, coarse cloths, and cotton goods, with wine, brandy, almonds, nuts, and other productions, are exported; in return for which, the same port receives the silks of Lyons, the hosiery of Nismes, various kinds of stuffs and cotton goods, German linen, and dried stock-fish from England, amounting to about 3,000,000 dollars. The exports of Valancia consist principally of silk, barilla (soda), coarse wool, dried fruits, wine, and brandy. The latter is exported chiefly by the Dutch, and carried to Normandy and Bretagne. The English carry to Spain chiefly woollen cloth; the French, linen, woollen cloth, cutlery, groceries, &c. From the port of Alicant, the Spaniards export chiefly dried fruits, silk, wool, barilla, wine, Castile soap, olives, saffron, a kind of cochineal called *grana*, and salt; of which last, the English and Swedes annually take upwards of 9,000 000 pounds. In Carthagene and Malaga, also, much business is done. From the latter, wines, dried fruit, almonds, sumach, anchovies, olive-oil, &c. are exported. Seville carries on a considerable trade in oil and oranges, which are exported from Cadiz—a port once of great commercial power, but now partaking of the declension of Spain. Almost the whole Spanish coasting trade is in the hands of the French, Dutch, and English. The independence of Spanish America has almost annihilated the colonial power of Spain.

TURKEY.

The Turks are as yet very far from being a commercial nation, although their commerce with Austria, France, Italy, Great Britain, Holland, &c., by means of the Jews, Armenians, and Greeks living in Turkey, who have the trade of this country almost wholly in their hands, is by no means insignificant. They offer cotton for linen, silk for cloths, gold for iron. Nature and habit recommend to them intercourse with Austria. On the other hand, the commerce with European Russia, by way of Constantinople to Odessa, was very much restricted by the Porte, subsequently to 1823, by the necessity of re-lading, to which it subjected the European vessels destined for Odessa, and by other burdensome regulations. This, however, has been changed by the peace concluded with Russia in 1829. Every vessel can at present pass the Dardanelles unmolested. This must soon have a great influence upon the Turkish trade also. In the Archipelago, the Greek struggle for freedom has given rise to many dangers to the commerce of neutrals. The chief commercial place is Constantinople, particularly in regard to the trade with Russia. Till within a short period, it distributed the Russian products through the ports of the Mediterranean. The exports of this city, which, under a wise and active government, might become the true mart of the world, are of such little importance, that the great quantities of goods imported for the use of Turkey have to be paid for almost wholly with gold and diamonds. In this port, the English, French, Italians, and Dutch, obtain the produce of Poland, the salt, the honey, the wax, the tobacco, and the butter of the Ukraine; the hides, the tallow, the hemp, the canvass, the peltry, and the metals of Russia and Siberia, and in exchange give the productions of their own countries. This business is transacted without the Turks having the slightest part in it.

ASIA.

The commerce of Asia is mostly inland, carried on chiefly in Western and Middle Asia, by means of those caravans (called by a poet *the fleets of the desert*), in which sometimes more than 60,000 merchants and travellers are collected, while the number of camels is far greater. The central point of this trade by caravans is Mecca, which, during the presence of the caravans, offers to the eye of the traveller a more active trade and a greater accumulation of merchandise than any other city in the world. The muslins and other goods of the East Indies, the productions of China, all the spices of the East, the shawls of Cashmere, &c., are transported on the backs of camels to Mecca, from whence they are scattered over, not only the Asiatic, but also the African continent.

The Arabs, who were, before the discovery of the passage to the East Indies around the Cape of Good Hope, the first commercial people of the world, have now no commerce of consequence. Coffee, aloes, almonds, the balsam of Mecca, spices, and drugs, and their African imports of myrrh, frankincense, and gumarabic, are their chief articles of export. Yemen, rich in the costly productions of nature, resorts for a market to Mecca. The Arabian Gulf and the Red Sea connect the commerce of Arabia with that of Africa, especially with that of Egypt and Abyssinia.

The chief places for Persian trade are the Turkish cities of Bagdad and Bassora. The harbour of Abuschar, or Buschir, on the Persian Gulf, is also a mart for Persian and Indian goods. Bagdad, once the centre of a brilliant and extensive commerce, may still be considered as the great mart of the East, though it is by no means what it has been. From Bassora, the productions of Arabia, India, Persia, and the Asiatic islands, are sent to Bagdad, where they find a very good market, and from whence they are scattered through the other cities of the Turkish empire. By means of the Arab caravans, Europe supplies Persia with goods of all kinds, and even with the productions of America. On the other hand, it has nothing to give but dates, tobacco, and a very moderate quantity of woollen stuffs, its whole trade consisting in the distribution and sale of the products of other countries. Bassora is, by its situation, the mart of the active East Indian, Persian, and Arabic trade, carried on in the Persian Gulf. Its trade with the East Indies is very considerable, it being the channel through which the Ottoman empire is supplied with the groceries of the East, and with the manufactures of the British possessions in the East Indies.

The principal port of the Levant is Smyrna, a very important depôt of the merchandise of the East and West. The articles exported from the Levant are coffee, cotton, wool, silk, madder, camels' and goats' hair, hides, raisins, figs, pearls, rotten-stone, whet-stones, nut-galls, opium, rhubarb, and other drugs. Angora sends to Smyrna, by caravans, considerable quantities of Angora goats' hair, and stuffs made of the same material; for the Angora goats' hair is manufactured into camlet, in the Levant itself, and in Europe, especially in England, France, and Holland, some of whose camlet manufactories keep agents in Angora, through whom they make their purchases. Damascus is the centre of trade in Syria, and does a good deal of business through the caravans, which go from the north of Asia to Mecca, and from Bagdad to Cairo. Aleppo has much commercial intercourse with Constantinople, Bassora, Bagdad, Damascus, and Scanderoon, or Alexandria, to which places caravans go every year through Aleppo. Its exports are its own silk and cotton goods, the shawls and muslins of the East Indies, the gall-nuts of Curdistan, copper, and drugs.

EAST INDIES.

For the long period of 4000 years, the products of India, so important in commerce, have remained the same; for all the commodities and treasures of India mentioned by the ancients are to this day those for which the nations of the other quarters of the world resort thither, viz. rice, indigo, cochineal, and other dyestuffs, opium, cotton, silk, drugs, cinnamon, cassia, cocoa-nuts, &c. The East India trade is mostly in the hands of the English, under the management of the East India Company. Next to the English, the United States are most extensively engaged in the East India trade. Denmark carries on but an inconsiderable trade with the East Indies, and that once carried on by Sweden is now almost annihilated, although, prior to the late great changes in the government of that country, the Swedish East India Company was, of all the commercial societies of Europe, the best regulated, and the most successful in its operations, next to the English. The trade of Portugal with the British possessions in the East Indies is of importance; that of Spain, on the other hand, inconsiderable. Calcutta is the most important commercial city of the East Indies.—For complete information on the trade of the East Indies, we refer to our article on that country.

The trade which China carries on with Europe, British India, the United States of America, Cochin-China, and Siam, with Japan, and the other Asiatic islands, is very considerable. The British imports into China have hitherto been partly shipped by the East India Company, partly by private merchants. From 1781 to 1791, the Company sent thither to the amount of L.3,471,521 in goods, and L.3,588,264 in bullion; from 1792 to 1809, L.16,502,338 worth of goods, and L.2,466,940 in bullion. The exports which the Company made to England amounted, from 1793 to 1810, including duties, freights, &c. to L.41,203,422, and they were sold for L.57,896,274, leaving the Company a net profit of L.16,692,852. From the different ports of the British possessions in the East, thirty-five ships entered the port of Canton in the years 1818 and 1819, and the value of their cargoes was 8,714,272 dollars; and including what was shipped to Macao, the total was 11,999,272 dollars. The exports of the English merchants not connected with the Company, to China, probably amount annually to L.500,000. Next to the English, the people of the United States have the most trade with China. Its amount has increased 387 per cent. in 25 years. The exports of tea by the East India Company, in this time, have also greatly increased.—For information on the subject of the tea trade and Chinese commerce, we refer to our article on China.

From Siam and Tonquin are exported tin, ivory, diamonds, and other precious stones, gold dust, copper, salt, betel, pepper, wax, silk, timber, and lackered wares, and the commerce of these two countries is mostly in the hands of the Chinese and Portuguese. The import trade of China is conducted to a great extent by smuggling, on account of the restrictions of the government.

Since the expulsion of the Portuguese from Japan, the commerce of this country has been almost wholly domestic. The only foreigners with whom the Japanese still have any trade, are the Chinese and the Dutch, and these are limited to the single port of Nangasaki. The Chinese supply the Japanese with rice, common porcelain, sugar, ginseng, ivory, silks, nankeen, lead, tin plates, alum, &c.; and, in return, receive copper, camphor, lackered wares, pearls, corals, and a metallic composition called *sowas*, consisting of copper and a small quantity of gold. The Dutch obtain chiefly copper, camphor, lacker, and lackered wares. The Japanese sabres and daggers are very excellent, and are perhaps surpassed only by the sabres of Damascus.

AFRICA.

The want of navigable rivers, and the immeasurable deserts by which the fruitful regions of Africa are separated, form an insurmountable obstacle to that extension of commerce which the great fertility of this quarter of the globe would promise. In addition to the intercourse of the interior, the commerce of Africa has its sources in Egypt, the Barbary States, on the west coast of Guinea, in the neighbourhood of the rivers Gambia, Niger, and Senegal, at the Cape of Good Hope, and the Portuguese colonies, and on the coasts of the Red Sea. The inland trade is carried on by means of caravans. The African caravans consist of from 500 to 2000 camels. The three principal countries from which they proceed are Morocco, Fez, and Egypt. The chief articles of the inland trade of Africa are salt, gold, and slaves. The greatest caravans go from the western coast and from the interior by way of Timbuctoo, the great mart of the inland trade, and other places of depôt, to the eastern coast. There is a considerable trade between the British settlements in the East Indies and Mozambique, and the English obtain elephants' and hippopotamus' teeth, tortoise-shell, drugs, cowries, gold, &c.

The commercial intercourse of the Barbary States with Europeans is very inconsiderable and vacillating, and the little business which is transacted is mainly in the hands of the French, British, and Americans. The exports consist of olive-oil, wax, wool, wheat, gums, almonds, dates, aromatic seeds, ivory, leather, hides, and ostrich-feathers. Even the coral fisheries on the coasts (from Cape Rosa to Cape Rouax) are in the hands of the French and Italians; and the annual produce of about 50,000 lbs. of coral is worth more than 420,000 dollars. But a far more important commerce is pursued by the Barbary States with Arabia, Egypt, and the interior of Africa. Tunis is the most important commercial state in Barbary. Tripoli has little trade, and its exports consist mostly of saffron, ashes, senna leaves, and madder.

The trade with the Cape of Good Hope is extremely advantageous to Great Britain. In 1820, the importation of English goods exceeded L.330,000, while the exports of the colony (mostly Cape wine) did not amount to L.6000. The amount of the trade has since been very much enlarged by the increase of colonisation. The average exports from Great Britain to the Cape of Good Hope amounted to 2,119,000 dollars, and the imports into England from the Cape to 1,501,000 dollars.

From its uncommonly favourable situation, in the centre of three portions of the globe, Egypt seems destined by nature to be also the centre of their commerce; but it has lost much of its former rank in the commercial world, since it has ceased to be the channel of the India trade; nevertheless, for some time great efforts have been making by its sovereign, Mohammed Ali, to restore and enlarge its traffic. The exports of Egypt are rice, corn, cotton, myrrh, incense, opium, dates, mother-of-pearl, ivory, gums and drugs of various kinds, hides, wax, &c., most of which go to Constantinople, the Barbary States, Great Britain, Venice, and Marseilles. It also exports the productions of Arabia. The chief commercial cities are Cairo and Alexandria, united by a complete canal since 1810. Cairo has two ports, Rosetta and Damietta. France sends to Egypt woollen cloth, red caps, fringes of all kinds, and ornaments of dress, ordinary china ware, arms, &c. England sends muslins, and cloths of different kinds, alum, iron, lead, vitriol, gums, &c. From Florence silks are imported.

Sierra Leone, and the Pepper, Ivory, Gold, and Slave Coasts, where the Dutch, French, English, and Danes, have settlements, export gold dust, ivory, gums, hides, &c., and formerly slaves, in exchange for woollen and cotton goods, linen, arms, gunpowder, &c. The coasts of Lower Guinea (Congo, Angola, &c.), and the Guinea Islands, mostly occupied by the Portuguese, export grain, provisions, cotton, indigo, sugar, and *slaves*.

Among the other African islands, the Azores raise, for exportation, wine and fruits. About 20,000 pipes of the former are annually exported by the English and Americans, chiefly to the East and West Indies. The island of St Michael sends every year to England and the United States, 60,000 to 80,000 boxes of oranges. The oranges of the island of Pico are remarkable for their superior quality. This island also produces a beautiful kind of wood, which is almost equal to mahogany. The staple productions of the Canaries are archil in its raw state, rosewood, brandy, and Canary wine. The last goes chiefly to the West Indies and England; in the latter country it is always sold for Madeira wine.

The Cape Verd Islands export archil in a raw state, and coarse cotton cloth for the use of the Africans. The staple produce of Madeira is valuable wine, which is divided into five kinds, according to the market for which it is designed. The most excellent is called *London particular.* The next in quality is also sent to the London market. Of inferior quality is that destined for the India market. The kind that goes to America holds the fourth rank, and the fifth is designated by the name of *cargo*. Of this wine the English annually receive more than 7000 pipes; the United States about 3000. The Isle of Bourbon produces coffee, cloves, white pepper, cotton, gums, benzoin, and aloes. Its trade is confined almost wholly to Madagascar, Isle de France, the Comoro Islands, and the settlements of the Arabs on the eastern coasts of Africa. The Isle de France, or Mauritius, exports coffee, indigo, cotton, sugar, nutmegs, cloves, ambergris, &c. The exports of Madagascar are cowries, betel-nuts, ambergris, wax, cocoa-nuts, and corn.

NORTH AMERICA.

United States.

The people of the United States, as already noticed, are equally remarkable with the British for their eager spirit of industry and pursuit of commerce. In this respect they far surpass the South Americans, who, though enjoying an equally productive region, and one as valuable in many respects for manufactures and trade as that of North America, have made no advances worth mentioning in the arts of civilised life. The large space of unsettled fertile territory fit for cultivation which the North Americans possess, has led them very judiciously to devote their labour and capital to the business of the farmer in preference to the arts of the tradesman. For this reason they form a nation which buys largely of British and foreign manufactured goods, which they are well able to pay for by the great abundance of their native produce. Strangely enough, although it is clearly demonstrable that this is the best course for the North Americans to pursue, their legislature has followed the blundering policy of European states, in imposing restrictions and duties on imports, with the view of forcing the people to leave the agricultural pursuits which they have naturally discovered to be most advantageous, in order that they may sink their capital in unprofitable processes of manufacture. The consequence of this folly has been most disastrous, not only to American foreign commerce, but to those for whose advantage the scheme was contrived. "Instead of the goods manufactured in the States (says Mr M'Culloch)* being as cheap as similar ones manufactured in Europe, they are admitted to be, at an average, from 30 to 100 per cent. dearer! The extent of the pecuniary sacrifice that is thus imposed on the Union has been variously estimated by American writers; but we have been assured by those who have the best means of knowing, that it may be moderately estimated at from 50,000,000 to 60,000,000 dollars, or from about L.11,000,000 to L.13,000,000! And this immense burden—a burden nearly *three* times as great as the whole public expenditure of the republic—is incurred for no purpose of public utility, and is productive of nothing but mischief. The whole effect of the scheme is to divert a certain amount of the national capital from the production of cotton, wheat, rice, tobacco, &c. (the equivalents sent to foreigners in payment of manufactured goods), to the direct production of these goods themselves! And as the latter species of industry is nowise suitable for America, a tax of L.13,000,000 a-year is imposed on the Union, that the manufacturers may be enabled to continue a losing business.

"We entertain too favourable an opinion of the Americans (continues this studious and intelligent writer) to suppose that such a system can be permanent. It has been established in opposition to the wishes of all but a majority of Congress; is exceedingly unpopular in the Southern States, and generally throughout the Union; and has been repeatedly condemned by committees of the legislature. In an able report by a committee of the house of representatives, dated 8th of February 1830, it is said, 'We had before us the prospect of a long and general peace, and our policy should have been regulated accordingly. Our revenue laws should have been restored gradually, but decisively, to their condition previously to the war. Our policy unfortunately took another direction. The tariff of 1816 laid the foundation of all our subsequent errors; and we have now been engaged for fifteen years in an unprofitable experiment to effect what embargo, non-importation, non-intercourse, and war, failed to accomplish. We have attempted, by the mere force of congressional decrees, to resist the natural and salutary tendency of our industry to commercial and agricultural pursuits. We have been steadily sacrificing the commerce, navigation, and capital, of New England, merely to bring forward new competitors in manufacturing, to embarrass our old and skilful artizans, and to ruin themselves. We have, from session to session, kept trade in such agitation and uncertainty, that the value of property could never be ascertained till the adjournment of Congress; and this we have called encouraging and protecting our industry! We have wasted millions of our ancient profits of commerce in a visionary experiment to increase our national wealth. In a legislative attempt to make ourselves more completely independent of foreign nations, we have effectually undermined the foundation of that naval power which can alone protect our country from foreign aggression.'"

With these observations on the present condition of the United States, as regards the principles which regulate their manufacturing and commercial economy, we proceed to notice the state of trade generally. The exports of domestic products for 1828, according to the custom-house estimates, were 50,669,669 dollars. (The dollar is worth about 4s. 6d. sterling.) Those of cotton, the great staple of the country, were 22,487,229 dollars, and, accordingly, nearly half of the entire amount. The next greatest export is that of tobacco, which amounted to 5,269,960 dollars. Of rice, the export amounted to 2,620,696 dollars. The value of these three articles, being over 30,000,000 dollars, thus constituted three-fifths of the whole. In the annual returns made to Congress, the exports of domestic products are divided into those of the *sea*, the *forest*, *agriculture*, and *manufactures*. The three species of agricultural articles above mentioned are mostly the productions of the Southern States, including Virginia and Kentucky. The other exports, coming under the same head, are mostly furnished by the Middle and Western States: namely, beef, tallow, hides and cattle, butter, cheese, pork, bacon and hogs, horses, mules, sheep, flour, buscuits, corn-meal, rye-meal, oats, potatoes and apples, flax-seed, and hops. Of these articles, the principal are flour and biscuit, the value of which was 4,464,774 dollars, being the third article in value among the exports. The fifth article in value is that of swine and their products—viz., bacon, pork, and lard, the value of which was 1,495,830 dollars, mak-

* Commercial Dictionary; article New York.

ing about one thirty-third part in value of the whole export. The articles of corn-meal and rye-meal amounted to 881,894 dollars, constituting a little more than one-sixtieth part of the whole exports. Cattle and their products, including butter and cheese, exceeded the last amount, being 896,316 dollars. This species of export is of far less comparative importance in the trade than formerly, being limited to its present amount, not by the capacity for production, but by the extent of demand in the foreign markets; for an increase of the foreign demand would very soon double and treble the quantity. Some of the articles comprehended in the above list, though agricultural products, yet involve some process of manufacture; such, for example, as butter, cheese, bacon, flour, biscuit, meal, and part of the tobacco. A great many, however, of the exports coming under the head of *manufactures*, include in them the value of materials supplied by agriculture, such as the cotton fabrics, those of leather, and spirits distilled from grain; so that, on the whole, the strictly agricultural products of the country constitute a larger proportion of the whole exports than the tables represent; and yet the proportion represented by the tables is very large, being 38,500,000 out of the 50,000,000; and if we add the value of the materials supplied by agriculture for the manufactured exports, we shall have at least six-sevenths of the whole domestic exportation consisting of the raw products of agriculture.

The products of the whale, cod, mackerel, and herring fisheries, exported mostly from the Northern States, amount to 1,603,980 dollars, being nearly a thirtieth part of the whole domestic export. Nearly one-half of this value consists of codfish, and more than one-third of the products of the whale-fisheries.

The value of skins, furs, ginseng, lumber, staves, bark, tar, pitch, rosin, and turpentine, and pot and pearl ashes, partly from the Northern and partly from the Southern States, which were formerly of much greater comparative importance in the trade of the country, now constitutes about one-thirteenth part of the whole value of the domestic exports, and amounts to 3,889,611 dollars. A large proportion of the trade in these articles, as well as in those of codfish and bread-stuffs, is carried on with the West Indies, Mexico, and South America. The skins and the furs go to Europe and Canton; the ginseng to Canton, but in less quantity than formerly, being, in 1828, but 91,164 dollars; and the pot and pearl ashes are sent to England and France.

The manufactures are as yet of the coarser sort, consisting partly of articles made of the products of the country, and partly of those fabricated from foreign materials. The articles in which the foreign materials from a considerable part of the value, are spirits manufactured from molasses, refined sugar, articles of iron, cordage, chocolate, gunpowder, umbrellas, and parasols, gold and silver coin, and jewellery.

The whole estimated value of exports of home manufactures is about 6,500,000 dollars, being about thirteen per cent. of the whole domestic exports of the country. The value of raw materials imported, and then wrought up in manufactured articles, and exported, and included in the list of domestic manufactures, may be estimated at about 200,000 or 250,000 dollars; leaving the net exports of manufactures from the raw products supplied by the country about 5,750,000 dollars. As cotton fabrics form a large item in this list of exported manufactures, and those fabrics are mostly of the coarser kind, the raw material will constitute a very considerable part of their value, and the proportional value of the direct wages of manufacturing labour incorporated in these exports will be proportionally less. Taking the whole list of domestic manufactured articles together, and making allowances for the cost of the raw materials, in their rudest state, after they are taken from the ground or from animals, and assume the character of merchandise, by deducting their value from the gross amount of that of the exported manufactures, the remainder, which is the result of the manufacturing labour, interest of capital, and profits incorporated into these materials, to bring them into the state in which they are exported, may be estimated at about 4,000,000 dollars.

We will now glance hastily at the descriptions of articles on which the arts of the United States are employed for the supply of foreign markets; and the most considerable of them is cotton twist, thread and fabrics, the exported value of which, for the year 1828, was 1,000,000 dollars and a fraction over, being one-fiftieth part of the whole domestic exports, the principal markets of which are South America, Mexico, and the Mediterranean. The value of leather, and its various manufactures, exported, is a little over 500,000 dollars, making one per cent. of the entire exports of the description of which we are speaking. The value of hats exported during the same year was about 333,300 dollars—a very large amount, considering the short period since this article has been sent to foreign markets. Soap and candles have long been supplied for the foreign markets, the amount for the year in question being about 900,000 dollars. The various articles manufactured, for the most part, of wood, such as furniture, or of wood, leather, and iron, such as coaches and carriages, besides various agricultural implements supplied to the West Indies and South America, constitute a very important branch of trade, which amounted to between 600,000 and 700,000 dollars. The American glass begins to appear in the foreign markets. The value sent abroad in 1828 was 51,452 dollars, and it bids fair to be increased. The other exports consist of a variety of articles in small quantities, among which are wearing-apparel, combs and buttons, brushes, fire-engines and apparatus, printing-presses and types, musical instruments, books, maps, paper and stationery, and trunks. It is apparent, from the above enumerat and estimates, that the manufactured articles, of which the export is most considerable and the most flourishing, are those of which the raw materials consist mostly of cotton, wood, and leather.

The foreign articles imported and again exported from the country, during the same year, amounted to 21,595,017 dollars. This transit trade thus appears to form a very important part of the American commerce. But one-third of this whole amount consists of an article which affords very little freight, namely, specie, the export of which during the same year was about 7,500,000 dollars. Another large item in value of this transit trade, consists of cotton fabrics, the exports of which were 2,000,000 dollars. The foreign silks exported amounted to about a quarter as much. The value of wines exported was about 333,300 dollars; that of teas about twice as much; that of coffee and cocoa, 1,500,000 dollars; and of sugar nearly 1,000,000 dollars. These are the most important articles of foreign export. The other exports of foreign articles, previously imported, amounted, during the same year, to about 8,000,000 dollars in the whole; but it is not necessary to enumerate them.

The imports for the same period, according to the custom-house estimates, amounted to 88,509,824 dollars, and exceeded the estimated value of the exports by about 16,250,000 dollars. In regard to the various kinds of goods imported, without pretending to great exactness, which is the less important as the proportions vary considerably from year to year, it appears that some of the principal articles have constituted nearly the following proportion of the whole imports, previously to 1828; viz. wool and woollen fabrics, 11 per cent.; cotton stuffs, 12; silk, 10; hemp and flax, and manufactures of them, 5; iron and steel, and manufactures of them, 5; spirits, $1\frac{1}{2}$; molasses, $2\frac{1}{2}$; teas, 4; coffee, $3\frac{1}{2}$; sugar, $5\frac{1}{2}$; and indigo, $1\frac{1}{2}$ per cent. The principal trade, both import and export, is with Great Britain and its dependencies, whence, in 1826, the imports were forty-two ninety-sixths of the whole importation.

From the official report of the treasury department, it appears that the imports into the United States, during the year ending September 30, 1829, amounted to 74,492,527 dollars, of which amount 69,325,552 dollars were imported in American vessels, and 5,166,975 dollars in foreign vessels; that the exports, during the same year, amounted to 72,358,671 dollars, of which 55,700,183 dollars were of domestic produce, and 16,658,478 dollars of foreign produce; that of domestic articles, 46,074,554 dollars were exported in American vessels, and 8,725,639 dollars in foreign vessels; and of the foreign articles, 15,114,807 dollars were exported in American vessels, and 1,543,591 dollars in foreign vessels; that 872,948 tons of American shipping entered, and 944,799 cleared from, the ports of the United States; and that 130,743 tons of foreign shipping entered, and 133,006 cleared, during the same period.

It appears from official statements that since 1829 the trade of the States has undergone an increase. For the year ending September 30, 1832, the total exports amounted to 87,176,943 dollars in value, and of imports 101,029,266 dollars. In the valuation of exports, the produce of the sea and land amounted to 49,416,183 dollars, while the total of manufactured commodities was only 5,044,014.

Mexico.

The commerce of Mexico is at present checked by natural and political causes. The want of river communication is a great impediment to its internal commerce. Roads lead from the *plateaux* to the seaports, but they are very imperfect, and beasts of burden, therefore, are preferred to carriages, which would not be able to make their way. The principal objects of export are gold and silver, either in bullion, coined, or worked up in various ways; cochineal, sugar, flour, indigo, salt meat, dried vegetables, tanned hides, sarsaparilla, vanilla, jalap, soap, Campeachy wood, and pimento of Tabasco. Among the articles imported are woollen cloths, silks of Lyons, linen from Germany, white and printed calicoes from France, England, and the United States, paper, china, spirits, cacao, quicksilver, iron, steel, wine, wax, jewellery, watches and clocks, and all kinds of ornaments. In 1826, 1267 vessels entered the ports of the republic. The chief port of Mexico is Vera Cruz.

British North American Possessions.

These consist of Upper and Lower Canada, New Brunswick, Nova Scotia, Cape Breton, Prince Edward's Island, Newfoundland, and Hudson's Bay. The manufactures of these countries are of that nature which might be supposed to subsist in a newly settled country. Their interest consists in the export of raw or partially prepared commodities, in exchange for manufactured goods, both for use and ornament. Thus, they export timber, oil, fish, seal-skins, grain, &c.; and by the British colonial regulations, they enjoy the benefit of importing goods in return from the United Kingdom duty free. Their corn is admitted into British ports on paying a small duty; and also their wood, which, though inferior to Baltic timber, is admitted in preference, with a view to benefiting the colonies and our own commerce. Halifax and Pictou, in Nova Scotia; St John's, in Newfoundland; Montreal and Quebec, in the Canadas; are the chief ports for export and import. The fisheries of Nova Scotia and Newfoundland are exceedingly valuable, and are much encroached upon by the citizens of the United States. In 1829, these colonies imported goods from the United Kingdom to the value of L.2,118,450, and exported thence to the value of L.1,141,288. The estimated value of the productions raised annually, including the fisheries, was L.17,620,020. A considerable trade is carried on with the West Indies, as well as with the mother country; some business is also done with the United States. The wealth and population of these colonies are increasing with the most gratifying rapidity.

SOUTH AMERICA.

This extensive and naturally fine country, both as respects its climate and its mineral riches and products of the ground, was originally peopled by Spaniards, Portuguese, and other ignorant and bigoted nations; and although in modern times its inhabitants, from nearly the one end of the Continent to the other, have assumed a species of political independence, they are still, generally speaking, the same slothful, impure, and ignorant race of beings they formerly were. The various nations into which they have been divided by political events, are little else than confederacies of robbers, with all the various classes of turbulent and troublesome individuals who have joined them from other countries. Brazil, Colombia, Buenos Ayres, Chili, Peru, Guatimala, are the names of the principal states; and having fully described their character in our article on South America, we do not require to extend our notices of their trade and character here. It may suffice to state, that the chief exports are gold and silver—the produce of the mines, cochineal, indigo, cacao, ox horns, hides, and tallow; also horse hides, wax, cotton, wool, flax, hemp, tobacco, sugar, coffee, ginger, pimento, Peruvian bark, and most kinds of medicinal stuffs and balsams, mahogany and other fine woods. The imports include every description of manufactured goods from Europe, and corn from North America. The people can make almost nothing themselves, and this quarter of the globe has long formed a good market for all kinds of British goods, although these have frequently been exported at a loss. The chief commercial cities of South America are Rio Janeiro, Buenos Ayres, Lima, Carthagena, Caraccas, Potosi, and Bahia.

The English, Dutch, and French possessions in South America, are Demerara, Berbice, Essequibo, Surinam, and Cayenne. From Cayenne are exported, cloves, Cayenne pepper, annotta, sugar, cotton, coffee, and cacao; from Berbice, rum, sugar, cotton, cacao, &c.; from Demerara, Surinam, and Essequibo, sugar, rum, cotton, coffee, and molasses. From Honduras, mahogany and logwood are exported to Great Britain; this trade at present engages 20,000 tons of shipping.

WEST INDIES.

The chief islands which constitute the West Indies are Cuba, St Domingo or Hayti, Jamaica, Barbadoes, Dominica, St Christopher or St Kitt's, Curaçao, and Guadaloupe. They have all very nearly the same productions, viz. sugar, coffee, wax, ginger, and other spices, mastich, aloes, vanilla, quassia, manioc, maize, cacao, tobacco, indigo, cotton, molasses, mahogany, long peppers, lignum-vitæ, Campeachy wood, yellow wood, gums, tortoise-shell, rum, pimento, &c. Before St Domingo or Hayti became an independent government of blacks, it was the depôt of the goods brought from Havannah, Vera Cruz, Guatimala, Carthagena, and Venezuela; but since that event, Jamaica has been the magazine of all goods from the Gulf of Mexico. Trinidad is the great seat of the contraband trade with Cumana, Barcelona, Margarita, and Guiana. The imports are manufactures of all kinds, wine, flour, and formerly slaves, who are still smuggled into many of the islands. These form one great source of the commerce of the world; and we must refer the reader, for more particular information, to our article on the West Indies, and to the Tables in this sheet.

AUSTRALIA.

This fifth great division of the globe, comprehending New South Wales, Van Diemen's Land, and adjacent islands, and belonging to Great Britain, is rapidly advancing in the arts of civilised life, and annually increasing in its amount of imports and exports, as well as in domestic trade and production. In 1833, the estimated value of land was L.1,500,000; of houses, stores, and merchandise, L.1,025,000; with a circulation of L.20,000. The imports, in 1829, amounted to L.96,123, and the exports to L.33,101. The exports are of raw produce, chiefly to Great Britain, from whence imports are made of manufactured goods. The most valuable article exported is Merino wool, for which there is now a large demand in this country. The native manufactures are wool, potteries, breweries, distilleries, &c., and these have attained a comparative degree of prosperity.

No. 33. PRICE 1½*d.*

ELECTRICITY AND GALVANISM.

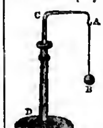
ELECTRICITY, from the Greek word *electron*, amber, is the name given to an important branch of Natural Philosophy, which treats of the phenomena and effects produced by the friction or rubbing of amber and other bodies which possess analogous properties. This science, which embraces so many subjects of inquiry, not only remarkable in themselves, but highly important from their relations with every department of nature, is wholly of modern creation. Although the ancients (as, for instance, Thales of Miletus, who founded a celebrated school of philosophy, called the Ionic) were acquainted with the mysterious power of attracting and then repelling light bodies which amber possessed after being rubbed, and the benumbing shocks which are experienced on touching the *torpedo*, or electrical eel, yet the scattered facts were never generalised into a scientific theory. Indeed, the philosopher above named ascribed these results to the presence of a soul or essence, which, roused by the friction, went forth to bring back the small particles floating around. It was only in modern times, when induction from facts began to be practised by philosophers, that the phenomena connected with electricity began to assume the dignity of a science. Dr Gilbert, an English physician, made the first step towards generalisation, in the year 1600. He published a valuable treatise, in which he observed, that not only amber, but various other substances, can by friction be made to draw light bodies to them. Boyle, Guericke, Newton, and some other philosophers of that period, contributed to extend human knowledge upon this interesting subject, but the real science of electricity took its rise in a latter age. About the middle of the eighteenth century, several very remarkable facts were ascertained, particularly that of Benjamin Franklin, which identified lightning with electricity; but the extensive relations which connect it with so many other departments of physical science were not discovered until the present century, nor was their importance until then appreciated. In this short era a new science has arisen, founded on that modification of electricity, which is known by the name of GALVANISM. The galvanic battery (which will be afterwards described), as an instrument for analysing or decomposing chemical substances, has connected it with chemistry in the most intimate manner. Hence has sprung ELECTRO-CHEMISTRY, one of the connecting branches between remote divisions of the philosophy of nature. ELECTRO-MAGNETISM is a still more recently discovered province of science, and which identifies as one, two powers which were previously regarded as distinct.

As the best method of conveying a clear and at the same time philosophical view of this interesting science, we shall in the first place, independently of all theory, state the most general and remarkable facts connected with it. After these have been enumerated, the reader will then be prepared for a review of the theories which have been advanced for the purpose of explaining phenomena, and for connecting the various facts in the mind. The general facts relating to this subject we think may be classed under two heads—1, The *Excitation* of Electricity; and, 2, the *Distribution* of Electricity. Connected with each of these heads are various phenomena which we shall notice as they occur, during the gradual developement of the subject.

EXCITATION OF ELECTRICITY, AND RESULTING PHENOMENA.

If a piece of sealing-wax, amber, the glass of a watch, or any other smooth piece of glass, be rubbed upon a piece of dry flannel or woollen cloth, or even the sleeve of a cloth coat, it will be found to have acquired a new and very singular physical property. This property is exhibited by holding the body which has been subjected to friction, over small and light substances, such as shreds of paper, gold leaf, feathers, straw, cork, &c. These will be first instantly *attracted* to it, some of them adhering to its surface, others falling back to the place whence they were withdrawn, whilst others are thrown off from the body as if they were *repelled* from it. The property which has thus been conferred upon the body by undergoing the process of rubbing, as above described, is called *electricity;* the body which has acquired the property is called an *electric;* and the attraction which is exhibited is called *electric attraction.* In this state it is said to be *excited*, and the body by which it is excited is denominated the *rubber.* Those substances which are not excited by similar treatment, are termed *non-electrics.*

In order to render the above phenomena perfectly clear, and also to illustrate certain remarkable facts, we shall employ the following figure:—



B is supposed to be a small piece of cork or the pith of wood, which is suspended from a stand A C D, by a dry silk thread A B. Having rubbed an electric, for instance a dry rod of glass, and presented it to B, the ball will be instantaneously attracted to the glass, and will adhere to it. After they remain in contact for a few seconds, if the glass be withdrawn without being touched by the fingers, and again presented to the ball, the latter will be *repelled* instead of being attracted, as in the first instance. By being touched with the finger, the ball can be deprived of its electricity; and if, after this has been done, we present a piece of sealing-wax in place of the glass formerly employed, the very same phenomena will take place. On the first application, the ball will be attracted; and, on the second, repelled. It is clear, then, in the first place, that both these electrics have the power of attracting another body before they have communicated to it any of their own electricity: and, secondly, that they repel the body after they have communicated to it a portion of their own electricity.

But a very remarkable circumstance takes place, if we, after having conveyed electricity to the ball B, by means of excited glass, which was for a moment or two in contact with it, should present to it, after the former was withdrawn, excited sealing-wax: the ball, instead of being repelled, as it would have been were the glass again applied, is attracted by the wax. If the experiment be reversed, and the excited wax first presented to the ball, and then the excited glass, the latter will be found to *repel* the ball. "Hence it follows," says Sir David Brewster,* "that excited glass *repels* a ball electrified by excited glass. Excited wax *repels* a ball electrified by excited wax. Excited glass *attracts* a ball electrified by excited wax. Excited wax *attracts* a ball electrified by excited glass. From which we conclude, that there are two opposite electricities; namely, that produced by excited glass, to which the name of *vitreous* or *positive* electricity has been given; and that produced by excited wax, to which the name of *resinous* or *negative* electricity has been given.

"If, when the pith ball B is electrified either with excited glass or wax, we touch it with a rod of glass, its property of being subsequently attracted or repelled by the excited glass or wax will suffer no change; but if we touch it with a rod of metal, it will lose the electricity which it had received, and will be attracted either by the excited glass or wax, as it was when they were first applied to it. Hence, the rod of glass and the rod of metal possess different properties, the former being incapable, and the latter capable, of carrying off the electricity of the pith ball. The metal is therefore said to be a *conductor*, and the glass a *non-conductor*, of electricity."

In these experiments, electricity has been produced by *friction;* but there are other methods of obtaining it, which, however, will be afterwards explained.

* Article Electricity in the Encyclopædia Britannica, the most comprehensive, philosophical, complete, and intelligible treatise upon this interesting science which we have ever yet met with.

With regard to attraction and repulsion, a few facts remain to be stated. Some substances remain longer in contact with the electric than others, and two bodies which have both been in contact with the same electric, mutually repel each other. If electrics of considerable size are employed, the phenomena of course are best observed; and if the experiment be performed in a darkened chamber, flashes of bluish light will be seen to extend over the surface of the electric submitted to friction, and which we shall suppose is a cylinder of sealing-wax, sulphur, or glass. Sparks, accompanied also with a sharp snapping sound, will be seen to dart round it in various directions. If a round body, as a metallic ball, be presented to it, and moved from one end to the other, a succession of sparks will be obtained as the ball passes along the surface; and if the knuckle be presented instead of the metallic ball, each spark will be accompanied by a prickling sensation. If the cylinder be brought near to the face, an unpleasant sensation of tickling is felt in the skin, as if it were covered with a cobweb. If a metallic globe be suspended in the air by silk threads, and in that situation rubbed by an electric, it will also become electrical, and exhibit the same properties as an electric. It is essential to the success of this experiment, that it be insulated; that is, cut off from all communication with any substance, except the air and the electric which sustains it. The instruments employed in experiments similar to those above described, are termed *Electroscopes.* Besides that one of which a representation has been given, there are various others, all of which are formed upon the same principles.

It is now proper to mention the principal electrical substances in nature. They are, amber, gum-lac, resin, sulphur, glass, talc, the precious stones, silk, the fur of most quadrupeds, and almost all vegetable substances (excepting charcoal) which have been thoroughly deprived of moisture, as, for instance, baked wood, and very dry paper.

DISTRIBUTION AND TRANSFERENCE.

We have noticed that when the excited electric was brought near the pith ball B, the latter was first attracted and then repelled. If we now remove the electric, and present to the ball which has thus touched it, a second ball, which has had no previous communication with an electric, we find that these two balls attract one another, and come into contact. The same actions are repeated between this second ball, and a third which may be presented to it; and so on in succession, but with a continued diminution of intensity. This diminution plainly indicates a diminished power, in consequence, as it would seem, of its being distributed amongst a number of bodies. It is clear, therefore, that the unknown power which we have called electricity, can, like heat, be transferred or communicated from one body to another, and that its intensity, like that of heat, is weakened by being diffused amongst a number of bodies. An electrified ball can be deprived of its electricity by being touched with a rod of metal of any kind; but if we touch it with glass or wax, it will not be carried off. Hence, metals are said to be *conductors*, and glass and wax *non-conductors*, of electricity. Bodies greatly vary in their power of conduction, and many of them owe it to the water which they contain. The conducting power of any substance depends on the state of the atmosphere at the time with regard to humidity, and on the intensity of the electricity employed. The following tables of conductors and non-conductors are by Sir David Brewster, and have been collected by him from various authors with great care. The bodies are placed in the order of their conducting or non-conducting power; "but it is probable," says Sir David, "that this order would be greatly changed, if the bodies were all submitted to a new and uniform examination."

List of Conductors.

All metals	River water.
Silver	Ice above 13° Fahr.
Copper	Snow
Lead	Living vegetables
Gold	Living animals
Brass	Flame
Zinc	Smoke
Tin	Steam
Platina	Soluble salts
Palladium	Rarefied air
Iron heated	Vapour of alcohol
Iron cold	Vapour of ether
Charcoal well burned	Moist earths
Plumbago	Anthracite
Concentrated acids	All the substances and minerals in the third class of Haüy's list, as given in Sect. II.*
Powdered charcoal	
Diluted acids	
Saline solutions	
Metallic ores	Powdered glass
Animal fluids	Flowers of sulphur
Hot water	Resins rendered fluid by heat
Sea water	
Spring water	Glass heated to redness

List of Non-Conductors.

Shell-lac	Leather
Amber	Air and all dry gases
Resins	Baked wood
Sulphur	Dry vegetable bodies
Wax	Porcelain
Jet	Dry marble, and
Glass	Siliceous and argillaceous stones in Class I. of Haüy's list
Vitrifications	
Mica	
Diamond	Camphor
Transparent gems	Caoutchouc
And all the minerals in	Lycopodium
Class I. of Haüy's list	Dry chalk
Raw silk	Lime
Bleached silk	Phosphorus
Dyed silk	Ice below 13° Fahr.
Wool	Ashes of animal bodies
Hair	Ashes of vegetable bodies
Feathers	Oils, the heaviest being the best conductors
Dry paper	
Parchment	Dry metallic oxides.

The two qualities of a capability of excitation, and a power of conducting electricity, appear to be incompatible with each other, for the one always diminishes in proportion as the other increases. Hence, it follows, as an invariable law, that *electrics* are *non-conductors*, and, on the other hand, that conductors are *non-electrics*. The most perfect *non-conductors* of electricity are also called *insulators*, from their power of insulating an electrified body, or preventing any of its electricity from escaping along its support. The insulating power of atmospheric air depends upon two circumstances, its density and its dryness. Air of the ordinary density of the atmosphere, if perfectly dry, is a remarkably good insulator, and no change of temperature appears to affect its insulating power; but rarefaction diminishes its power of confining electricity, and, when greatly rarefied, it may be classed amongst conductors. The conducting power of air of the ordinary density depends upon the quantity of moisture which it contains, water being a very good conductor of electricity. Changes of temperature and also of form affect the conducting powers of most bodies. Thus, though water, in its ordinary liquid state, is an excellent conductor, yet, when it appears in the solid form of ice, its conducting power is much impaired, and at a very low temperature it ceases entirely. Glass, when cold, is a non-conductor, but when heated to redness, it conducts tolerably well. Hence, although some bodies are said to be perfect non-conductors, yet this is not strictly true. In Dr Faraday's interesting researches on this subject, he gives the following summary of conditions of conduction in bodies, which, although they apply chiefly to voltaic electricity, are yet true within certain limits of ordinary electricity:—

1. All bodies conduct electricity in the same manner from metals to lac and gases, but in different degrees.

2. Conducting power is in some bodies powerfully increased by heat, and in others diminished, yet without our perceiving any accompanying essential electrical difference, either in the bodies or in the changes occasioned by the electricity conducted.

3. A number of bodies insulating electricity of low intensity when solid, conduct it very freely when fluid, and are then decomposed by it.

4. There are many fluid bodies which do not sensibly conduct electricity of this low intensity; there are some which conduct it and are not decomposed, nor is fluidity essential to decomposition.

5. There is but one body yet discovered (periodide of mercury), which, insulating a voltaic current when solid, and conducting it when fluid, is not decomposed in the latter case.

6. There is no strict electrical distinction of conductors which can as yet be drawn between bodies supposed to be elementary, and those known to be compounds.

It is to Coulomb that we owe the useful discovery, that *shell-lac* is the most perfect of all insulators; and hence its value in electrical inquiries. He found that the electricity of a pith ball five or six lines in diameter, could be completely insulated by a cylinder of sealing-wax or gum-lac about half a line in diameter, and about twenty inches long; that a fine silk thread, penetrated and covered with melted wax, so as to form a cylinder one-fourth of a line in diameter, had the same insulating power when it was five or six inches long; and that an equal degree of insulation could not be obtained by a fine thread of glass, of five or six inches in length, or by a hair or a fibre of silk, unless the electricity insulated was very weak, or the air extremely dry. Coulomb found that the insulating power of a fibre of gum-lac was ten times greater than that of a silk fibre of the same diameter and length; and he established the following general law, that the densities of electricity insulated by different lengths of fine cylindrical fibres, such as those of gum-lac, hair, silk, &c., vary as the square root of the lengths of the fibre.

There are various other circumstances upon which the conducting power of bodies depends. That of silk, for instance, is affected by the colour of the thread, or rather by the nature of the dye-stuff by which it has been tinged. When of a brilliant white, or a black, its conducting power is the greatest; and a high golden yellow or a nut-brown renders it the best insulator. Mr Coulomb, who has investigated the subject with great ability, assigns three causes as chiefly operating in depriving a body in a state of imperfect insulation of its electricity; first, the imperfection of the insulating property in the solids by which it is supported; secondly, the contact of successive portions of atmospheric air, every particle of which deprives the body of a portion of its electricity; thirdly, the deposition of moisture upon the surface of the insulating body, which establishes communications with its remote ends, thus virtually increasing its conducting power. There is another very remarkable circumstance relating to the dissipation of electricity, namely, the shape of the body which holds the electricity. Its retaining power is materially affected by the form which it possesses. The spherical shape is that most favourable to its retention; whilst, from bodies of a pointed figure, especially if the point projects to a distance from the surface, electricity escapes most readily. On the other hand, these bodies receive electricity more readily than those of any other form.

With regard to the distance to which electricity can be conveyed, an experiment of a very interesting nature was made by Mr F. Ronalds. He erected at Hammersmith an electrical telegraph, on which the inflections of the wire composed one continuous length of more than *eight miles*. "When a Canton's pith ball electrometer was connected with each extremity of this wire, and it was charged by a Leyden jar, both electrometers appeared to diverge suddenly at the same moment; and when the wire was discharged by being touched with the hand, both electrometers appeared to collapse as suddenly. When any person took a shock through the whole length of the wire, and the shock was compelled to pass also through two insulated inflammable air pistols, one connected with each extremity of the wire, the shock and the explosion seemed to occur quite simultaneously; but when the shock was compelled to pass through the gas pistols, and any one closed his eyes, it was impossible to distinguish more than one explosion, although both pistols were discharged. When people did not look at the pistols, and when I sometimes charged only one highly, and sometimes both lowly, they could never guess, except by mere chance, whether one or both were fired. Thus, then, three of the senses—namely, sight, feeling, and hearing—seemed to receive absolute conviction of the instantaneous transmission of electrical signs through my pistols, my eight miles of wire, and my own proper person."*

OF THE TWO KINDS OF ELECTRICITY.

We have already noticed the origin of the names *vitreous* or *positive*, and *resinous* or *negative*, electricity, and also described the phenomena connected with each. Although, taken separately, the one acts in a manner precisely similar to the other, yet in all their relations to each other they display a marked contrariety. Indeed, they may be viewed as agents having opposite qualities, which completely neutralise one another by combination, just like an acid and an alkali. It is remarkable that the excitation of one species of electricity is always accompanied by the presence of the other, and both are produced to an equal extent. Thus, when a piece of glass is rubbed by silk, just as much resinous electricity is produced in the silk as there is vitreous electricity produced in the glass; and whatever electrified bodies are repelled by the one, are attracted by the other. Of course, these two surfaces, having acquired opposite electricities, invariably attract each other. A white and a black ribbon rubbed against each other between the finger and thumb, exhibit electrical phenomena in a very marked manner. The black is resinously and the white vitreously electrified; of course they attract each other; and if separated, the one attracts the light bodies which the other repels. When two pieces of the same ribbon of the same length are rubbed, the one being drawn lengthways and at right angles over a part of the other, the one which has been subjected to friction in its whole length, acquires vitreous and the other resinous electricity. In like manner, when the whole length of the bow of a violin is drawn over a limited part of the string, the hairs of the former exhibit a vitreous, and the latter a resinous, electricity. It is to be observed, that the body whose excited portion is of the least extent, is generally found to be resinously electrified.

To know the species of electricity evolved, it is merely necessary to communicate beforehand, to the slips of gold leaf, a known electricity, either from excited glass or sealing-wax. If they be divergent with the former, then the approach of a body similarly electrified will augment the divergence, but that of one oppositely electrified will cause their collapse.

The following is a table of several substances which acquire the vitreous electricity, when we rub them with those which follow them in the list; and the resinous electricity, when rubbed with those that precede them:—

The skin of a cat	Paper
Polished or smooth glass	Silk
Woollen stuff or worsted	Lac
Feathers	Roughened glass.
Dry wood	

No visible relation can be pointed out between the nature or constitution of the substances, and the species of electricity developed by their mutual friction. The only general law among the phenomena is, that the rubbing and the rubbed body always acquire opposite electricities. Sulphur is vitreously electrified when rubbed with every metal except lead, and resinously with lead and every other kind of rubber. Resinous bodies rubbed against each other acquire alternately the vitreous and resinous electricity; but, rubbed against all other bodies, they become resinously electrical. White silk acquires vitreous electricity with black silk, metals, and black cloth; and resinous with paper, the human hand, hair, and weasel's skin. Black silk becomes vitreously electrical with sealing-wax, but resinously with hares', weasels', and ferrets' skins; with brass, silver, iron, the human hand, and white silk. Woollen cloth is strongly vitreous with zinc and bismuth; moderately so with silver, copper, lead, and specular iron. It is resinous with platina, gold, tin, antimony, grey copper, sulphuret of copper, bisulphuret of copper, sulphurets of silver, antimony, and iron. Dry air impelled on glass becomes resinously electrical, and leaves the glass in the opposite state. Silk stuffs agitated in the atmosphere with a rapid motion, always take the resinous electricity, while the air becomes vitreously electrified.

Numerous experiments have been made with the view of ascertaining the conditions that determine the species of electricity exerted in the respective bodies of which the surfaces are made to rub against each other, but they have led to no satisfactory conclusions. The mechanical configuration of the surface appears to have a greater influence in the result than the peculiar nature of the substance itself. If a plate of glass with a polished surface be rubbed against one which is roughened, the former always acquires the vitreous and the latter the resinous electricity. Various substances, if rubbed when polished, exhibit a different kind of electricity than that with which they are excited, if rubbed when roughened or scratched. No purely scientific explanation has ever yet been given of these remarkable phenomena.

INDUCTION.

If a body is charged with electricity, and insulated so perfectly as to prevent the escape of the electricity which it contains, it nevertheless tends to produce an electrical state of the opposite kind in all the bodies around it. Thus the vitreous induces the resinous, and the resinous the vitreous, electricity in a body that is situated in the vicinity of either of them, and this to a degree proportioned to the smallness of the distance which separates the bodies. The electricity is in this case said to be induced, and the phenomenon is called *electrical induction*. The operation of this law is a key to the principal phenomena of electricity. In illustration of it, we shall quote an able writer upon the subject. "If an electrified body, charged with either species of electricity, be presented to an unelectrified or neutral body, its tendency, in consequence of the law of induction, is to disturb the electrical condition of the different parts of the neutral body. The electrified body induces a state of electricity contrary to its own in that part of the neutral body which is nearest to it; and, consequently, a state of electricity similar to its own in the remote part. Hence, the neutrality of the second body is destroyed by the action of the first; and the adjacent parts of the two bodies, having now opposite electricities, will attract each other. It thus appears that the attraction which is observed to take place between electrified bodies, and those that are unelectrified, is merely a consequence of the altered state of those bodies, resulting directly from the law of induction; and that it is by no means itself an original law or primary fact in the science.

"The effect of induction will be in proportion to the facility with which changes in the distribution of electricity among the different parts of a body can be effected, a facility which corresponds with the conducting power of the body. Hence, the attraction exerted by an electrified body upon another body previously neutral, will be much more energetic if the latter be a conductor than if it be an electric, in which these changes can take place only to a very small extent. This is confirmed by the following experiment:—Suspend by fine silk threads of equal length, two small balls of equal dimensions, both made of gum-

* Of course, we can only refer the reader to Haüy's work, where these minerals are all enumerated. It would be impossible to give them in this place.

* Description of an Electrical Telegraph, &c. London. 1823.

lac, but one having its surface covered with gold leaf. Place these two pendulums, as they may be called, at a little distance from one another, so as to admit of a comparison of their motions; and then present to them an excited electric, which may be either a tube of glass, or a cylinder of sealing-wax. It will at once be seen that the ball, with a metallic covering, which readily admits of the transfer of electricity from one side to the other, will be much more readily and powerfully attracted than the other ball, which allows of no motion in its electricity. The latter ball will, by slow degrees however, assume electrical states of the same kind as the gilt ball, and will be fully attracted. As this change is very slowly effected, so it is more permanent when once produced; and the plain ball adheres for a considerable time to the electric which has attracted it. The gilt ball, on the contrary, is sooner repelled, by its readily receiving the charge of electricity imparted to it by the electric. A degree of permanent electricity, however, is also induced on this ball, in consequence of its gradual penetration into the substance of the gum-lac."

THEORIES OF ELECTRICITY.

Electrical phenomena are generally accounted for by supposing that there is an extremely subtile and highly elastic fluid which pervades all material substances, but is itself devoid of any sensible gravity. It is supposed to move with various degrees of facility through the pores or actual substance of various kinds of matter. Hence, in proportion as they admit of the fluid passing through them with ease or difficulty, bodies have been divided into conductors and non-conductors. According to the doctrine of there being but one species of fluid, it is supposed that the electrical equilibrium which constitutes the natural state of matter is disturbed by friction, and that one of the two bodies brought near to each other, attracts to itself a surcharge of the fluid, and is *over-saturated*, whilst the other is left in a deficient state, and is *under-saturated*. For this view of the subject we are indebted to the immortal Franklin; and hence the terms of positive or plus, and negative or minus, have arisen. But as some of the appearances cannot easily be reconciled to the hypothesis of a mere excess or deficiency of one fluid, there is another theory which supposes the fluid to be a *compound*, susceptible of decomposition by friction and other means; and hence the origin of the terms vitreous and resinous electricities. Without entering into the subtleties of the question, which of the two theories is the more correct one, we shall attend to the facts of the case. The facts, both as presented to us by nature, and developed by experiments, are those of excitation, attraction, and repulsion; and distribution, induction, and transference.

Excitation.—The two electricities are supposed to exist in bodies naturally in a state of union, which, from various causes, such as friction, can be destroyed; the vitreous electricity is impelled in one direction, whilst the resinous is transferred to the opposite side; and the peculiar energies or powers, formerly latent, now display themselves. When accumulated in any part of a body, each fluid acts in proportion to its relative quantity; that is, to the quantity which is in excess above that which is still retained in a state of neutrality by its union with electricity of an opposite kind. Hence, when two bodies are rubbed together, say glass and a metallic amalgam, only the electricity at the surfaces subjected to friction is decomposed, the resinous adhering to the amalgam, whilst the vitreous attaches itself to the glass. All the rest of the electricity remaining on each surface undecomposed, is in a state of perfect quiescence or inertness.

Distribution and Transference.—The particles of the same kind of each of these highly elastic bodies mutually repel each other with a force which increases as the distance is less. Indeed, it has been proved that the intensity of this force, like that of gravitation, is inversely as the square of the distance. Like gravitation, also, it acts at all distances, and it is not impeded by any intervening body, provided it be not in an active electrical state. We will recur to this subject again. But whilst the particles of each fluid repel those of the same kind, they exert, as we have seen, a high attractive power over those of an opposite kind. The intensity of this attraction, also, like that of gravitation, increases with a diminution of distance. It is evident, therefore, that from the powerful attraction which they have for each other, they would always flow towards each other and coalesce, were it not that the non-conducting properties of electrics offer an impediment to their motion. When these obstacles are removed, they immediately rush into union, and give rise to the remarkable phenomena already noticed.

Attraction and Repulsion.—The repulsive power evinced by bodies charged with the same electricity, has been already mentioned. To explain the circumstance more minutely, let us suppose a body charged with electricity to be suspended in the air, or otherwise surrounded by a non-conducting medium, which allows it to move freely. As long as this body remains alone, the outward pressure which the electric fluid exerts against the insulating medium that confines it, will, by the laws of hydrostatics, be equal on all sides; and the body, thus balanced by equal and opposite pressures, will have no tendency to move. But if another body, similarly circumstanced, be brought near to it, the repulsive action between the similar electricities contained in these bodies, will diminish the outward pressure of each fluid against the sides of the bodies, which are adjacent to each other; and it will, at the same time, increase the outward pressure on the opposite or remoter sides. Both these causes conspire to destroy the equilibrium; each body is impelled in the direction of the preponderating force, that is, in a direction from the other body; and an effect, which may be called *repulsion*, takes place. The very same explanation, it is evident, applies to both kinds of electricity, their properties being in this respect exactly alike.

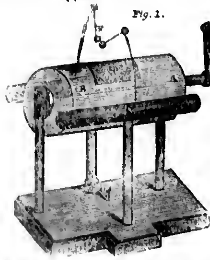
If, on the other hand, a body charged with vitreous electricity be presented to one charged with resinous electricity, the attraction of these two fluids will diminish the outward pressure on the remote sides of the bodies, and increase it on the adjacent sides; hence, the bodies will be urged towards each other, and motions indicative of attraction will result. Thus, in all cases do the movements of the bodies represent the forces themselves which attract the particles of the developed electricities contained in them.

Induction.—The law of induction naturally results from the hypothesis which we have been considering. Either of the two electricities existing in an active state repels the particles of the same electricities in all surrounding bodies, and attract those of the opposite species. On the hypothesis of two fluids, it may be said to decompose their united electricities, and render the body thus acted upon no longer neutral. Although Franklin's theory of there being only one fluid, and the incessant struggle, as it were, of that fluid to establish an equilibrium, one body sending off its overplus electricity to another which has less, accounts for most of the phenomena, yet a difficulty occurs when we attempt to apply it to the case of two bodies which are both in a state of negative electricity; that is, in which there exist in both certain quantities of matter unsaturated with electrical fluid. It is plain that from this theory no action can take place; for both being minus or deficient in the electric fluid, the one has none to spare for the other, and there is no communication or relationship established between the two bodies, and yet we know for certain that they repel each other. In order to reconcile this hypothesis with fact, it has been supposed that the particles of simple matter, or matter uncombined with the electric fluid, naturally exert a repulsive action on one another. We cannot help thinking, however, that this condition is far-fetched, and it is scarcely reconcilable with our ideas of the primary laws of matter, particularly that of gravitation. Nevertheless, it is convenient to employ the Franklinian hypothesis of a single fluid, as being the simplest and most convenient; and it is to be observed, that the one is as well calculated as the other to facilitate our comprehension of the phenomena and of their connections. The further developement of the theories will appear as we proceed.

ELECTRICAL MACHINES.

For the purpose of carrying on electrical investigations, and producing powerful electrical results, the aid of mechanism has been found essential, and these instruments have been called electrical machines. There are various kinds of them, but all constructed upon the same principles. Below is a representation of that which is most commonly used, in our description of which, the essential parts constituting such instruments will appear

Fig. 1.



A B, fig. 1, is a hollow cylinder of polished glass, which revolves upon a horizontal axis, and is from eight to sixteen inches diameter, and from one to two feet long. For the purpose of insulation, it is supported on two upright pillars of glass, which are fixed in a wooden stand. Two hollow metallic conductors, equal in length to the cylinder, and about one-fourth of its diameter, are placed parallel to it, one on each side, upon two insulating pillars of glass, which are cemented into two separate pieces of wood, that slide across the base, so as to allow of their being brought within different distances of the cylinder. To one of these conductors the cushion is attached, which is of the same length with the conductor C. The cushion is usually made of soft leather, generally basil skin, stuffed with hair or wool, so as to be as hard as the bottom of a chair, but yet sufficiently yielding to accommodate itself, without much pressure, to the surface of the glass to which it is applied. The prime conductor is a cylindrical tube, each end terminating in a hemisphere. As the electricity is only contained at the surfaces, it is made hollow, generally of thin sheet brass, copper, tin, or pasteboard covered with gold leaf or tin-foil. It must be carefully freed from all points and asperities; and if perforations are made in it for the purpose of attaching wires and other kinds of fixtures for the purposes of experiment, they should be made about the size of a quill, and should have their edges well rounded and smoothed off. The pressure of the cushion against the cylinder is regulated by an adjusting screw, adapted to the wooden base at E, on which the glass pillar that supports the conductor is fixed. From the upper edge of the cushion there proceeds a flap of thin oiled silk D, which is sewed on the cushion about a quarter of an inch from its upper edge. It extends over the upper surface of the glass cylinder to within an inch of a row of metallic points, proceeding, like the teeth of a rake, from a horizontal rod, which is fixed to the adjacent side of the opposite conductor. The motion of the cylinder, which is given by a single handle, or by a multiplying wheel, must always be given in the direction of the silk flap. That part of the cushion which comes in contact with the glass cylinder should be coated with an amalgam of tin, zinc, and mercury, applied by means of hogs' lard. The amalgam should be placed uniformly over the cushion, until level with the line formed by the seam which joins the silk flap to the face of the cushion. No amalgam should be placed over this line, nor on the silk flap; and it is even requisite to wipe the silk flap clean whenever the continued motion of the machine shall have soiled it, by depositing dust or amalgam on its surface. The best amalgam is that formed by melting together one ounce of tin and two ounces of zinc, which are to be mixed, while fluid, with six ounces of mercury, and agitated till cold in an iron or thick wooden box. After being reduced to powder, a sufficient quantity of hogs' lard is mixed with it, so as to form it into a paste.

This machine acts in the following manner:—When the cylinder is driven round by the handle, the friction of the cushion upon it produces a transfer of the electric fluid from the latter to the former; that is, the cushion becomes negatively, and the glass positively, electrified. By the revolution of the cylinder, the fluid adhering to the glass is carried round, and its escape is at first prevented by the silk flap which covers the cylinder, until it arrives near to the metallic points, which absorb most of the electricity, and convey it to the prime conductor. This being positively electrified, the conductor connected with the cushion being deprived of this electricity, is negatively electrified; so that light balls suspended by threads at F, being oppositely electrified, will attract each other. After the action has gone on for some time, the cushion and its conductor become exhausted of their electricity; so that a new supply must be brought from the earth, the great reservoir of the fluid. This is easily done, by establishing a communication between the cushion and the ground by means of a metallic chain or wire. In this manner, a constant stream of positive electricity flows to the prime conductor. Negative electricity is obtained by insulating the conductor to which the cushion is attached, and connecting the prime conductor with the ground, so as to carry off the fluid collected from the cylinder. If the person who works the machine be supported upon a stool having glass legs, and connected with the conductor by means of a metallic rod, or if he touch it with his hand, he is found to be in the same state of electricity; and another person standing upon the ground can draw sparks from him by presenting his knuckles to his body.

EFFECTS OF ELECTRICAL ATTRACTION AND REPULSION.

By using the electrical machine in the above manner, we are enabled to collect a considerable quantity of electricity, and thus perform experiments upon an ample scale. A pith ball, or a fragment of gold leaf, is very strongly and immediately attracted by the electrified conductor; and, the instant after it has come into contact with it, it is repelled; but it is now attracted by the other bodies in its neighbourhood, to which it communicates its own electricity, and then is again in a state to be influenced by the conductor, and to be again attracted; and this alternation of effects will continue as long as the conductor remains charged. This alternation of attractions and repulsions accompanying the transferring electricity by moveable conductors, is also illustrated by the motions of a ball suspended by a silk thread, and placed between two bells, of which the one is electrified, and the other communicates with the ground. The alternate motion of the ball between the two bells will keep up a continual ringing. This amusing experiment has been applied to give notice of changes taking place in the electrical state of the atmosphere.

The mutual repulsion of bodies that are similarly electrified gives rise to many interesting experiments. A small figure in the shape of a human head, covered with hair, when placed upon the conductor, and electrified, will exhibit the appearance of terror from the bristling up and divergence of the hair.

The intensity of the electricity which bodies may contain, is measured by a delicate instrument, called an *Electrometer*, of which there are several invented by various distinguished individuals. Our limits, however, will not admit of our giving a minute account of them. They all depend upon the repulsive property of electrified bodies, and the distance to which the one is repelled by the other, is indicated by an index of one kind or another.

DISTRIBUTION OF ELECTRICITY.

We have already observed, that, upon the extent of the surface of a body, its capacity for receiving electricity principally depends. Electricity is therefore supposed not to spread throughout the whole mass of a body, at least equally, but to remain principally, if not altogether, at the surface. For the purpose of measuring the proportional quantities of electricity with which different parts of the same or of different bodies are charged, Coulomb invented an instrument, which he called the *Torsion-balance*. It is a glass jar closed at both ends. From the top descends a single fibre of the web of the silk worm, which suspends by the middle a needle made of gum-lac, or other similar substance. This is provided at one end with a pith ball, and at the other with a counterbalance of varnished paper. On one side of the jar there is inserted a small bar, having at each extremity a metallic sphere, the one on the outside, and the other within. The upper end of the silk fibre is affixed to a kind of button having a small index, and made to turn easily round upon a circular plate, divided into degrees. Now the method of operation is plain: when the metallic and pith balls are both similarly electrified, the distance to which the latter is repelled is shown by the index, and thus the power of the electricity employed is indicated. It is incompatible with our limits to enter minutely into the details connected with the experiments performed by means of this extremely delicate instrument. They all go to prove the superficial distribution of electricity, and, of course, the influence of shape in lessening or augmenting its intensity. By an expansion of surface, the intensity of electricity is lessened, although the actual quantity present in the body remains the same; and if the conducting substance be drawn to a point, nearly the whole of the electricity is concentrated there, so that its power is exceedingly great. This is found to take place in all points that project beyond the general surface.

TRANSFERENCE OF ELECTRICITY.

Several remarkable phenomena occur when electricity is drawn off by means of a conductor from those bodies in which the electrical equilibrium has been destroyed. A sharp snapping sound is heard, accompanied by a vivid spark, whilst intense heat is evolved in the path which the electric fluid takes. A perfect conductor, offering no impediment to its course, it is unattended with light during its passage through such a body, light only appearing when there are obstacles in its path, such as imperfect conductors. Of the velocity with which it is transmitted, we have already spoken. It is so great, that in experiments performed with a chain of considerable length, each link became instantaneously luminous. There are various methods of showing the intensity and colour of electrical light. Conductors having a rounded form give the longest and most vivid sparks, which are sometimes seen to take a zig-zag course, similar to that of a flash of lightning. This deviation in its course is supposed to be occasioned by the fluid darting to minute conducting particles, such as those of moisture floating in the air. Electrical light is similar to light obtained from other sources, and its brilliancy depends upon its intensity. Sir David Brewster found that it was capable of polarisation. It displays every shade of colour, that quality being dependent upon the nature of the substance through which the fluid passes.

An interesting question arises—Whence comes the light; is it the electric fluid which thus renders itself visible? This was really supposed to be the case by the early electricians, but later philosophers have substituted other theories to account for the phenomena. That of M. Biot, a celebrated French philosopher, is, that electric light has the same origin as the light disengaged from air by mechanical pressure; "and that it is purely the effect of the compression produced on the air by the explosion of electricity." This hypothesis has been objected to, however, on the ground that electrical light is produced in the best vacuum that can be formed; and although he has replied to the objection, that no perfect vacuum can exist, yet his arguments, though they carry weight, do not bring conviction. An eminent foreigner, Dr Fusinieri, has lately placed the subject in a clear and remarkable point of view. He has proved that the spark which issues from a metallic body contains a portion of the metal in a state of fusion, and also incandescent molecules of the same substance. Hence it has been concluded, that the electric spark is *a flame*, and consists, like other flames, of incandescent molecules in a state of minute subdivision.

We have already observed, that various sounds accompany the various modes of transference of the electric fluid; a peculiar odour has also sometimes been felt near a machine which has been sharply wrought; but whence its origin, is unknown. All sharp pointed bodies, we have said, concentrate the electric fluid at their apex, from whence it has a powerful disposition to escape; and every discharge is accompanied by currents of air. Upon this principle, many ingenious experiments are founded. An apparatus, consisting of wires terminating in points, and having balls annexed to them to represent the planets, may be constructed so as to revolve when electrified, and thus to imitate the planetary motions. We cannot enter further into this subject, but may state in general terms, that the appearances of the electric spark depend upon the nature of the surface from whence it issues, and towards which it is directed. When it escapes *from* a pointed body, the luminous appearance is that of diverging streams, resembling the filaments of a brush, and forming what is termed a *pencil of light*; but when the fluid goes *to* a point, the light concentrates at the point itself, and assumes the appearance of a star.

OF INDUCTION AND ACCUMULATION OF ELECTRICITY.

The principle of induction we have already explained. All the phenomena connected with it may be accounted for by either of the laws already laid down. In addition to the facts which we have enumerated as resulting from the general operation of this law, little can be added, although a number of particular cases might be adduced.

The most convenient mode of obtaining an accumulation of electricity arising from induction, is by the employment of coated glass; that is, of a plate of glass on each side of which is pasted a sheet or coating of tin-foil. Care must be taken to leave a sufficient margin of glass uncovered with the metal, for preventing the transfer of electricity from one coating to the other, round the edge of the glass; and all sharp angles or ragged edges in the coatings should be avoided, as they have a great tendency to dissipate the charge.

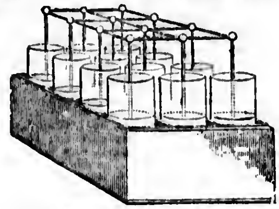
The form of coated glass best adapted to experiments is that of a cylindric jar; this is coated, within and without, nearly to the top. The cover consists of baked wood, and is inserted with sealing-wax, to exclude moisture and dust. A metallic rod, rising two or three inches above the jar, and terminating at the top in a brass knob, is made to descend through the cover till it touches the interior coating. The name of the *Leyden phial*, or *jar*, is applied to this instrument. It is used in the following manner:—The outer coating being made to communicate with the ground, by holding it in the hand, the knob of the jar is presented to the prime conductor when the machine is in motion; a succession of sparks will pass between them, while, at the same time, nearly an equal quantity of electricity will be passing out from the exterior coating, through the body of the person who holds it, to the ground. The jar, on being removed, is said to be charged; and if a communication is made between the two coatings, by a metallic wire extending from the external one to the knob, the electric fluid which was accumulated in the positive coating rushes, with a sudden and violent impetus, along the conductor, and passes into the negative coating; thus at once restoring an almost complete equilibrium. This sudden transfer of a large quantity of accumulated electricity is a real explosion; and it gives rise to a vivid flash of light, corresponding in intensity to the magnitude of the charge. The effect of its transmission is much greater than that of the simple charge of the prime conductor of the machine; and it imparts a sensation, w[illegible] passing through any part of the body, of a peculiar k[illegible]d, which is called the *electric shock*.

The arrangement of the parts in a Leyden jar is shown in the following figure:—

Fig 2

Here the simple bent *discharging* rod, for establishing a direct communication between the inner and outer coating of a jar or battery, and restoring the electrical equilibrium without the operator receiving the charge of the jar, is exhibited. E represents the insulating handle, and A the ring of brass reaching from the ball to the external coating. When opened to a proper degree, one of the balls is made to touch the exterior coating, and the other ball is then quickly brought into contact with the knob of the jar, and thus a discharge is effected.

By uniting together a sufficient number of jars, we are able to accumulate an enormous quantity of electricity. For this purpose, all the interior coatings of the jars must be made to communicate by metallic rods, and a similar union must be established among the exterior coatings. When thus arranged, the whole series may be charged, as if they formed but one jar; and the whole of the accumulated electricity may be transferred from one system of coatings to the other, by a general and simultaneous discharge. Such a combination of jars is called an *electrical battery*.



An arrangement of this description is represented above, in which twelve jars are united in one box, and the whole series connected together by wires and balls.

If we wish to send the whole charge of electricity through any particular substance which may be the subject of experiment, we must so arrange the connecting conductors as that the substance shall form a necessary part of the *circuit of the electricity*, as it is termed. With this view, we must place it between two good conductors, one of which is in communication with the outer coating; and the circuit may then be completed by connecting the other conductor with the inner coating, by means of a discharging rod, to one branch of which, if necessary, a flexible chain may be added.

MOTION OF ACCUMULATED ELECTRICITY.

In forming arrangements for directing the passage of accumulated electricity, it should be borne in mind that the electric fluid will, on these occasions, always pass through the best conductors, although they may be more circuitous, in preference to those which are more direct, but have inferior conducting power; and it must also be recollected, that, when different paths are open for its transmission along conductors of equal power, the electricity will always take that which is the shortest. Thus, if a person holding a wire between his hands discharges a jar by means of it, the whole of the fluid will pass through the wire, without affecting him; but if a piece of dry wood be substituted for the wire, he will feel a shock; for, the wood being a worse conductor than his own body, the charge will pass through the latter, as being easier, although the longer circuit. During its transit through the human body, in like manner, the shock is felt only in the parts situated in the direct line of communication; and if the charge be made to pass through a number of persons, who take one another by the hand, and form part of the circuit between the inner and outer coatings of the jar, each will feel the electric shock in the same manner and at the same instant; the sensation reaching from hand to hand, directly across the breast. By varying the points of contact, however, the shock may be made to pass in other directions, and may either be confined to a small part of a limb, or be made to traverse the whole length of the body from head to foot.

By accurate experiments, it appears that the force of the electric shock is weakened, or its effects are diminished, by employing a conductor of great length for making the discharge. A retardation in the passage of electricity also takes place if the conductor is not of a sufficient size; and when this is the case, as well as in those instances where the conductor is not a good one, the discharge will not be effected so instantaneously or so completely. It has also a tendency to diverge from the direct line of its course, being drawn towards conducting bodies which may attract it. The motion of electricity through perfect conductors is attended with no perceptible alteration in the mechanical properties of the conducting bodies, provided they be of sufficient size for the charge of the electric fluid transmitted. On the contrary, very considerable effects are produced when a powerful charge is sent through a wire which is too small to allow the whole quantity to pass with perfect freedom, or through an imperfect conductor, though of large size, as is proved when a tree is struck by lightning.

CHANGES PRODUCED BY ELECTRICITY ON INORGANIC BODIES.

The effects of electricity passing through various substances are both of a mechanical and chemical nature. The former resemble those which would be produced by a material agent driven with great velocity through the substance of the body. But there are many changes induced by electricity, such as cannot be attributed to mechanical agency, and are undoubtedly of a chemical nature. Some of the mechanical effects have already been noticed. Dr Priestly discovered that it expanded bodies. This is proved by passing a stream of the fluid through a capillary or thermometer tube filled with mercury; the latter will be so much expanded as to break the glass to shivers. The tendency to expand will of course be greater as the conducting power of the body which transmits it is less. Although we know nothing of the nature of electricity, yet it has been found convenient to speak of it as a fluid. Its action upon bodies which either obstruct its motion, or afford it a ready passage, renders its analogy with a fluid very striking. Solid bodies are capable of being diffused into metallic vapour, by passing electricity through them, as is shown by the following experiment:—Take three strips of window glass, each about three inches long and one wide, and having placed two narrow strips of gold leaf or leaf brass between them, so that the ends of the gold leaf project a little beyond the glass, transmit the charge of a large Leyden jar through the gold leaf. The gold leaf will be found to be melted by the shock, and driven into the surface of the glass. The outer plates of glass are generally broken in this experiment, and the middle one, which frequently remains entire, has an indelible metallic stain upon each of its surfaces. This stain is obviously the metallic vapour of the gold driven into the pores of the glass.

The metallic colours thus obtained have been employed for impressing ornamental figures upon paper or silk. In order to do this, trace the outline of the figures on thick drawing paper, and having cut it out as in stencil plates, place it on the silk or paper intended to be ornamented. When a gold leaf is laid upon it, and a card above the gold leaf, the whole is placed in a press or beneath a weight, and an electrical charge sent through it; the metallic stain is limited to the portion of the drawing paper that is cut away, and, consequently, any outline figure may be readily impressed upon the ground employed to receive it.

Chemical Changes.—The effects of electricity as a chemical agent are strikingly displayed in its power of evolving heat, and, consequently, of inflaming and fusing bodies, and its power of promoting chemical composition and decomposition. Combustible bodies, such as a common candle, can be lighted in various ways, by passing the electric fluid through them. The heat evolved by electricity, like most other of its effects, is in proportion to the resistances opposed to its passage. Nor is its heating power in the smallest degree diminished by its being conducted through any number of freezing mixtures which are rapidly absorbing heat from surrounding bodies. Sparks taken from a piece of ice are as capable of inflaming bodies as those from a piece of red-hot iron. Amongst the more striking chemical effects of electricity, are the decomposition of water, the oxidation of metals, and the restoration of the oxides to their metallic state. But the agency of electricity in producing chemical composition and decomposition, one of the most interesting parts of chemical and electrical science, will be fully treated of under GALVANISM.

Many experiments have been made for the purpose of ascertaining the changes affected in *phosphorescent* bodies by electricity, and the results are not without importance. It has been discovered, for instance, that substances not naturally phosphorescent, such as statuary marble in its natural or calcined state, were not only rendered phosphorescent by heat after being strongly electrified, but acquired this property with a beauty, a variety, and an intensity of colour, superior to those which occur in specimens that possess natural phosphorescence. It has also very recently been discovered, that electricity exercises a curious influence upon odoriferous bodies. When a current of the fluid is made to traverse camphor, the odour gradually disappears. After being withdrawn from electrical influence, it remains odourless for some time, and then slowly resumes its former properties.

EFFECTS OF ELECTRICITY UPON ANIMALS.

The influence of electricity upon the human frame, whether it is administered in small quantities so as to excite and surprise us, or in the more powerful and awful form of a stroke of lightning, must be well known to every one. When the human frame forms part of the electric circuit, or when the charge of a Leyden phial is made to enter the body at one hand, and pass out of it at the other, a violent concussion or shock is felt along the line of its passage across the breast and through the arms. This shock, and the motion which accompanies it, no doubt result from the body being composed of various substances of different degrees of conducting power, thus presenting various obstacles to the free passage of the fluid. If the charge is increased, the patient falls down paralysed, suffering a temporary cessation of vital action; and if it be increased to a still greater extent, it produces instantaneous death. This is frequently exemplified in the cases of individuals who are killed by the lightning stroke. It is upon the nervous system that electricity produces the most powerful influence. A strong charge passed through the head, gives the sensation of a violent but universal blow, and is followed by a transient loss of memory and indistinctness of vision. If a charge be passed through the spine, the person who receives it loses his power over the muscles to such a degree, that he either drops on his knees, or falls prostrate on the ground. Small animals, such as mice and sparrows, are instantly killed by a shock from thirty inches of square glass. If a shock be sent through the whole body of an eel, it is irrecoverably deprived of life; but if only through a part of the body, the destruction of irritability is confined to that particular part, whilst the rest retains the powers of motion. Different persons are affected in very different degrees by electricity, according to their peculiar constitutional susceptibility.

The powerful influence of electricity on the human frame led the more sober part of the medical profession to view it as a valuable auxiliary in the healing art, while those who were more sanguine regarded it as an universal medicine, which might be resorted to in every form of disease. Charlatans of every degree found the electrical machine a lucrative article of trade; and there were not wanting well-meaning enthusiasts who contributed to prolong the reign of medical electricity. But though electricity has not yet taken up a position in the healing art, there can be no doubt that in various disorders its application has been found advantageous, and that patients have, in a particular class of diseases, experienced instantaneous relief.

We think some ingenious individual should make a catalogue of the diseases in which electricity gives relief, and, generalising the facts, give us a new science with the title of *Electro-Medicine*. Why not, since we have electro-magnetism and electro-chemistry, from the identity of electricity with the former fluid, and its relations to the latter science.

Although many ingenious electrical experiments have been made upon *vegetables*, some of which seem to indicate that the fluid exercises considerable influence over vegetable life, yet the subject is still involved in too great obscurity to admit of our treating the subject as a branch of electricity. Plants, of course, are destroyed, like animals, when a powerful charge is sent through them; but feeble electricity exerts no influence on either animal or vegetable life, as far as can be perceived, whilst, when transmitted in powerful shocks, it destroys them like lightning.

CHANGES IN THE ELECTRICAL STATE OF BODIES, RESULTING FROM CHANGES OF TEMPERATURE AND FORM, FROM CONTACT, COMPRESSION, &c.

There are certain mineral bodies, which, from being in a neutral state at ordinary temperatures, acquire electricity simply by being heated or cooled. This property is possessed only by regularly crystallised minerals; and of these the most remarkable is the tourmalin. It is a stone of considerable hardness, and the form of its crystals is generally that of a nine-sided prism, terminated by a three-sided pyramid at one end, and by a six-sided pyramid at the other. When heated to between 100° and 212°, the latter extremity becomes charged with positive electricity, whilst the former remains negative. On cooling, the electric states are generally reversed, that end becoming positive which was formerly negative. Other gems possess similar properties, such as the topaz, some species of diamonds, &c. There are a great many substances which become electrified by passing from the liquid to the solid form, such as sulphur, gum-lac, and in general all resinous bodies. The conversion of a body into the aëriform state, is also generally attended by some change in its electrical state.

There are some bodies which are rendered electrical by pressure. The substance which possesses this property in the most remarkable degree, is that variety of the carbonate of lime, known by the name of *Iceland spar*. Cork, bark, hairs, paper, and wood, also possess the property of producing electricity by compression. A number of substances, when reduced to powder, exhibit electricity, if they are made to fall upon an insulated metallic plate. The relation subsisting between electricity, and the chemical properties of matter, is the most important branch of this inquiry. It is observed by Sir H. Davy, that most of the substances that act distinctly upon each other electrically, are also such as act chemically when their particles have freedom of motion; this is the case with the different metals, with sulphur and the metals, with acid and alkaline substances. Of two metals in contact, the one which has the greatest chemical attraction for oxygen acquires positive electricity, and the other the negative. There is little doubt, indeed, that electricity is not only elicited, but is intimately connected with all chemical action; and there is every reason to believe that electricity is essentially concerned in the processes that are carried on in the living system, both of animals and vegetables. For an account of the electricity evolved during the contact of metals, as well as the other relations of the electric fluid with chemical science, see GALVANISM.

THE ELECTRICITY OF THE ATMOSPHERE.

We have now arrived at that part of our subject which is perhaps the most generally interesting of all. Every ear has heard, and every bosom acknowledged by its terror or its awe, the grandeur of the rolling thunder, as it pealed in the dusky sky, like the trump of doom, "convulsing earth and heaven."

The resemblance between the electric spark, and more especially the explosive discharge of the Leyden jar, and atmospheric lightning and thunder, struck the mind of Dr Franklin with so much force, that he was determined, if possible, to verify their identity by experiment.

Having constructed a kite, by stretching a large silk handkerchief over two sticks in the form of a cross, on the appearance of an approaching storm he went into a field in the vicinity of Philadelphia, and raised it, taking care to insulate it by a silken cord attached to a key, with which the hempen string terminated. No sooner had a dense cloud, apparently charged with lightning, passed over the spot on which he stood, than his attention was arrested by the bristling up of some loose fibres on the hempen string: he immediately presented his knuckle to the key, and received an electric spark. Overcome with the emotions which his discovery evinced, he heaved a deep sigh, as if he felt conscious of having achieved immortal fame. The rain now fell in torrents, and, wetting the string, rendered it conducting in its whole length; so that electric sparks were now collected from it in great abundance. The discovery of Franklin soon engaged the attention of all the philosophers of Europe, and the truth of the theory, that lightning and electricity are the same fluid, was put beyond all question.

The atmosphere is very generally in an electrical state. This is ascertained by employing a metallic rod, insulated at its lower end, elevated at some height above the ground, and communicating with an electroscope. In order to collect the electricity of the higher regions of the air, a kite may be raised, in the string of which a slender metallic wire should be interwoven. The atmosphere is almost invariably found to be positively electrified; and its electricity is stronger in the winter than in the summer, and during the day than in the night. From the time of sunrise, it increases for two or three hours, and then decreases towards the middle of the day, being generally the weakest between noon and four o'clock. As the sun declines, its intensity is again augmented, till about the time of sunset, after which it diminishes, and continues feeble during the night.

In cloudy weather, the electrical state of the atmosphere is much more uncertain; and when there are several strata of clouds, moving in different directions, it is subject to great and rapid variations, changing backwards and forwards in the course of a very few minutes. On the first appearance of fog, rain, snow, hail, or sleet, the electricity of the air is generally negative, and often highly so; but it afterwards undergoes frequent transitions to opposite states. On the approach of a thunder-storm, these alternations of the electric condition of the air succeed one another with remarkable rapidity. Strong sparks are sent out in great abundance from the conductor; and it becomes dangerous to prosecute experiments with it in its insulated state.

The protection of buildings from the destructive effects of lightning is the most important practical application of the theory of electricity. The conductors, for this purpose, should be formed of metallic rods, pointed at the upper extremity, and placed so as to project a few feet above the highest part of the building they are intended to secure; they should be continued without interruption till they descend into the ground below the foundation of the house. Copper is preferable to iron as the material for their construction, being less liable to destruction by rust, or by fusion, and possessing also a greater conducting power. The size of the rods should be from half an inch to an inch in diameter, and the point should be gilt, or made of platina, that it may be more effectually preserved from corrosion.

An important condition in the protecting conductor is, that no interruption should exist in its continuity from top to bottom; and advantage will result from connecting together by strips of metal all the leaden water-pipes, or other considerable masses of metal in or about the building, so as to form one continuous system of conductors, for carrying the electricity by different channels to the ground. The lower end of the conductors should be carried down into the earth, till it reaches either water, or at least a moist stratum.

For the protection of ships, chains, made of a series of iron rods linked together, are most convenient, on account of their flexibility. They should extend from the highest point of the mast some way into the sea, and the lower part should be removed to some distance from the side of the ship, by a wooden spar or outrigger.

THUNDER AND LIGHTNING.

We have already mentioned, in general terms, that these terrible visitations are to be classed with electrical phenomena. The lightning is to be identified with the electric spark, and the thunder with the sound which we have seen accompanies it, but augmented by being prolonged by the successive echoes of the clouds, which, it has been proved, are capable of reflecting sound. Sir John Herschell has lately thrown considerable light upon the rolling sound of thunder; and his observations seem in some measure to supersede the theory above stated. "To understand this cause," says he, "we must premise, that, *cæteris paribus*, the estimated intensity of a sound will be proportional to the quantity of it (if we may so express ourselves) which reaches the ear in a given time. Two blows, equally loud, at precisely the same distance from the ear, will sound as one of double the intensity; a hundred struck in an instant of time will sound as one blow a hundred times more intense than if they followed in such slow succession that the ear could appreciate them singly." Now, let us suppose two flashes of lightning of equal intensity and length, both to begin at, say one mile's distance from the auditor, but one of them to run out in a direct line from him, and the other to describe one of a circle of which he is the centre. The sounds arising from each of the two streams of electricity may be regarded as originating at one and the same instant, since the speed of lightning is incomparably greater than that of sound. Now, it is perfectly clear that the sound will reach the ear under very different circumstances in the two cases. That of the circular flash will arrive all at once, and affect the ear as a single explosion, whilst the other will reach the ear in successive peals, each arriving after the other as the distance between the auditor and the lightning-vein is increased. Such is a general view of Sir John's theory, and it is scarcely possible to doubt its correctness for a moment.

Distance of Thunder.—The distance of the point in the atmosphere where the lightning is generated, may be readily computed by multiplying 1090 by the number of seconds which elapse between the flash and the first stroke of thunder. The product will give in feet the distance required.

The ordinary cases of thunder and lightning occur when the electricity passes between two clouds oppositely electrified, or one of which has an inferior charge of the same kind of fluid. When, however, the accumulated electricity of the clouds descends to the earth, it then assumes its most appalling form, and spreads destruction around its path, like the sword of the destroying angel. The strongest fabrics reared by human hands, and the most firmly rooted oaks, cannot withstand its desolating fury. Down it comes, setting the forest in flames, shivering walls of Babylonian thickness and adamantine strength, and laying man, his works, and whatever obstructs its path, in one common ruin. The thunderbolt, which the terror of the vulgar mind, as well in ancient as in modern times, has aggravated into a really solid substance, darting sheer down from "the crystal wall of heaven," as Milton hath it, is to be identified with the passage of the electric fluid from the clouds to the earth. Sometimes, however, the earth, as it were, retaliates, and the fluid shoots upwards to the clouds; this is called the *ascending thunderbolt*, of which there are some striking cases on record. It has been seen to rise in the form of a flame six feet high, and followed by a loud noise.

There are various interesting electrical phenomena, but they belong more immediately to the subject of Meteorology. A few of them, however, may be noticed, and of these the transport of ponderable substances by lightning is none of the least remarkable. To Fusinieri, whose name has already been mentioned, we are indebted for our knowledge of this interesting subject. The general facts at which he arrived, are:—"That lightning contains, like the common electric spark, matter in a state of extreme division, and in a state of ignition and combustion. In the matter deposited by lightning on houses and on trees which have been struck by it, he has found *iron*, *sulphur*, and *carbon*. Lightning divides and subdivides itself indefinitely into sparks, which end in being not much larger than those of ordinary machines; and each of these sparks contains ponderable substances in the state of extreme division already mentioned. The lightning deposits the substances with which it is charged while it passes through them, and while it breaks hard bodies; and it deposits them on the surface by which it enters the body, as well as on that by which it escapes, and also on the surfaces of fracture."

The connection between the formation of hail, and a highly electrical state of the atmosphere, is certain; but how the production of hail under such circumstances is to be accounted for, we cannot tell. To electricity is, also, to be attributed the phenomena of waterspouts, sheet or summer lightning, the aurora borealis, fireballs, columns of light, and other luminous appearances of the atmosphere. The fire of St Elmo, or Castor and Pollux, is a brilliant light which frequently appears on the summits of ships' masts, on the points of bayonets, on the tops of spears, and on the tips of the ears of horses, and also on their manes. It is nothing more than the electricity discharging itself into or from pointed bodies, and is intimately connected with a peculiar electrical state of the air.

ELECTRICITY OF LIVING ANIMALS.

During the chemical processes and changes which are incessantly taking place in living bodies, electricity is developed in greater or less quantities. The friction which takes place between the clothing and the skin of the human body, also tends to generate this power. Cardan relates, that sparks were emitted from the hair of a Carmelite monk whenever it was stroked backwards; other cases are also on record, of the fluid having been developed by the body being rubbed. But independent of these electrical phenomena, we find in certain fishes a regular system of electrical organs, by which they either defend themselves from the attacks of their enemies, or seize the prey nature has provided for their use. Amongst the most remarkable of these is the *Raia Torpedo*, which is capable of giving a great many shocks to a number of individuals connected together, in the same manner as in the experiment with the Leyden jar. Another is the electrical eel, which, when provoked, discharges its electricity, and the shock is experienced if the hand be dipped in the water containing the fish.

GALVANISM.

This science has been named after the celebrated Galvani, an Italian philosopher, on account of the following circumstance:—A recently killed frog having been accidentally touched in the limb with the blade of a knife which was held by a person who was experimenting with an electrical machine, was immediately thrown into violent convulsions. Galvani was not present when this occurred, but being informed of the circumstance, he lost no time in repeating the experiment, and extending his observations upon the phenomenon. He found that other metals besides that composing a knife answered the purpose, and very justly inferred that they owed this property of exciting muscular contractions to their being good conductors of electricity. Such was the origin of that science which has opened up to mankind a rich and boundless field of investigation.

Galvani proceeded with his experiments upon animals by means of metallic substances, and arrived at the conclusion, that the different parts of an animal are in opposite states of electricity, and that the effect of the metal is merely to restore the equilibrium. But this theory was proved to be erroneous by Volta, a celebrated philosopher of Pavia, who, about the year 1801, discovered the *Galvanic* or *Voltaic pile*. He was led to it by meditating on the developement of electricity at the surface of contact of two different metals. He tried the effect of his compound plates of metal upon animals, and was led to infer that the electricity is derived, not from the living system, but from the action excited between the metal and the humid animal fibre, that the animal matter acts merely as a medium conducting this electricity, and that the effects produced are to be ascribed to the stimulus of the electric fluid passing along the nerves and fibres, as in a shock from a Leyden jar.

Volta further discovered, that the metallic plates which he used, such as silver and zinc, are excited, the former negatively, and the latter positively; and also that the galvanic energy could be greatly augmented by employing several pairs of plates, connecting them in such a manner that the electricity excited by each pair should be diffused through the whole, and this constituted the voltaic pile. It consisted of any number of pairs of zinc and copper or zinc and silver plates, each pair being separated from the adjoining ones by pieces of cloth, nearly of the same size as the plates, and moistened in a saturated solution of salt. The relative position of the metals in each pair was the same in the whole series, so that if the copper was placed below the zinc in the first combination, the same order was preserved in all the others. The pile was contained in a frame, fixed into a piece of thick wood, which afforded the apparatus both support and insulation.

Volta invented another apparatus, and several improvements were made upon the voltaic pile by other philosophers, but we pass from these to the

CONSTRUCTION OF THE GALVANIC APPARATUS.

The simple contact of different conducting bodies is all that is necessary for the excitement of galvanic electricity. Conductors of electricity have been divided into perfect and imperfect; the former comprehending the metals, plumbago and charcoal, the mineral acids, and saline solutions; the latter including water, alcohol and ether, sulphur, oils, resins, metallic oxides, and compounds of chlorine. The least complicated galvanic arrangement is termed a *simple galvanic circle*. It consists of three conductors; of which one at least must be solid, the second fluid, the third may be either solid or fluid. In the following tables, some different simple circles are arranged in the order of their powers, the most energetic occupying the highest place:—

Table of electrical arrangements, which, by combination, form voltaic batteries, composed of two perfect conductors, and one imperfect conductor.

Zinc Iron Tin Lead Copper Silver Gold Platina Charcoal	Each of these is the positive pole to all the substances below it, and negative with respect to those above it in the column.	Solution of nitric acid ——— muriatic acid ——— sulphuric acid ——— sal ammoniac ——— nitre ——— other neutral salts.

Table of electrical arrangements, consisting of one perfect conductor and two imperfect conductors.

Solution of sulphuret of potash ——— potash ——— soda	Copper Silver Lead Tin Zinc Other metals Charcoal	Nitric acid Sulphuric acid Muriatic acid Any solutions containing acids

In explanation of these tables, it may be observed, that in all those cases where the fluid menstrua afford oxygen, those metals which have the strongest attraction for oxygen are those which form the positive pole. But when the fluid menstrua afford sulphur to the metals, the metal, which, under the existing circumstances, has the strongest attraction for sulphur, determines the positive pole. Thus, in a series of copper and iron plates, introduced into a porcelain trough, the cells of which are filled with water or with acid solutions, the iron is positive, and the copper negative; but when the cells are filled with a solution of sulphuret of potash, the copper is positive, and the iron negative. When one metal only is concerned, the surface opposite the acid is negative, and that in contact with the solution, or the alkali and sulphur, or of its alkali, is positive.

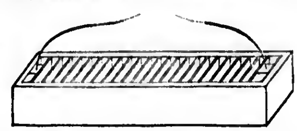
Simple galvanic circles are possessed of but feeble powers; yet these are often sufficiently obvious, as in the instance above alluded to, of a slip of zinc laid upon the tongue, and a piece of silver under it. In this case, we have an example of the arrangement of two perfect conductors (the metals) with one imperfect one (the tongue, or rather the fluids which it contains). A piece of zinc immersed in water which is freely exposed to the atmosphere, oxidises very slowly; but when placed in the same situation, in contact with a piece of silver, its oxidation is much more rapid. By immersing iron and silver (also in contact with each other) in dilute muriatic acid, the action of the acid upon the iron is considerably increased; and hydrogen gas is evolved from the water, not only where it is in contact with the iron, but where it touches the silver. These facts explain why, in the sheathing of ships, it is necessary to use bolts of the same metal which forms the plates; for if two different metals be employed, they both oxidate very speedily, in consequence of their forming, with the water of the ocean, a simple galvanic circle.

Compound galvanic circles, or galvanic batteries, are formed by multiplying those arrangements which compose simple circles. Thus, if plates of zinc and of silver, and pieces of woollen cloth of the same size as the plates, and moistened with water, be piled upon each other in the order of zinc, silver, cloth; zinc, silver, cloth; and so on, for twenty or more repetitions, we have the voltaic pile. The power of such a combination is sufficient to give a smart shock, as may be felt by grasping in the hands previously moistened, the wires connecting the upper and lower extremities of the pile. The shock may be renewed at pleasure, until, after a few hours, the activity of the pile begins to abate, and finally ceases altogether.

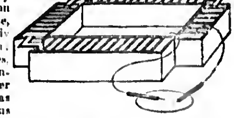
But the galvanic apparatus, by far the most convenient and generally used, was invented by Mr Cruickshank.

GALVANIC TROUGH.

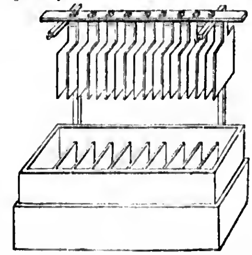
The galvanic trough, as it is named, and which consists of a long and narrow trough, made of baked wood, is shown beneath.



Grooves are cut in the trough, opposite to and at the distance of one-half and three-fourths of an inch from each other, and into these are let down, and secured by a cement, square plates of zinc and copper, previously united together by soldering. The space, therefore, between each pair of plates forms a cell for the purpose of containing the liquid by which the combination is to be made active. The plates may be from three to six or eight inches square, and care is to be taken, in their arrangement in the trough, that the order in which they are inserted be not in any instance reversed, but that the copper side of each double plate be always towards one hand, and the zinc side towards the other. The galvanic trough thus constructed, is more easily put in action than the pile, & more easily kept clean, and, besides, it can be continued longer in action, as it contains more liquid.



The voltaic battery has been improved by keeping the plates detached, instead of soldering them together. They are connected at the upper edge by a metallic arc, and are introduced into a trough divided into cells by partitions of glass (or sometimes into troughs wholly made of earthenware), in such a manner that one plate is on one side of the partition, the other on the other. This arrangement has the advantage, that, both surfaces of each plate being acted on, a greater power is obtained.

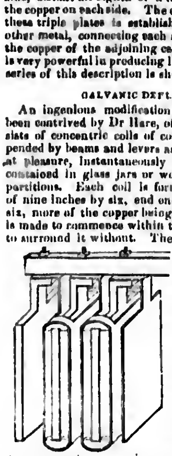


In the above engraving the plates are shown suspended over a porcelain trough, which is the best form in which they can be constructed. The only practical objection to the arrangement is, that in some cases the acid acts on the glazed surface of the porcelain, and the troughs leak.

Dr Wollaston has heightened the improvement, by placing in each cell one plate of the one metal, as the zinc, and two of the other, the copper, so that each surface of the zinc may be opposed to a surface of copper. The plates of copper are connected by metallic arcs, both at the top and bottom; and between them, supported by pieces of wood, is the plate of zinc, distant an eighth or a fourth of an inch from the copper on each side. The communication between these triple plates is established by arcs of lead or other metal, connecting each central zinc plate with the copper of the adjoining cell. This arrangement is very powerful in producing light and heat. A single series of this description is shown in the engraving.

GALVANIC DEFLAGRATOR.

An ingenious modification of this apparatus has been contrived by Dr Hare, of Philadelphia. It consists of concentric coils of copper and zinc, so suspended by beams and levers as to be made to descend, at pleasure, instantaneously into the exciting fluid contained in glass jars or wooden troughs, without partitions. Each coil is formed from a zinc sheet of nine inches by six, and one of copper fourteen by six, more of the copper being required, as this metal is made to commence within the zinc, and completely to surround it without. The sheets are so coiled as to leave between them interstices of a quarter of an inch. In the original apparatus, they were arranged in two rows, 40 coils in each; on their immersion in the appropriate fluid, the immediate evolution of heat and light was found to be most intense, and far exceeding that of voltaic piles or troughs of an equal number of series and extent of surface; and



on account of its superior power of causing the combustion of metallic wires and leaves, the instrument was named by its inventor the *galvanic deflagrator*.

The size of the plates composing the galvanic series has been varied from one or two inches square, to that of a great number of feet. The battery of Mr Children consisted of twenty pairs of copper and zinc plates, each plate being six feet long by two feet eight inches broad. Each pair was connected by leaden straps at the top, and had a separate wooden cell. These cells were capable of containing 945 gallons of liquid. The plates were suspended from a wooden beam, by means of which they could at once be lowered into the cells, and again raised at pleasure.*

Different liquids are employed to fill the cavities of the trough; and it is essential to employ those which exert a chemical action upon one of the metals, the effect with pure water being very inconsiderable. In general, the galvanic effect is proportional to the rapidity with which the more oxidable metal is acted upon by the intervening fluid. Thus, where the liquid employed is pure water, the electric excitement is very feeble, for the action on the metals is feeble; still the zinc is, even in this arrangement, observed to be oxidised more rapidly than it would be, were it not in contact with the copper. A saline solution, as of muriate of soda, or muriate of ammonia, is found to cause a more rapid oxidation of the zinc; and, accordingly, the electric power is greater; and, lastly, an acid fluid, which oxygenates and dissolves the metals much more rapidly, produces the highest activity of which the battery is capable. The fluid generally used is nitric acid, diluted with twenty or thirty times its weight of water.

With regard to the electrical effects produced by the galvanic battery, it is unnecessary to speak, as they are, of course, similar to those already described as resulting from an excited electric. We shall now proceed to the most important part of the subject, that which relates to the chemical changes effected by galvanism, and which has been called

ELECTRO-CHEMISTRY.

Some of the chemical changes effected by electricity were noticed under that head, but those resulting from the operation of galvanism, whose power is infinitely greater than that of ordinary electricity, are of incalculably more importance. Its application, indeed, to chemical analysis, has led to a series of discoveries which constitute a new era in the history of chemistry, and rank amongst the most brilliant recorded in the annals of physical science. In order to acquire clear ideas of chemistry as relating to galvanism, we will trace them from their origin, and attend to what takes place in the simplest galvanic circle, composed of two dissimilar metals, and an interposed fluid.

If a plate of zinc, and another of copper, be immersed in very dilute sulphuric acid, without touching or communicating with each other, the zinc will be acted upon by the acid; part of the water will be decomposed, its oxygen combining with the zinc, and forming oxide of zinc, and its hydrogen will be disengaged in the form of gas from the surface of the zinc plate. The copper is not acted upon. If the metals be brought into contact, the oxidation goes on with greater rapidity and energy, although without the evolution of the same quantity of hydrogen gas from the oxidating surface. But, from the whole fluid, hydrogen is disengaged in quantity exactly corresponding to that of the oxygen derived from the water, and the greater portion of it rises in a copious stream of bubbles from the surface of the copper plate, which remains unacted upon as before.

If, however, an acid, such as the nitric acid, capable of acting upon the copper, as well as upon the zinc, be employed instead of the sulphuric acid, similar phenomena will take place, with this additional circumstance, that the action of the acid upon the copper will cease the instant the galvanic circuit is completed; and instead of nitrous gas being formed on the surface of the copper, which happens before the circuit is formed, only bubbles of pure hydrogen will make their appearance; and the copper is protected from all further action, the zinc being, as in the former case, oxidated and dissolved with additional energy. It is on this principle that Sir H. Davy has effected the protection of the copper sheathing of ships from the corrosion of sea-water, by placing in contact with it pieces of zinc, or iron, on which sea-water exerts a greater chemical action than on copper. Among the simplest effects of galvanism upon fluid-conductors, is the resolution of water into its two gaseous elements, oxygen and hydrogen. If the water employed be not perfectly pure, other substances besides the two components of water make their appearance at the two wires employed in the experiment. The apparent formation of these substances greatly puzzled the early experimentalists, but Sir H. Davy proved, in a most masterly manner, that, when the water is perfectly free from any foreign ingredient, only the two simple gases of which it is composed are obtained. He also discovered, that, under the influence of voltaic electricity, neutral salts existing in any solution were decomposed, the acid portion being accumulated around the positive wire on the same points where oxygen was disengaged; while the bases, whether earthy, alkaline, or metallic, were at the same moment transferred along with the hydrogen to the negative wire.

Phenomena of a still more extraordinary nature presented themselves to Sir Humphry Davy in the further prosecution of these inquiries. It was discovered that the elements of compound bodies were actually conveyed by the influence of the electric current through solutions of substances, on which, under other circumstances, they would have exerted an immediate and powerful chemical action, without any such effect being produced. Acids, for example, may be transmitted from one cup, connected with the negative pole, to another on the opposite or positive side, through a portion of fluid in an intermediate cup, tinged with any of the vegetable-coloured infusions, which are instantly reddened by the presence of an acid, without occasioning the slightest change of colour. The same happens also with alkalis. If three cups be arranged, and connected with each other in a series by moistened cotton, the middle cup, and also the one next to the positive side of the battery, being filled with blue infusion of cabbage or of litmus, and the cup next to the negative side containing a solution of sulphate of soda, on the series being placed in the voltaic circuit, a red tinge will soon be perceived in the water of the positive cup, which will become strongly acid. It is evident that the sulphuric acid so transferred must have passed through the fluid in the middle vessel, but without affecting the coloured solution in its passage. By reversing the connections with the poles of the battery, a similar transfer of the alkali will be made: it will be collected in the tinged water of the negative cup, which it will render green; but the intermediate portion of fluid will not, either in this or in the former case, exhibit any trace of the substance which is carried through it by the influence of electricity. Cohesion, however, where powerful, as might have been expected, intercepts the transmission of the substance. Sulphuric acid cannot be transmitted through a solution of barytes or strontites, nor these earths through sulphuric acid; for when the attempt was made, they fell down as insoluble precipitates. Solids are also decomposed, and their elements transferred to the opposite wires, by means of the galvanic energy. So powerful is this mysterious agent, that the minutest portions of a substance, acted upon by either of the wires, is collected around it.

The reader has now obtained a general view of the principles and discoveries developed in Sir H. Davy's great Bakerian Lecture on the Chemical Agencies of Electricity, which was crowned by the National Institute of France with the Napoleon prize, to the glory of the country of the chemist, no less than to his own. The grand law of electro-chemical decomposition may be again stated in full. Metals, inflammable bodies, alkalis, earths, and oxides, are determined to the negative surface or pole; and oxygen, chlorine, iodine, and acids (may we add bromine and fluorine?) to the positive pole. The decomposition into their constituent elements of the alkalis and earths, which crowned the brilliant career of the great philosopher above named, is, in point of theory, only a particular instance of the general fact above stated.

Various other applications have been made of the voltaic battery to the purposes of chemical decomposition. Sulphuric acid is resolved into oxygen and sulphur; phosphoric acid into oxygen; and phosphorus and ammonia into hydrogen and azote, and a minute proportion of oxygen. Oils, alcohol, and ether, when acted on by a powerful battery, deposit charcoal, and give off hydrogen or carburetted hydrogen. But it is unnecessary to enumerate all the instances of decomposition effected by this the most powerful instrument of analysis in the hands of man.

We have now arrived at a general law, namely, that when compounds are placed in the galvanic circuit, they are decomposed, and their elements collect, some around the negative, some around the positive pole of the battery. How this arises, what is the cause of this remarkable effect, it is difficult to say. Various theories have been brought forward to explain these singular results.

CHEMICAL THEORY OF GALVANISM.

The general fact which forms the basis of this theory is, that chemical action occurring between a fluid and a solid body is always accompanied by the disturbance of electric equilibrium, and thus a quantity of electricity passes from a latent into an active state. For instance, during the oxidation of metallic bodies by means of an acid, a large quantity of electricity is developed, or, in other words, the metal becomes negatively electrified, whilst the liquid becomes positively electrified to the same extent. Now, this can be accounted for in a certain degree, by supposing the existence of either one or two fluids. According to the first theory, we have only to suppose that the fluid is abstracted from the metal and transferred to the zinc; or, according to the second hypothesis, that the two electricities are separated by chemical action, and the determination of the resinous or negative electricity in the direction of the zinc, and of the vitreous or positive fluid in the direction of the oxidating liquid. Why the electrical equilibrium should be disturbed during chemical composition, and what is the obstacle which prevents its restoration, is yet a mystery to us, but the fact is beyond all doubt. It may be asked, is chemical action the *cause* or the *effect* of electricity being transferred from a latent to an active state? That chemical attraction itself is a modification of electricity, and that the same power which communicates attractive and repulsive properties to masses of matter, may, when acting upon the ultimate particles of different bodies, induce them either to separate or unite, as their natural electrical states are the same or different, is extremely probable. Sir H. Davy, who advanced the above theory, conceived that all bodies possess natural electrical energies, which are inherent in them, whether they are in a state of combination or not. Oxygen, chlorine, iodine, and acids, according to the theory, are naturally negative; while inflammables, as hydrogen, sulphur, &c., and metals, are naturally positive. Hence, when the combinations of these substances are subverted by the galvanic influence, the substances are evolved in the electric state natural to them; and, as it is a law of electricity that bodies in opposite states attract each other, the oxygen, being negative, is immediately attracted by the positive wire, while the inflammable or metallic base, being naturally positive, is attracted by the negative wire. In this way, the uniform appearances of these bodies at their particular poles are accounted for. Thus, if hydrogen is naturally positive, and oxygen naturally negative, according to the laws of electricity, they must attract each other; and if these opposite states are sufficiently elevated to give them an attractive force, superior to the power of aggregation, they may be expected to combine; and, in like manner, other bodies, whose particles are in different states, may from this cause be united together. If a body, also, whose electrical energy exceeds that of one of the substances combined, be brought to act upon these, it may expel that ingredient, and take its place; and this may be the cause of what is called decomposition from elective affinity.

The effect of heat, likewise, in promoting combination or decomposition, may often depend on its exciting electrical energy; and the elevation of temperature and production of light, so frequently attending chemical action, may depend on the changes attending the electrical states, since such changes are accompanied with the evolution of heat and light. The agency of the galvanic apparatus, then, in producing decomposition, it is conceived on this hypothesis, is, that the two wires placed in contact with the compound are, in states of electricity, more intensely elevated than the natural states of the two ingredients; hence the attraction of these two highly electrified points overcomes that subsisting between these ingredients: they are separated, and immediately drawn to the respective poles—the positive constituent to the negative wire, and the ingredient, which is naturally negative, to the positive wire. A number of facts might be brought forward in support of these views.

The transfer of material ponderable substances, such as those which constitute water to the respective poles of the battery, has been thus explained by Dr Roget, in a paper which was read to the Philosophical Society of Manchester, in 1807:—"We may conceive the agency of electricity to extend throughout the whole of the fluid line connecting the two wires. The hydrogen existing in every particle of water in this line will, if it possess a positive electrical polarity, according to the hypothesis of Mr Davy, be repelled by the positive and attracted by the negative wire. We may consider the row of particles of hydrogen abstractedly from those of oxygen. While the former are moving together, by the agency of electricity, in a direction towards the negative wire, all those particles which have not yet reached that wire will merely have to pass over in succession from one particle of oxygen to the next, among those of the other row. They will not appear in the form of gas, because the instant each has quitted the particle of

6″

oxygen with which it was associated, it meets with another to combine with; and this process will be continually repeated until it has arrived at the end of the line, when, finding no oxygen to unite itself with, it will make its appearance in the form of gas. In like manner, the first particle of hydrogen in the series, by its abandoning the first particle of oxygen, which finds no other particle of hydrogen to replace it, causes the oxygen to appear at that point in the form of gas. We have thus the two gases formed at each end, not from the same individual particle of water, but from the two which happen to be at that moment in contact with the wires. The production of the two gases will take place at the same instant in both places, each particle having only to move one step, that is, from one particle to the adjoining one, instead of having to traverse the whole extent of the line, and no current will be perceptible in the fluid. If this theory be correct, the operation of gravity in favouring the descending current of the heavier element, namely, oxygen, might be rendered sensible; and that this is actually the case, appears by an observation of Mr Sylvester, that when the wire giving out oxygen is placed at a much lower level than that which gives out hydrogen, the effect is sensibly greater than when the positions are reversed."

Similar explanations of the mode of transfer have been given by Dr Henry, and by Grotthus; and from the following passage in Sir H. Davy's last paper on the subject, it would seem that he entertained views somewhat similar:—"If it be supposed that the fluid is divided into two zones, directly opposite in their powers to the poles of the battery, the virtual change may be regarded as taking place in the two extremities of these zones nearest the neutral point; so that, by a series of decompositions and recompositions, the alkaline matters and hydrogen separate at one side, and oxygen, pure, or in union, at the other. In this way, the electricity may be regarded as the transporter of ponderable matters, which assume their own peculiar characters at the moment when they arrive at the point of rest." That visible motions are sometimes produced in fluid-conductors when transmitting the electric current, has been shown by Sir H. Davy, who noticed the very singular convulsive agitations into which mercury is thrown, when placed within the circuit of a powerful voltaic battery discharged through water. These motions, which are frequently of a violent and capricious kind, have also attracted the attention of Sir John Herschel, who, in 1824, made them a subject of very interesting research.

Before concluding this part of the subject, it should be remarked, that, in the production of the different effects arising from the operation of galvanism, a different law is observed with regard to each of these effects, according as the structure of the galvanic arrangement varies. Thus, a few metallic plates, of a surface containing two or three square feet, will be powerful in producing heat and light, and will therefore deflagrate metallic leaves placed in the circuit, and illuminate charcoal points vividly; but the battery which they form will display little power of electrical attraction and repulsion, will have comparatively little effect on sentient organs, scarcely producing any shock, and will act feebly in producing chemical decomposition. Thus the great battery of Mr Children, and the deflagrator of Dr Hare, which melted many feet of platina with ease, had no very remarkable power in effecting decomposition, or in giving shocks. If the same amount of surface, however, as existed in either of these arrangements, had been disposed in a battery, so as to have formed four times the number of plates, the result would have been a diminution of the burning effect, while it would have exhibited more evidently the different electrical states, and been more powerful in exciting sensations in animal organs, and in giving rise to chemical decompositions.

PHYSIOLOGICAL EFFECTS OF GALVANISM.

In treating of electricity, we observed that the energy of that fluid was chiefly exerted on the functions of the nervous system in living animals. It is shown in the production of sensation, in the excitation of muscular contraction, and in altering the products of secretion. The shock received by the human body from the voltaic pile is similar to that resulting from a large electrical battery very weakly charged. Twenty pair of plates are generally sufficient to give a shock which is sometimes felt in the arms. With a hundred pair, it extends to the shoulders. A continued flow of the current through the body is accompanied by a continued aching pain. The impression made upon some of the nerves of the face when they form part of the circuit, is accompanied by the sensation of a vivid flash of light. When a piece of zinc and a piece of copper are placed, the one above and the other below the tongue, which must be in a moist state, a peculiar taste is experienced. This is supposed to arise from the saliva of the mouth having been decomposed by the galvanic action, and not merely the effect of a direct impression of the electric current on the nerves of the tongue. When the current of voltaic electricity is made to pass along a nerve distributed to any of the muscles of voluntary motion, they are thrown into violent convulsive contractions. The susceptibility of some animals is very great, and numerous curious experiments may be performed with them. If an earthworm be placed upon a crown piece which lies upon a plate of zinc of larger size, it will suffer no inconvenience as long as it remains in contact with the silver only; but the moment it has stretched out its head, and touched the zinc, so as to complete the galvanic circle, it suddenly recoils, as if it had felt a severe shock. If the battery be powerful, small animals may be easily killed. Striking effects are produced by galvanism, in the muscles of an animal, after death, as long as they retain their contractility. The convulsions are so general as often to impress the spectator with a belief that the animal has been restored to the power of sensation, and that it is suffering the most cruel torture. The eyes open and shut in their sockets spontaneously, as if re-endued with vision; the nostrils vibrate, as in the act of smelling; and the movements of mastication are imitated by the jaws.

But the experiments which are calculated to produce the greatest terror and astonishment, are those made upon the bodies of recently executed criminals. The following is an account of one performed by Dr Ure, upon the body of a murderer named Clydesdale, and it is perhaps the most striking on record:—

GALVANISATION OF A DEAD BODY.

In the first experiment, one rod was connected with the spinal marrow, and the other with the sciatic nerve. Every muscle of the body was thrown into convulsive movements, resembling a violent shuddering from cold. One rod having been removed from the hip to the heel, the knee being previously bent, the leg was thrown out with such force as nearly to overset one of the scientific operators who attempted to prevent its extension. In the second experiment, the nerves and muscles connected with the respiratory organs were acted upon, and the effect was truly wonderful. Full and laborious breathing instantly commenced. The chest heaved and fell; the belly protruded and collapsed with the relaxing and retiring diaphragm; and this continued as long as the galvanic discharges were given. In the third experiment, one rod was connected with the eyebrow, and the other with the heel. Every muscle of the countenance was thrown into convulsive emotion, and every terrible passion became then fearfully embodied. In rage, horror, despair, anguish, and ghastly smiles, the expression of the murderer's face far surpassed the most fearful representations of a Fuseli or a Kean. One gentleman who was present at this awful exhibition fainted, and others were compelled to leave the room through terror or faintness. In the fourth and last experiment, one of the arms was electrified, and the fingers were set nimbly into motion like those of a violin player. The fist being closed, and the rod applied to the tip of the forefinger, it instantly extended, and from the convulsive agitation of the arm, the criminal seemed to point to the spectators, some of whom thought that he had come to life. It remains to be stated that the positive pole or wire connected with the zinc end of the battery was that which was applied to the *nerve*; and the negative, or that connected with the copper end, was that which was applied to the *muscles*. The battery consisted of 270 pairs of four-inch plates. Dr Ure, who deserves the highest praise for the admirable manner in which he conducted the above experiments, was of opinion, that, had the respiratory organs been acted upon before the body had lost a large quantity of blood from incisions having been made in it in various places, there is a probability that the malefactor would have been brought to life. But this event, he justly remarks, was scarcely desirable in the case of a murderer, however important in a philosophical point of view.

The effects of galvanism upon the functions of secretion are the most remarkable as well as the most inexplicable. That it acts especially, and in a peculiar manner, upon the gastric juice, a fluid essentially subservient to the process of digestion, there can be no doubt. Perhaps the various functional parts of the body form a sort of galvanic battery, by which a regular circulation of this subtile and mysterious fluid is kept up.

ELECTRO-MAGNETISM, OR MAGNETO-ELECTRICITY.

The strong resemblances between the phenomena exhibited by magnetism and electricity, were long ago pointed out by philosophers. The analogy was strongly corroborated by the fact often observed, that magnetism was communicated to bodies by a stroke of lightning, and that the compass needles of ships have lost their virtue, and had their polarity changed by a similar cause. Dr Franklin, in enumerating the points of analogy between lightning and electricity, remarks, that they both have the power, not merely of reversing the poles of magnets, but of completely destroying their magnetism. Other analogies were discovered; but it was not until 1819, when Professor Oersted of Copenhagen, led by theoretical views, established a most interesting relation between these two powers, and laid the foundation of the new science, called Electro-Magnetism. The facts which this philosopher discovered may be thus expressed:—

When a wire conducting electricity is placed parallel to a magnetic needle properly suspended, the needle will deviate from its original or natural direction. This deviation follows a regular law.

1. If the needle is *above* the conducting wire, and the positive electricity goes from right to left, the *north* end of the needle will be moved *from* the observer.

2. If the needle is *below* the wire, and the positive electricity passes as before, the *north* end of the needle will be moved *towards* the observer.

3. If the needle is in the same horizontal plane with the wire, and is between the observer and the wire, the *north* end of it will be *elevated*.

4. If the needle is similarly placed on the opposite side, the *north* end of it will be *depressed*. In these two experiments the needle must be very near the wire.

From these simple facts, Mr Oersted concludes that the magnetical action of the electrical current has a circular motion round the wire which conducts it.

The metallic wire to be made use of in this experiment, should be two or three feet in length, to allow of its being bent in various directions. It is called the *conjunctive wire*. Ampère and Davy discovered two very important facts soon after Oersted had made his experiments public—namely, that the conjunctive wire itself becomes a magnet, and that magnetic properties might be communicated to a steel needle, not previously possessing them, by placing it in the electric current; and the degree of magnetic power thus communicated, Davy showed was always proportional to the quantity of electricity transmitted through it. When the conjunctive wires of two distinct galvanic batteries are made to approach each other, they exhibit magnetic attractions and repulsions. Two wires of copper, silver, or any other metal, connecting the extremities of two galvanic troughs, being placed parallel to each other, and suspended so as to move freely, immediately attract and repel each other, according as the directions of the currents of electricity flowing through them are the same or different.

Upon this experiment is founded the most plausible theory of magnetism, viz., that it arises from the attractions and repulsions of currents of electricity, constantly circulating round every magnet. This is conceived to explain the reason why the magnetic needle places itself at right angles to a wire conducting electricity, namely, that the current passing along the wire may coincide with that circulating round the magnet. Dr Faraday has considerably extended our knowledge upon this interesting subject; and, by some beautiful experiments, he has clearly proved the tendency which one of the poles invariably has to move always to the right and the other to the left.

Reviewing the various experiments which have been made upon this subject, it seems clearly proved that electricity and magnetism are identically the same. A permanent magnet is supposed to be thus constituted:—It is a mass of iron or steel, round the axis of which electric currents are constantly circulating, and these currents attract all other electric currents flowing in the same direction, and repel all others which are moving in an opposite direction. The electric currents flow round every magnet in the same direction in reference to its poles. For instance, if we place a magnet with its north pole pointing to the north, in the usual position of the magnetic needle, the current of electricity flows round it from west to east (that is, the direction in which the earth and other planets revolve round the sun), or, on the eastern side of the magnet, it is moving downwards, and on the western side upwards, on the upper side from west to east, and on the lower side from east to west. This is found to be a uniform law. To complete the view of this doctrine, it remains only to explain the influence of the earth on the magnet, by which the needle is kept always in one position, nearly coinciding with the meridian. It is conjectured that currents of electricity, analogous to those which circulate round every magnet, are constantly flowing round the globe, as the current of electricity in a galvanic apparatus moves in an unbroken circuit from the negative to the positive pole, and from it, by the connecting wire, round again to the negative pole. The direction of these currents is inferred to be the same as has been stated with regard to artificial magnets; and it is simply by the attractions and repulsions of these terrestrial currents, bringing the currents round the needle to coincide with them, that the latter always points to the north.

To detect these currents, and to prove the truth of the whole theory, many ingenious experiments have been made; but as an account of them is incompatible with our limits, we refer the reader to the best work upon the subject—that of Mr Watkins of London.

To conclude: With regard to the abstract nature of this singular agent whose properties we have described, the first question that presents itself is, whether it be a material substance or not. Although many of the phenomena seem at first sight to indicate that such is the case, yet, after due consideration, they will be found resolvable into the sudden action of a repulsive power exerted amongst the particles of matter situated in a continuous line. The materiality of electricity, indeed, still rests upon a similar foundation with that of heat and light, which, as we observed in the number of this work devoted to Chemistry, is still a disputed point. We have already spoken at sufficient length upon the subject of there being one or two fluids. We may remark, that as all the facts can be explained by either of the two hypotheses, and as we are still in ignorance whether or not it be a *fluid* at all, speculation upon it, however amusing, is utterly useless.

THE EAST INDIES.

GEOGRAPHICAL BOUNDARIES.

INDIA, or Hindostan, or the East Indies, as it is called, to distinguish it from the West India Islands, is a large country in Asia, forming, as may be seen by the adjoining map, an extensive triangular-shaped territory, pointing with its narrow peninsular extremity southward to the Indian Ocean. India is nearly comprehended between the latitudes of 8° and 35° north; its extreme length from north to south is about 1900 miles, and from east to west about 1500; its superficial area measures 1,280,000 miles. The northern boundary of this extensive region is formed by a range of mountains running from east to west, which are higher than any other on the surface of the globe, some of them reaching 15,000 feet above the level of the sea: they are called the Himalaya Mountains, from an Indian word, "heem," signifying snow—some of their peaks being perpetually clothed with ice and snows. From the extremities of this mountain-chain flow two large rivers, which form on either side the boundary of India; that on the east is called the Brahmaputra, and that on the west, the Indus—a river from whose name the whole country has derived its present designation. Each of these streams with their tributaries waters an immense tract of fertile country, and affords excellent means of internal trade to the people situated on its banks. From the mouths of these rivers the coast stretches both ways to the southward, the eastern and western side inclining to the same point, so as to meet at Cape Comorin. Beyond this, the adjoining Island of Ceylon extends a little farther outward, and reaches to within about six degrees of the equator.

MAP OF THE EAST INDIES.

This large country presents a great variety of surface, being diversified in some places with wide sandy deserts; in others with fine undulating hill countries, well watered and fertile; a third portion consists of flat high-lying regions, called table-lands, which, from their height above the sea, are cool and temperate; and a fourth division consists of immense fertile plains, watered by the large rivers of the country, and their numerous tributaries. A considerable portion of the low-lying country is of a marshy shrubby character, called jungle, and unfitted for cultivation. Each of these divisions of India presents an aspect peculiar to itself, and all of them are distinguished by natural productions, both plants and animals. Besides the Indus on the west, and the Brahmaputra on the east, there are other large and important rivers descending from the outskirts of the Himalaya Mountains, or from ranges of hills called Ghauts, and descending to the sea both on the east and west coasts. The principal of these streams is the Ganges, which, with its tributaries, drains a large portion of the north-east division of the country, and enters the sea in the province of Bengal, along with the conjoined waters of the Brahmaputra. The valley of the Ganges, and the vallies of its tributaries, form the fairest and richest portion of India. This district, in its largest extent, may be described as a semicircle with its base extended along the line of the Himalaya Mountains, and its curve running along from Boodiana on the Indus, to Delhi, Gualior, Punnah, Sumbhulpoor, and Balasore, where it meets the sea and the mouths of the Ganges, thence along the coast to Chittagong, and north by Silhet and Rungpore, to include the country of the Brahmaputra.

The first sight of India to European voyagers has little which can please or interest. The coasts are remarkably flat, and frequently dangerous to approach through the raging surf; the shore is only discernible by the tall cocoa-trees which surround the villages or temples. This extreme flatness of the shores of India is one of the peculiar distinguishing traits of the country, and is exceedingly disadvantageous in a maritime commercial point of view.

The southern district of this magnificent valley is called Bengal, and extends along the sea from Chittagong to Balasore, about four hundred miles, and reaches about the same distance northward. The sea-coast is not the most fertile or useful part of this territory; great part of it towards the centre being composed of marshy ground, or of mud islands, among which the branches of the river are spread like network. These islands are covered with a rank vegetation of reeds, which are sometimes twenty or thirty feet high; or with trees and underwood so tall and dense, that it is impossible to penetrate them. They afford shelter to tigers and other wild animals, but the air of the whole of them is pernicious to health. About 150 miles upwards, the soil becomes higher and less marshy, so as to afford good ground for cultivation; and the country is here fertile and thickly peopled. It is in this district, immediately above the mouths of the Ganges, that Calcutta, the capital of British India, is situated. The inundations of the Ganges cover and fertilise immense tracts of the level country near the river, while others more remote procure the same advantages from an artificial irrigation. Luxuriant fields, divided by groves of tall trees, with villages under their shelter, and swarming with a population beyond any thing that Europe can show, form the general features of the vast alluvial plain of Bengal.

DIVISIONS OF THE COUNTRY.

The modern territorial and political subdivisions of India may thus be specified:—First, NORTHERN HINDOSTAN, an extensive and rugged territory, comprehending—

1. The country between the Sutuleje and Jumna	4. Kemaoon
2. Gurwal or Serinagur	5. Painkhandi
3. Sources of the Ganges	6. Bhutant
	7. Dominions of Nepaul

Second, HINDOSTAN PROPER, which is the most comprehensive division.—It stretches across the centre of India, and obtains the most prominent place in the history of the old Mahommedan empires of India. It reaches south to the Nerbudda river, where the Deccan commences, and includes the following thirteen large provinces:—

1. Bengal	8. Cashmere
2. Bahar	9. Ajmeer
3. Allahabad	10. Moultan
4. Oude	11. Cutch
5. Agra	12. Guzerat
6. Delhi 7. Lahore	13. Malwa

Third, THE DECCAN.—This division lies next in a southerly direction to the above, extending from the Nerbudda river on the north, which flows into the sea on the west coast, to the Krishna, a river flowing into the sea or Bay of Bengal on the east coast. Between these rivers lies the Deccan, a much less fertile division of India than the preceding; Bombay, a small island on the west coast, belongs to the province of Aurungabad in this division. The Deccan comprehends the following provinces, a portion of which once formed the Mahratta empire:—

1. Gundwana	6. Beeder
2. Orissa	7. Hyderabad
3. The Northern Circars	8. Aurungabad
4. Candeish	9. Bejapoor
5. Berar	

Fourth, India South of the Krishna.—This division forms the extreme southerly portion of the Indian peninsula, and comprehends the following provinces:—

1. Canara	6. Mysore
2. Malabar	7. Coimbatoor
3. Cochin	8. Salem, and the Barramahal
4. Travancore	
5. Balaghaut, ceded districts	9. The Carnatic, in which is situated Madras

Besides the foregoing divisions and provinces, the large territories of Ave and the Burmese empire, lying east from the Brahmaputra, are now attached to India, besides other conterminous regions in different quarters.

HISTORY.

What was the original political condition of the vast territory now composing the British Indian empire, it would be needless to detail minutely. Like other portions of Asia, it was early inhabited by a primitive people, more or less barbarous, professing different pagan religions, and speaking many more different languages. The principal religion, however, was Hindooism, which we shall afterwards allude to; and it has been said by some historians that the early Hindoo race of inhabitants manifested many symptoms of civilisation, and even a knowledge of some of the sciences. However this may have been, the inhabitants generally were in some measure an industrious but simple race, and little inclined to war. Reasoning from what has occurred in their history, as well as from the information communicated regarding them, they seem, from the earliest times, to have had little or no care with regard to who ruled over them, provided they were insured in the possession of their ancient religious usages, and their system of living in small communities under a primitive species of local government. They were reckless of what sovereign was placed over them, or to what dynasty they were transferred, so long as the internal economy of their village districts remained the same. This species of political apathy produced the results which might have been expected. From the most remote period of which any record is preserved, the inhabitants of India, including those tribes which possessed more decided warlike propensities, or who had the spirit to resist aggression, were subjected to the government of strangers, who seized upon their territories, and made them the objects of taxation. Among other warlike princes who thus made inroads on the country, Alexander the Great, in the course of his ambitious career, marched with an army to India, the northern part of which he conquered.

Of this remote period of Indian history, little is correctly known: all that may be said of it is, that both the Greeks and Romans were supplied with some of their articles of luxury from Hindostan, and that for many centuries this eastern clime was supposed, by the ill-instructed inhabitants of distant parts of Asia and Europe, to be the richest and most sumptuous country on the globe. The tales related of Indian grandeur appear to have in time excited the avarice and ambition of Mahommedan or Saracen chiefs. The first of this barbarous though intrepid race, who made a successful inroad upon India, was Mahmoud, sultan of Ghizni, or Afghanstan, a kingdom on the north-west of India. Mahmoud commenced his successful expeditions into India about the year 1000, and he continued them till 1024, making the destruction of pagan idolatry more the object of his visits than the acquisition of wealth or power. In this period of twenty-four years he had subdued a considerable number of the native princes, and, notwithstanding his professions, exacted immense tributes in gold and every kind of valuable commodity. A successor of Mahmoud, named Mahommed, after carrying on war with the Indian princes for some time, at length, about the year 1193, entered Hindostan with an exceedingly large force, and bore down all opposition. The king of Delhi was slain in battle, and having advanced to that ancient capital, Mahommed there left a viceroy to maintain his authority. In this manner a Mahommedan dominion was for the first time established in the heart of India, and in one of its greatest cities, and thus commenced the Afghan or Patan sovereigns and their dynasty.

The dynasty so planted continued in existence for rather more than three hundred years, when, in 1525 or 1526, it was subverted by Baber, who was considered one of the most adventurous warriors of his time, and who, like his prototype Mahommed, was of the Moslem faith. Baber was either descended from a Mogul or Tartar chief, or in some way, not clearly explained by historians, connected with a race called Moguls, who assisted him in his attempts upon India; and from causes of this nature, the empire which he founded in Hindostan has ever since been called the Mogul empire. From the year 1526, a series of Mahommedan emperors, whose seat of authority was at Delhi, ruled the largest and finest portions of India. By them the country was in many places newly subdivided into provinces, and put under the government of tributary kings or nabobs, who superseded the Hindoo rajahs or petty princes. One of the greatest of these Mogul emperors was Akbar, who flourished between the years 1556 and 1605. By his daring and judicious management, the central provinces were preserved in complete tranquillity, and Guzerat, Bengal, and part of the Deccan, were added to his already extensive empire.

BEGINNING OF EUROPEAN INTERCOURSE.

While the emperors of India were thus establishing their power, multifarious schemes were formed in Europe for getting possession of some of the wealth, if not some portions of the territory, of Hindostan. The commodities of Indian manufacture or produce were hitherto imported into the European states only by means of tedious overland journeys, or partly by the Red Sea, and were endangered in their passage by the attacks of ferocious Tartar and Turkish tribes. The discovery of a new and safe road to India thus became a matter of very great consequence. A route by sea round the Cape of Good Hope was at last found by the Portuguese, who, under the command of Vasco de Gama, in 1498, landed in Hindostan, on the coast of Malabar, where they at once established themselves. The whole commerce of the East Indies was now in the hands of the Portuguese for nearly a century—and this was the golden age of Portugal. Lisbon became the great depôt of Indian spices and other commodities, greatly to the envy of the Dutch and other nations. Portugal was united to Spain in 1580—the Spaniards oppressed Holland, and caused it to revolt—this revolt was followed by the capture of the Dutch ships trading to Lisbon—and this capture compelled the Dutch to engage in a direct trade to India. The English soon followed their example. The political and spiritual tyranny of the Portuguese in India, as well as the abuses which they permitted in commerce, gradually subverted their power, and divested them of respect. The Dutch and English, therefore, found every thing in that state of division which is favourable to the establishment of a third party. The Dutch established an East India Company in 1602, and a prosperous trade was thereafter carried on. The Dutch adopted quite a different line of policy from that of the Portuguese in their transactions with India. They cared nothing about the religion of the Hindoos, and set up no inquisition to force Christianity on those they dealt with; all they wanted was commercial intercourse, and their excellent management soon secured them in a large share of the Indian traffic. They possessed themselves of Batavia, in the island of Java; in 1641, they acquired Malacca, the capital of the Portuguese East Indies; they subsequently acquired the Cape of Good Hope for a settlement; and these colonies were a great assistance to the intercourse between Europe and India. The Dutch subsequently acquired a number of other possessions in the East; but most of these came afterwards into the possession of the British.

RISE OF THE EAST INDIA COMPANY.

We now enter upon the history of the rise and progress of the British power in India. The English became animated with a desire to open a commercial intercourse with India as early as the reign of Edward VI. (1553); but their expeditions failed in reaching the desired country, from their want of geographical knowledge: and it was not till the shutting of Lisbon against the Dutch, that they were so far excited as to persevere in their maritime attempts till they were successful. They at length learned which was the true course to steer for India; whereupon, in 1600, a company of merchants was formed in London to prosecute the traffic with the East; being empowered to do so by a charter from Queen Elizabeth, which was to last fifteen years. The first expedition of these adventurers cost L.69,091, and consisted of five ships, the largest of which was 600, and the smallest 130 tons burden. The articles which they took were principally bullion, iron, tin, broad-cloths, cutlery, and glass. Their expedition proved remarkably successful, and led immediately to a repetition of annual voyages of the same nature. This early trade was nevertheless considerably hampered by the Portuguese; and it was found necessary to try to secure the favour of the Mogul emperor. In 1607, therefore, Captain William Hawkins was sent out by the Company, to endeavour if possible to open a commercial intercourse with the dominions of the Mogul. Hawkins, after surmounting great difficulties placed in his way by the Portuguese, reached the court of the Mogul emperor Jehangire, son of the famous Akbar, already mentioned. This visit was unfortunately of no avail, from the pernicious interference of the Portuguese Jesuits; and another English mission, on a greater scale, and from the king, was sent forth in 1615. This embassy, which was conducted by Sir Thomas Roe, proved more successful in securing the favour of the Mogul, but did not lead to any important results. The affairs of the Company, nevertheless, continued prosperous, and factories were in many places planted on the coasts of India. These factories were warehouses for the reception of native produce, and the storing of imported goods from England, and were no doubt of considerable use in the objects of their establishment. From the real or pretended dread of being attacked by marauders, the keepers, merchants, and servants, at these places, at length began to strengthen the defences; and so, from being mere mercantile warehouses, the factories partook of the decided character of armed garrisons. It does not appear that the native powers of India took any active measures to prevent this insidious process of planting settlements. The natives were fond of dealing with foreigners, and the princes were so eaten up with jealousy of each other, that the British always contrived to gain the friendship of one by taking part against another, and in the end getting the advantage of both. Besides, it was not for some time that the British disclosed any intention of securing the jurisdiction of provinces, or a property in the soil. A watchful hypocrisy led them to yield, on all occasions, a reverence towards the political sway of the native emperors, rajahs, and nabobs. The original East India Company, with its charters at different times disputed and renewed, continued throughout the seventeenth century to carry on a profitable traffic with the East. Its factories were extended to Java, Sumatra, Borneo, the Banda Islands, Celebes, Malacca, Siam, the coasts of Malabar and Coromandel. In 1640, the native authorities gave permission for the building of Fort St George, at Madras; and in 1645, a factory was established on the banks of the Hooghley, a branch of the Ganges near its mouth, which formed the foundation of Calcutta. The island of Bombay was also procured as a settlement in 1664-5, after a struggle with its Portuguese possessors. The affairs of the Company were not, however, in a prosperous state; and soon after the revolution of 1688, the question of the validity of the old royal charter was started. The consequence followed of the Company not being able to perform its obligations, on account of losses occasioned by wars, infidelity of officers, extravagance, &c.; and Parliament, in 1698, granted a charter to a new East India Company, on condition of a loan of L.2,000,000 sterling to the state, and which was required to carry on King William's wars. But the great contentions between the two Companies soon made it necessary to unite them, and a union was effected in 1702, when an act of Parliament was passed, establishing the conjoined association under the title of the United Company of Merchants trading to the East Indies. Stock was raised by the sale of shares, and the shareholders to a certain amount were entitled to elect the directors of the Company.

The progress of the Company's settlements in India was, on several occasions about this period, caused by the superior skill of the British in medicine. In 1715, an embassy being sent on a commercial commission to Delhi, it happened that a medical gentleman named Hamilton, who accompanied the factory, had the good fortune to cure the emperor Feroksere of a severe illness, which could not be overcome by the ignorant native physicians. In gratitude for this important service, though it is likely some very valuable presents from the Company had an equally liberalising effect, the emperor granted liberty to the Company to purchase in Bengal thirty-seven townships in addition to that of Calcutta; he also conferred upon them some important commercial privileges, which soon rendered Calcutta a flourishing settlement.

The charter of the East India Company was from time to time renewed during the eighteenth century, though, but not without great difficulty, against a powerful opposition. But loans to government carried them always through these embarrassments. In 1744, they advanced L.1,000,000 at three per cent., in consideration of an extension of their privileges till 1780. Hitherto we have seen this company of English merchants acting only for the avowed object of commercial intercourse with India; we now open a new page in their history, and show the origin of their political power.

THE COMPANY'S ASSUMPTION OF POLITICAL POWER.

The East India Company assumed the qualifications of a military and political power in the year 1748. But their advances towards territorial dominion were retarded by a rival, which gave them no small trouble. This competitor was France, which had in the meantime hastened to share in the commerce and spoils of India. In 1746, a French battalion had destroyed the army of the nabob of the Carnatic, and soon after the French officers succeeded in disciplining Indian troops according to the European method. The inferiority of the native Indian troops opposed to European soldiers, and the facility of instructing Indian soldiers, known by the name of *Sepoys*, in the European tactics, was thus proved. Ambition and avarice, political and mercantile cunning, could now act on a larger scale; and the independence of the Indian princes was gone whenever this trading Company, which was already encroaching upon all the rights, both of the rulers and the people of these countries, should establish a permanent military force. Thus far the military organisation of the Company had been merely on the defensive; it now became able to act offensively; and the entire difference of the European and Indian notions of law could never fail to furnish opportunities to put this new means of power into action. The rights of succession, and all the rights of princes, subjects, and families, were so much disputed on the different principles of the Indian, Mahommedan, and British laws, that the Company, which often interfered as arbitrator, easily succeeded in extending their legal jurisdiction. If called to account in England for any of its undertakings, it was easy to uphold the correctness of its conduct, politically, on the ground of self-defence, which, at the distance of several thousand miles, could not be called in question; and, in legal matters, by taking advantage of the impenetrable labyrinth of the law. Edmund Burke, who experienced, in the case of Warren Hastings, the head of the Company's affairs in the east, this impregnability of the association, accused them justly "of having sold every monarch, prince, and state in India, broken every contract, and ruined every state who had trusted them." In 1749, the robberies of the Company began with the protection of the pretender of Tanjore, a fine province of the Carnatic. Under pretence of illegitimacy, the nabob of this district was driven out for the purpose of obtaining some cessions of territory, and then restored on making further concessions. The rapid progress of the Company in the art of extending their possessions, appears from their treaties with the Surrajah-Dowlah, the nabob of Bengal, whom they contrived to depose in 1757, when large and rich provinces were the reward of their faithless policy. The French, who in a similar manner had acquired considerable territorial possessions in the Carnatic, now came into collision with the British merchants, and a hot war was carried on in India between these contending Europeans. The indecency of this conflict as to which party should be the greatest robber, seems to have shamed both France and England, and commissioners were mutually sent to India to reconcile the differences which existed, as well as to check the acquisition of territory either by the English or French companies. As a matter of course, this affectation of justice ended in nothing. After the commissioners had agreed that each should restore its acquired territories, and after a "solemn" treaty to that effect had been arranged, hostilities commenced as before. It would be needless to recount the particulars of this struggle for power; it will suffice to state, that the French ultimately were deprived by the British of their possessions.

OVERTHROW OF THE MOGUL EMPIRE.

By the defeat of the French forces in 1761, the British were left at liberty to pursue their schemes on India, being in no small degree favoured by the unhappy political condition of the Mogul empire. This large empire came under the rule of Aurungzebe, a descendant of Akbar, in 1658, and his reign lasted till his death in 1707. Under this celebrated Mahommedan emperor, the empire of the Moguls came to the height of its glory, and attained its largest extent. After Aurungzebe had added to it the kingdoms of the Deccan, it included nearly the whole peninsula of Hindostan, with the neighbouring regions of Cabul and Assam. The revenues extorted from this populous and wealthy territory amounted to L.32,000,000 sterling. During the reign of Aurungzebe, it was attacked by the Persians under the bold prince Nadir, and also by a growing nation, called Mahrattas, whose kingdom comprehended large portions of the provinces of Malwa, Candeish, Aurungabad, and Bejapore, in the Deccan. By Nadir, and his successor Ahmed Abdalla, the Mogul empire, after the death of Aurungzebe, was almost entirely subverted to the character of a tributary to the Persians. Under these circumstances there was scarcely a native power that did not consider itself entitled to trample on the feeble authority of the throne of the Mogul; and between the Afghans, whose kingdom lay to the north-west, and the Mahrattas, the empire was distracted, and made the object of greedy contest. The Afghans were at length victorious over their enemy; and in 1753 they placed a descendant of the old dynasty on the throne, and in the possession of the empty but still venerated title of Great Mogul, to be the tool or captive of the first daring power which should seize the capital.

HYDER ALI AND TIPPOO.

From this period the dignity of the empire was at an end, and a favourable opportunity was offered to the various dependent princes to throw off their allegiance, as well as to enterprising chiefs to take advantage of the unsettled state of things, and establish new kingdoms for themselves. In this state of general revolution, a bold Mahommedan adventurer arose from an obscure rank, named Hyder Ali, who, by summoning round him bold and predatory bands, and waging war with considerable address, established his power as a sovereign in the Mysore—a territory forming one of the most remarkable of those elevated table-lands that diversify the southern provinces. Hyder was succeeded in 1782 by his son Tippoo, a person equally bold, though less prudent and fortunate. Against both these powerful rulers the British for a number of years waged war with various success. In 1792, Seringapatam, the capital of the Mysore, was besieged by the Marquis Cornwallis, with a strong British army, and after some show of resistance, Tippoo was fain to offer terms of surrender. He agreed to give up half of his dominions, and pay L.3,560,000 in bullion. For the fulfilment of the treaty he was under the necessity of giving up two of his sons as hostages. Having fulfilled his engagement, these young princes were returned in 1794; but after this he again commenced hostilities, and in 1799 the British forces, under General Baird, once more attacked and now captured Seringapatam. In the general slaughter which occurred in entering this strongly-fortified place, Tippoo was shot, and his body was afterwards found among a heap of the slain. Thus terminated a dynasty which, though short, and limited in respect of territorial dominion, was undoubtedly the most vigorous and best organised of any that had sprung out of the wreck of the Mogul empire. The principal war in which the East India Company was engaged after this successful contest, was that with the Pindarees, roving tribes of Mahrattas, who, without any territory, carried on predatory warfare against all whom they could rob with impunity. The war with the Pindarees was one of great difficulty, and it cost the British a number of years before they finally quelled them. The Pindaree war terminated in 1817, and it was followed by a contest betwixt the British and the Birman empire, which was successfully closed in 1826, and by which the Company gained a considerable territory along the Bay of Bengal, east of Brahmaputra river. By the foregoing, and other less conspicuous contests with native princes, among which may be reckoned the war against the Nepaul, in 1814, and also by means of purchases, negociations, and voluntary or involuntary renditions of territory, including the capture or cession by treaty of the French and Dutch settlements, the British power was at length established as supreme over nearly the whole of India.

EXTENT AND POPULATION OF INDIA.

The following has been given by the best authorities as an estimate of the extent and population of the territories now included in British India:—

	Square Miles.	Population.
Presidency of Bengal,	220,312	69,710,071
Districts, the population of which is doubtful,	85,700	...
Madras,	141,923¼	13,508,535
Bombay,	59,438½	6,251,546
Districts, the population of which is doubtful,	5,550	...
	512,923¾	89,470,152

The population of the above doubtful districts is probably not large, so that the whole will not much exceed ninety millions. The territory of the allied or protected, that is, the subject states, is estimated at 614,610 square miles; their population, however, is not supposed nearly equal to that of the territories under the immediate government of the Company. Mr Hamilton, in the second edition of his East India Gazetteer, estimates it as follows:—

The Nizam,	10,000,000
The Nagpoor Rajah,	3,000,000
The King of Oude,	3,000,000
The Guickwar.	2,000,000
The Satara Rajah,	1,500,000
The Mysore Rajah,	3,000,000
Travancore and Cochin,	1,000,000
Kotah, Boondee, and Bopaul,	1,500,000
Rajpoot and other petty states,	15,000,000
	40,000,000

The same author makes the following conjecture as to the states that still remain independent:—

Sindia,	4,000,000
Lahore, Rajah Runjeet Singh,	3,000,000
Sind,	1,000,000
Nepaul,	2,000,000
Cashmere and other districts belonging to the King of Cabul,	1,000,000
	11,000,000

This would give for the whole of India a population of upwards of 140 millions; but in the foregoing estimate, notice is not taken of the portion of India beyond the Ganges, including part of the Burmese territory, having, according to Mr Hamilton, an extent of 77,000 square miles, and a population of 301,000.

GOVERNMENT OF INDIA.

Hitherto the Company have governed their Indian territories by means of the presidencies of Calcutta, Madras, and Bombay, each of these places being the head-quarters of a local military and civil government. In future there will be another presidency, that of Agra, a place of note in the interior. The whole are under the supreme control of a governor-general appointed by the British court; these governors-general seldom retain their situations above a few years, there having been no fewer than nine from the year 1798 till the appointment of Lord Bentinck in 1828. Mr Pitt, in 1784, passed an act establishing a Board of Control, composed of six privy councillors, to superintend the territorial concerns of the Company, which check is still continued, and reappointed under the act of 1833. To retain possession of so large a territory as India, the Company require to keep up a numerous and well-appointed armed force, which is composed chiefly of natives or sepoys, with British officers, and partly of troops raised in Great Britain. The Company further employ a number of king's regiments, who have double pay allowed them. Mr Hamilton gives the following statement of the amount of the forces employed:—

Artillery,	15,782
Native cavalry,	26,094
——— infantry,	234,412
Engineers,	4,575
King's troops,	21,934
Total,	302,797

Of these the irregulars of all descriptions amounted to 82,937 men. This formidable army of native and European soldiers is distributed throughout Hindostan, at appointed stations, forming a chain of military posts, and keeping up a continual communication with the seats of the various presidencies.

The relations which subsist betwixt the Company and the tributary and dependent states may thus be described:—The Company undertake the defence of the dependent prince's territories against all enemies, domestic or foreign. He is bound, on the other hand, to enter into no alliances with other sovereigns or states without the Company's consent; and he pays them a certain annual subsidy out of his revenues for their protection, while he generally keeps up an army at the same time for the maintenance of internal tranquillity. In some cases, instead of paying a subsidy, the prince cedes a portion of his territories, of which the Company draw the entire taxes. The Company keep a resident at the prince's court, who is entitled to demand an audience at any time; and by this agent, the Company do in fact interfere pretty regularly in the internal concerns of the state, particularly in settling the succession to the throne. The princes are in reality mere viceroys, or rather tax-collectors for the Company; and when in any state gross mismanagement or breach of engagement repeatedly occurs, these pageants are dethroned and pensioned off, and the Company take the government of the country into their own hands. The Company's protection is often found to shelter internal misgovernment; for the prince being secured by the British army against the resentment of his own subjects, is tempted to indulge the more freely in extortion and oppression.

REVENUE SYSTEM OF INDIA.

To sustain not only the above military force, but the civil management of India, a revenue of L.22,000,000 requires to be levied. About two-thirds of this large sum is derived from a tax on land; and as the mode of collecting, imposing, and administering it, enters deeply into the system of Indian policy, and has a powerful influence on the social condition of the people, we shall here attempt its explanation.

Under the old Mogul empire, the sovereign was considered the universal proprietor of the soil; but the ryots, or cultivators, or actual owners, were held to have a perpetual right of occupancy, so long as they paid the fixed annual tribute or rent demanded by the sovereign. The rent was fixed at a third, and sometimes at a half, of the value of the produce, and the functionaries appointed to ascertain the amount leviable and to collect it, were called zemindars. In 1793, Lord Cornwallis, governor-general, with a view to establish a better system for all parties, changed the zemindars from the character of hereditary tax-collectors, to that of proprietors of the soil, though still accountable to government for the rent. This created a vast deal of misery at the time; thousands of poor ryots were ejected from their ancient possessions; but ultimately the country at large was benefited. It was arranged that the sum payable by the ryot for several years, should be fixed as the permanent rent; one-tenth of this was allowed as the zemindar's share, and the other nine-tenths the proportion payable to the government or Company. The rent paid to the Company being fixed, great quantities of land which had been "concealed," that is, left out of the rough and partial returns formerly made, and which had lain in a wild state, or in pasture, were now put under crop. The practice is, to allow the ryot to occupy waste lands rent-free, for three years, and to charge only a moderate rent for a few years more. In this way a considerable extension of cultivation has taken place; and some of the zemindars acquired wealth. From their improvident habits, however, such wealth seldom lasts more than one generation; and no progress has been made towards the institution of a rural aristocracy. The Company have begun very recently to retrace their steps. When zemindaries fall into their hands, as they are always doing from time to time, by the inability of the holders to fulfil their engagements, the Company replace the ryots as nearly as they are able in their original situation, allowing them to hold their lands under payment of a rent which remains fixed, either permanently, or for a period of years. The Company in this case come in the room of the zemindar, and collect the rents in detail from the ryots by their agents.

This system of "zemindary settlement" prevails generally in Bengal, Bahar, Orissa, and Benares. It has also been tried on a small scale in the Madras presidency, but with very bad success; but in a modified form it has long existed in some parts of Southern India, where hereditary chiefs, called polygars, occupy a similar situation to that of the zemindars in Bengal.

There are other two modes of collecting the rent or land-tax (for it may receive either name); the *Ryotwar*, and the *Mouzawar*.

The ryotwar was first extensively introduced by the late excellent Sir Thomas Munro, when governor of Madras, in 1802. In this system, the government collects the rent directly from the ryots, without the intervention of zemindars. An actual survey was made with great labour and expense, of the lands of the villages in which it was attempted to fix the extent and value not merely of every occupancy, but of every field. The records showed the whole sum which the village had paid in former years; and from this, with the opinions of practised assessors, checked and guided by the advice of the village potail and curnum (the headman and accountant), an estimate was formed of the gross produce, forty-five per cent. of which was assumed as the rent. The sum thus ascertained was fixed as the maximum which the tenant should be called on to pay. The rent is taken from the ryots in monthly payments, and very summary means are used to extort it. The system was extremely unpopular at its introduction, and occasioned great distress; but this was attributed to the excessive amount of the tax, rather than to defects in its imposition. The reader should be told, that the perquisites of the potail, curnum, brahmin, astrologer, schoolmaster, and a long train of other village functionaries, are supposed to absorb ten per cent. of the ryot's crop, so that the forty-five per cent., which government took in a good year, was, and was meant to be, one-half of the clear produce after this deduction was made. In consequence of the outcry against the tax, considerable abatements were made; and the *ryotwar* system remains in operation in a part of Madras presidency at this time, with, we believe, comparatively few complaints.

Village Settlements.

The third system is the *Mouzawar*, or "village settlement." A village in India does not mean a collection of houses at a particular spot, but corresponds to what is called a township in America. "It is a tract of country (says Mr Hamilton) comprising some thousands of acres of arable and waste land; politically viewed, it resembles a corporation or township. Its proper establishment of officers and servants consists of the following descriptions:—The potail, or head inhabitant, who has the general superintendence of the affairs of the village, settles the disputes of the inhabitants, attends to the police, and performs the important duty of collecting the revenues within his village—a duty which his personal influence, and minute acquaintance with the situation and concerns of the people, renders him best qualified to discharge. The curnum, who keeps the accounts of cultivation, and registers every thing connected with it. The tallier (constable), or totie (watchman); the duty of the former appearing to consist in gaining information of crimes and offences, and in escorting and protecting persons travelling from one village to another; the province of the latter appearing to be more immediately confined to the village, consisting, among other duties, in guarding the crops, and assisting in measuring them. The boundary man, who preserves the limits of the village, or gives evidence concerning them in cases of dispute. The superintendant of the tanks and watercourses, who distributes the water therefrom for the purposes of agriculture. The brahmin, who performs the village worship. The schoolmaster, who is seen teaching the children in the villages to read and write in the sand. The calendar brahmin, or astrologer, who proclaims the lucky or unpropitious periods for sowing and threshing. The smith and carpenter, who manufacture the implements of agriculture, and build the dwelling of the ryot. The potman, or potter. The fisherman. The barber. The cowkeeper, who looks after the cattle. The doctor. The dancing girl, who attends at rejoicings. The musician and the poet. These officers and servants generally constitute the establishment of a village; but in some parts of the country, it is of less extent, some of the duties and functions above described being united in the same person; in others, it exceeds the number of individuals which have been described. Under this simple form of municipal government, the inhabitants of the country have lived from time immemorial. The boundaries of the villages have been but seldom altered; and though the villages themselves have been sometimes injured, and even desolated, by war, famine, or disease, the same name, the same limits, and even the same families, have continued for ages. The inhabitants give themselves no trouble about the breaking up and division of kingdoms; while the village remains entire, they care not to what power it is transferred, or to what sovereign it devolves; its internal economy remains unchanged; the potail is still the head inhabitant, and still acts as the petty judge and magistrate, and collector, or renter, of the village."

It will be understood that under the zemindary settlement, the government transacts with one individual for an extensive district, probably as large as a county; under the mouzawar or village settlement, it transacts with the chief person of the village for the whole community; and, under the ryotwar settlement, it transacts with each individual cultivator. It may be proper to add, that in India a ryot seldom holds more land than he and his family are able to cultivate, and that there are few farm servants in our sense of the word.

Of the three modes of settlement, it may be stated that the zemindary plan has yielded the largest revenue; the method of "village settlement" does not cause much more trouble to the government, and is better liked by the cultivators; the ryotwar is the most expensive and troublesome, and has been the least productive of revenue; but it would be the most equitable and most advantageous to the people, if the ends of justice were not defeated by the frauds of the native officers entrusted with its details, and whose corruption is almost universal.

The revenue derivable from land by these various processes of exaction, amounts, as has been said, to two-thirds of the whole revenue of the Company, or the sum of L.14,000,000. The next greatest head of revenue is the receipt from native princes, or from ceded and conquered countries, and which averages in amount from L.7,000,000 to L.8,000,000.

The Company have hitherto gained a million sterling per annum by the monopoly of opium. They have offered a price annually, which has been fixed at the lowest rate that will remunerate the producer; and ryots, whose lands have been suited to the cultivation, entered into engagements to deliver certain quantities. About two-thirds of the opium is sold in China, into which empire it is regularly smuggled; and one-third is sent to the eastern isles, Java, Sumatra, &c. Salt has also been an article of valuable taxation. It has been manufactured on the coast of the Bay of Bengal exclusively for the Company. Before it reaches the consumer, its price is enhanced five, eight, or ten fold. The Company have realised a gross revenue of two millions per annum from this monopoly.

The customs drawn by the Company consist partly of taxes collected at the seaports on foreign goods brought in, and partly of *transit* duties levied on goods passing through the country. There are provincial duties paid in passing from one presidency to another; town duties on certain articles at the gates of towns; and market duties levied at the market stations where fairs are held. To collect these taxes, and guard against contraband trade, there are customhouses, called *Chokies*, at every considerable village. In the single district of Madura, with a million of souls, in Madras presidency, there are twenty-one customhouses, each of which has four or five subordinate establishments; and at these stations, even when no duties are exigible, fees are charged by the native officers for the trouble of examination, and a good deal of delay is caused in the transmission of merchandise. These taxes are sources of annoyance and occasional extortion to the trading classes. They produce a gross sum of L.1,800 000, which is reduced to L.1,600,000 by the charges of collection, &c. We believe that a considerable portion of the revenue derived from these duties on traffic is laid out by the Company in the construction of roads and bridges, where improvements of this kind are most wanted.

Territorial Revenue of India, for the year 1829-30.

Mints	36,483
Post office	132,565
Stamps	424,692
Judicial (fees)	114,670
Land revenue	14,314 660
Customs	1,837,127
Ceded territory	569,676
Burmese cessions	103,240
Salt	2,421,619
Opium	1,757,400
Marine	61,769
Ava indemnification	92,220
Bhurtpore	34,800
Subsidies	392,355
Bank profits	8,640
	L.22,301,646
Deduct amount calculated to be over-estimated in the receipt from land revenues at Bombay	247,600
Total revenues	L.22,054,416

DEBT AND ASSETS OF THE COMPANY.

The expenditure of the Company, on its military, political, and civil establishments, has ever, on an average, been greater than the revenue. It appears, by the official account made by the auditor-general of the East India Company (Melville), "that the gross territorial revenue, during the fourteen years ending in 1829, amounted to L.284,804,085; but the gross charges during the same period amounted to L.304,188,859, exhibiting a deficit of L.19 384 774. The circumstance of the expenditure being generally greater than the revenue, has produced the natural result of a considerable debt. However, this debt of the Company is small in proportion to their resources, the value of their possessions, and the large subsidies received from the tributary princes. What is termed the territorial debt exceeds L.39,000,000, the floating debt L.7,000,000; both together, in 1828, to L.47,506,558; the commercial debt was exceedingly small, only amounting to L.167,443; the grand total of the debts being L.47,672,001. To meet this amount of debt, the Company at the same time possessed assets to the amount of L.25,955,111; thus leaving L.21,716,890 as the total amount of debt unprovided for. Considering the enormous outlay in the progress of conquering such a vast territory as India, and considering the manner in which the affairs of the Company have been conducted, and other circumstances, it will appear remarkable that the deficiency of funds is so exceedingly small.

ACT OF PARLIAMENT OF 1833.

As may be generally known, an act of Parliament was passed in the year 1813, permitting the free trading of British subjects with India, reserving the commerce of China to the Company; the territorial and commercial branches were separated, as well as all accounts connected with them; and the king was empowered to create a bishop of India, and three archdeacons, to be paid by the Company. This act, which was in force till the 22d day of April 1834, did not afford perfect freedom of trade to India, yet it led towards that desirable result, and greatly increased the commerce with the East. By the act 3. 4. Gul. IV. cap. 85, passed in August 1833, entitled "An act for effecting an arrangement with the East India Company, and for the better government of his majesty's Indian territories, till the 30th day of April 1854," the Company were deprived of the exclusive right of trading with China, and ordained to close the whole of their commercial business, and make sale of their merchandise, stores, and effects, so far as regarded commercial assets. It was further ordained, that the whole debts of the Company should be chargeable upon the revenues of their Indian territories, but leaving a yearly dividend of ten per cent. to be retained by the Company. This dividend to be redeemable by Parliament. The Company to pay into the Bank of England two millions annually, till the sum of twelve millions is accumulated as a security fund to the government. The other principal provisions were—A board of commissioners, to be appointed by the king, to superintend affairs of India; Bengal presidency to be divided into two presidencies—Fort William (Calcutta) and Agra; the whole government, civil and military, of India, to be vested in a governor-general and councillors.

The 81st clause is in these terms:—"And be it enacted, that it shall be lawful for any natural born subjects of his majesty to proceed by sea to any port or place having a customhouse establishment within the said territories, and to reside thereat, or to proceed to, and reside in, or pass through, any part of such of the said territories as were under the government of the said Company on the 1st day of January 1800, and in any part of the countries ceded by the nabob of the Carnatic, of the province of Cattack, and of the settlements of Singapore and Malacca, without any licence whatever; provided that all subjects of his majesty, not natives of the said territories, shall, on their arrival in any port of the said territories, from any port or place not within the said territories, make known in writing their names, places of destination, and objects of pursuit in India, to the chief officer of the customs, or other officer authorised for that purpose, at such port or place as aforesaid." Clause 86 permits his majesty's natural born subjects to purchase lands in India: 87 enacts that no native of India, or natural born subject of his majesty, shall, by reason only of his religion, place of birth, descent, colour, be disabled from holding any place, office, or employment under the Company: 112 enacts that St Helena be placed under his majesty's government.

By this act, it will be perceived that several very important provisions are made for the benefit both of Hindostan and Great Britain. India is henceforth open to the settlement of British emigrants; trade may be carried on freely with either India or China; and Indo-Britons, Hindoos, or other natives, are now placed on a level as to political, military, or civil distinctions, with Englishmen. The multifarious advantages which must arise out of these and other provisions of the statute, need not be commented on. The act seems only a preliminary to the final and complete cession of India to the British government.

HINDOOS.

The bulk of the population of India is composed of Hindoos, the primitive inhabitants of the country, and forming one of the most ancient nations in the world. This race is distinguished for their humanity, gentleness, industry, and polished by letters and arts, at a time when most of their Asiatic neighbours were yet only in the first stages of civilisation. This remarkable people have preserved their national character for thousands of years, even under the dominion of foreigners, and have retained to the present day their language, their written characters, their local government, religion, manners, customs, and habits of life. The Hindoos are in general of a brownish-yellow complexion, but the higher and richer classes are almost as white as Europeans. They are somewhat above the middle height, well proportioned, and very flexible and dexterous. Temperance, frugality, hospitality, and obliging manners, are the favourable traits in their character; but they are now reproached with indolence and avarice. With proper discipline, they form excellent soldiers and faithful servants of the Company. They possess great natural talents, but are at present deprived of opportunities for their developement. They practise agriculture, breeding of cattle, fishing, hunting, and mining, and are largely engaged in manufactures, commerce, and navigation. They manufacture cloths of great variety and value, particularly cotton and silk, among which are the finest muslins and shawls, mats, cordovan leather, &c. and are inimitable in dyeing. In the arts of music and singing they are backward, but in dancing, statuary, and architecture, they are more advanced. They are acquainted with arithmetic, astronomy, and chronology, and are fond of poetry.

The most extraordinary peculiarity in the Hindoos is their divisions into *castes*, or perfectly distinct orders of society, which have existed from the remotest times. There are four castes, and it is strictly enjoined by the Hindoo religion that no transition from one to another shall take place; no connection between them by marriage or any other way is allowed, and no individual of one class can assume the habits or engage in the occupations of another. The distinction is complete in every sense, hereditary and personal; all the privileges or disabilities are inherited; no one is permitted to become what he is destined to be by his natural abilities, but is obliged to become only what his birth permits, or to remain what it condemns him to be. The slightest transgression of these laws is punished with loss of caste, and sometimes, in particular cases, with death. Even the difference of food is precisely marked out. The three higher castes are prohibited entirely the use of flesh; the fourth is allowed all kinds except beef; all others are outcasts, and may eat what they please. Thus, the lower the rank of the Hindoo, the less he is restricted in his meat and drink; but, on the other hand, the burdensome restrictions increase with the inferiority of rank.

The first, or most noble caste of the Hindoos, are denominated Brahmins; they are priests, scholars, teachers, lawyers, and state officers, and are required to be virtuous, learned, peaceable, just, and self-denying. The second order is the Kyetra, who are kings and warriors; and they are required to have a thirst for glory, to die rather than retreat, and to be generous to captives. They preserve the ancient name of rajaputs, by way of distinction, in their old hereditary dominions. The third order, which is called Bhyeya, or Vaisa, are husbandmen and merchants. The fourth caste is that of the Soodras, who are labourers, and they are enjoined to serve with patience and fidelity. A lower caste, if it can be called such, are the Parias—those unhappy beings who have lost their station in the noble orders, and who are obliged to do whatever no one else can do without pollution. They are not only reckoned unclean themselves, but they render unclean every thing they touch. They are deprived of all civil privileges, and stigmatised by particular laws, regulating their mode of life, their houses, and their furniture; they are not allowed to enter the temples of the other orders, but must worship by themselves. Their houses are miserable hovels, distant from cities and villages.

The Brahmins, who are not legitimately entitled to possess property, and who must live upon the bounty of others for their support, cherish in the people the most debasing superstitions, and exact from them the most profound veneration. Instead of being holy, harmless, and undefiled, they are vicious, tyrannical, avaricious, and to the last degree impure. This infamous aristocracy is the curse of India, and presents a barrier to the attempts which have been made to meliorate the condition of the inferior orders. We believe the Kyetra and Bhyeya castes are nearly extinct, and that the Hindoo nation is now composed principally of Brahmins and Soodras, with their subdivisions. These subdivisions are innumerable:—Every trade, every peculiar department of service, has its class, wherefore the retinue of servants to be kept is very large; for the man who carries in your water cannot wait at table, nor the man who cooks a dinner serve it up, nor the servant who waits at table sweep the room, and the same kind of classification goes on through all the pursuits of life. In a number of instances, Brahmins have become soldiers in the service of the East India Company, but without engaging in menial employments; and they still claim precedence even of kings, in point of etiquette. This rigorous classification of the Hindoos undoubtedly presents an obstacle to the advancement of Christianity, which, though hardly thought of by the British at home, is next to insurmountable, and will retard proselytism for an indefinite period. The Hindoo who becomes a Christian loses his caste by partaking of the Lord's Supper, and it therefore requires an extraordinary strength of mind to make a profession of faith in the Gospel; for by losing his caste in this or any other way, no one will speak to him, or touch him, or have any intercourse with him—his own wife and family will disown him—he becomes a Paria, a dog.

From recent investigations, it appears that the foregoing rigorous classification of the Hindoos is much less an obstacle to improvement in manners than was formerly supposed. It would seem that the classification is more theoretic than practical. The altered state of society has obliged members of the aristocratic castes to engage in divers employments or trades not permitted by their religion; but to accomplish this object, various subterfuges and self-deceptions are practised. Besides, there have arisen a prodigious variety of subdivisions by the intermixture of castes; and the employments allowed to these mixed or impure castes may be said to be every description of handicraft and occupation for which the wants of human society have created a demand. In point of fact, we are told by the best authority, that men of all castes may be seen working together in one handicraft employment. A kind of purity of caste is perhaps, nevertheless, kept up by the members of different castes not eating with each other, or not eating forbidden things. It is related that purity of caste is sustained by means of clubs or lodges scattered throughout Hindostan, and existing in considerable force in every large town; yet it seems that excommunication from these fraternities, is, upon the whole, unable to prevent the breaking down of ancient habits, or to subdue the disposition to imitate the English in the arts of civilised life. The Hindoo races are, indeed, described as now exceedingly anxious for improvement; and it is rational to expect, that, through the means of schools for education, and a conciliatory behaviour on the part of their British neighbours, they will attain no small degree of cultivation. On this subject, Bishop Heber—an authority on whom every dependence may be placed—makes the following statements in his work on India:—

"To say that the Hindoos or Mussulmans are deficient in any essential feature of a civilised people, is an assertion which I can scarcely suppose to be made by any who have lived with them; their manners are at least as pleasing and courteous as those in the corresponding stations of life among ourselves; their houses are larger, and, according to their wants and climate, to the full as convenient as ours; their architecture is at least as elegant; nor is it true that in the mechanic art they are inferior to the general run of European nations. Where they fall short of us (which is chiefly in agricultural implements, and the mechanics of common life), they are not, so far as I have understood of Italy and the south of France, surpassed in any degree by the people of those countries. Their goldsmiths and weavers produce as beautiful fabrics as our own; and it is so far from true that they are obstinately wedded to their old patterns, that they show an anxiety to imitate our models, and do imitate them very successfully. The ships built by native artists at Bombay are notoriously as good as any which sail from London or Liverpool.

In the schools which have been lately established in this part of the empire, of which there are at present nine established by the Church Missionary, and eleven by the Christian Knowledge Societies, some very unexpected facts have occurred. As all direct attempts to convert the children are disclaimed, the parents send them without scruple. But it is no less strange than true, that there is no objection made to the use of the Old and New Testament as a class-book; that so long as the teachers do not urge them to eat what will make them lose their caste, or to be baptised, or to curse their country's gods, they readily consent to every thing else: and not only Mussulmans, but Brahmins, stand by with perfect coolness, and listen sometimes with apparent interest and pleasure, while the scholars, by the road-side, are reading the stories of the creation and of Jesus Christ.

The different nations which I have seen in India (for it is a great mistake to suppose that all India is peopled by a single race, or that there is not as great a disparity between the inhabitants of Guzerat, Bengal, the Dooab, and the Deccan, both in language, manners, and physiognomy, as between any four nations in Europe), have of course, in a greater or less degree, the vices which must be expected to attend on arbitrary government, a demoralising and absurd religion, and (in all the independent states, and in some of the districts which are partially subject to the British) a laxity of law, and an almost universal prevalence of intestine feuds and habits of plunder. Their general character, however, has much which is extremely pleasing to me: they are brave, courteous, intelligent, and most eager after knowledge and improvement, with a remarkable talent for the sciences of geometry, astronomy, &c., as well as for the arts of painting and sculpture. In all these points they have had great difficulties to struggle with, both from the want of models, instruments, and elementary instruction; the indisposition, or rather the horror, entertained, till lately, by many among their European masters, for giving them instruction of any kind; and now from the real difficulty which exists of translating works of science into languages which have no corresponding terms."

RELIGION OF THE HINDOOS.

The religious belief of the Hindoos is called Brahminism, and is founded on a most extensive collection of sacred records, of which the Brahmins are allowed to be the sole expounders. "These sacred writings (says Mr Statham, in his 'Indian Recollections') are of two kinds—the Vedas and Shasters. The former may be termed their Scriptures, the latter expositions of them. Beass Muni (that is, Beass the Inspired), a prophet who lived in the reign of Judistheer, on the banks of the Jumna, near the present city of Delhi, collected all the detached pieces which form the Vedas, from all parts of India, and gave them their present form and arrangement. They are divided into four books, all written in the Sanscrit. The first book is called Rug Veda, which signifies the Science of Divination, concerning which it principally treats. The second is distinguished by the title of Sheham, which signifies Piety or Devotion, and this book treats of religious and moral duties. The third is the Judger Veda, which, as the word implies, includes the whole science of Religious Rites and Ceremonies. The fourth is denominated Obater Bah: in the Sanscrit, *obater* signifies the being or essence, and *bah*, good: this, literally interpreted, is the knowledge of the Good Being, and accordingly this book comprehends the whole science of theology and metaphysical philosophy.

The Vedas, as also the Shasters or commentaries, pretend to great antiquity; so much so, that many Europeans have been strangely staggered in their belief of the Mosaic chronology, by reading them. But it only requires a little consideration and research to discover a vein of imposition running through the whole of their details. They reckon the duration of the world by four ages, or jogues, extending altogether to about eight millions of years; but the fallacy of this reckoning has been fully exposed by astronomical observation.

The idea which their Shasters give of God is, that there is one supreme Being, whom they style Bhogabon or Esher, sometimes Khodah: proceeding from him, are three powers or deities, viz. Bruhmha, the Creator of all; Vishnu, the Preserver of all; and Seeb or Sheva, the Destroyer of all. Now, whilst the latter is worshipped by all, the former has scarcely any attention paid to his temples; and even Vishnu, the Preserver, has few votaries compared with the destroyer Seeb. Subordinate to these are 330,000,000 inferior gods and goddesses, each representing some peculiar virtue or vice. The Hindoos suppose that each of the three presiding powers oftentimes seeks to encroach upon the prerogative of his compeer, and thus are often quarrelling and seeking to subvert each other's arrangements."

One of their most superstitious practices consists in their worshipping or deifying the waters of the Ganges. This large and beautiful river extends from west to east across an extensive district in Hindostan Proper, and with its tributaries may be reached by a very large proportion of inhabitants in the most populous and productive part of India. The sacred ceremony of adoring the Ganges consists in the population crowding morning and evening to bathe in it, and quantities of the water are carried to all parts of India, and are sworn by in courts of justice. "At Allahabad (continues the above entertaining writer), where the streams of the Ganges and Jumna unite, the country for many miles round is considered sacred ground; and so great is the number of pilgrims who resort thither for bathing, that the vizier has received in one year half a lac of rupees for permission to enjoy the benefit of immersion in the sacred flood. Many are the lives sacrificed here annually. The persons who thus fall victims to their superstition are generally females, who come from all parts of the country to perform the tragic deed, and who show a firmness of purpose worthy a better cause. Several of them, accompanied by the priests, embark in a boat, and proceed to the spot where the streams unite, when each of the victims in succession descends from the boat to the river, with a large earthen pan fastened to her body, and is supported by a priest till she has filled the pan with water from the stream, when the priest lets go his hold, and she sinks to rise no more, amidst the applauses of the spectators, whilst the Brahmins enjoy the scene, and extol the fortitude of the last victim to her who is about to follow."

The cow is an animal held sacred among the Hindoos, and cow-dung is used in the temples and other places as a species of holy ointment. The lotus, a plant with tall luxuriant leaves, is likewise held in deep veneration. Some of the temples or pagodas of the Hindoos are of high antiquity and gigantic conception, majestic appearance and tasteful architecture. The entrance is always made in a huge pyramid, in a number of stories, which gradually grow narrower as they approach the top. Inside may be seen the cow lying down, a serpent, or some other object of adoration. Here sacrifices take place. One of the most extensive pagodas of India is that of Juggernaut, whose towers are seen at twenty miles' distance. Here, as at other places, there are processions of idol cars, large heavy ornamented structures, which are dragged along by the multitude amid the shouts of assembled thousands. As the wheels pass swiftly on, self-devoted victims rush forward, throw themselves before them, and are crushed to death, exulting in the hope of thus securing a passage to the celestial abodes. The practice of widows sacrificing themselves on the funeral pile of their husbands, is another horrid rite; but it has been suppressed in recent times by the British government.

Besides Brahminism, there are a variety of religious beliefs and sects in India, but all less or more founded on the most gross superstitions. Each possesses its own temples, images, and orders of priesthood. The Boodhists, previous to their violent expulsion by the Hindoos, were second in point of numbers, but their religion is now little practised in India, and is confined chiefly to Thibet, Birmah, Siam, and Ceylon.

INDIAN LANGUAGES.

There are, it is believed, four original languages in India, and of these there are some hundreds of dialects, differing less or more from each other and from the originals, and maintaining also a partial distinction from the introduction of Arabic, Persic, and other foreign words. While, however, each tribe has its own peculiar dialect, all use one language, the Sanscrit, in their sacred writings. The Sanscrit is a dead language, though probably once spoken; it is wonderfully perfect in its construction, and extremely copious. Its alphabet is called *Devanagari*, divine alphabet, because it is said to have had its origin from the gods, whose language it is: it consists of fifty letters, and has three genders. The next language in estimation is the Pracrit, which comprehends the various dialects used in common writing and social intercourse. The dialects of the Pracrit are spoken in Bengal, and include that which is called Hindostanee, the principal spoken tongue in India.

MAHOMMEDANS AND OTHER CLASSES.

According to Mr Hamilton, "the modern Mahommedans may with safety be estimated at one-seventh of the total population; and notwithstanding the subversion of their political predominance by a Christian power, their religion continues to expand. They are no longer, however, the sanguinary zealots who, eight hundred years ago, in the name of God and the prophet, spread desolation and slaughter among the unconverted Pagans. Open violence produced little effect on so patient a people; and although the Mahommedan subsequently lived for centuries intermixed with Hindoos, no radical change was produced in the manners or tenets of the latter; on the contrary, for almost a century past, the Mahommedans have evinced much deference to the prejudices of their Hindoo neighbours, and a strong predilection towards many of their ceremonies." The warlike portion of the Mahommedans having recently been dislodged by the British from the Mahratta courts, where they had found shelter, and they have been obliged to seek employment in inferior stations. The Mahommedans of India are more intelligent, and possess greater strength and courage than the Hindoos; but they are also more proud, jealous, revengeful, and rapacious, and their fidelity is much less relied on by the British government. In some districts the Mahommedan population is nearly as numerous as that of the Hindoos, and both seem to live in a state of mutual amity.

Besides the Hindoos and Mahommedans, there are various scattered tribes in India of a very different character from either, and often inhabiting mountainous tracts of country, and called Garrows, Monguls, Tartars, &c. Among the different races is found that of the Parsees or Persians, the ancient worshippers of fire, long since driven from their native country by the persecuting sword of the Arabs. Many of this people are opulent, and they take the lead in the commercial transactions of Bombay, Surat, and other north-western parts. Their general conduct is quiet, orderly, and respectable.

Notwithstanding what has been related of the strictness of the Hindoos regarding modes of living, they seem liable to fall in with European usages. In Calcutta, and other large towns, many of the wealthy natives imitate the British in their dress, household furniture, equipages, and style of living, and show a strong desire to mix in their social parties, to which, however, they rarely find access. The English take no pains to conciliate the friendship of the native tribes, however well behaved and intelligent they may be. "Of this foolish, surly, national pride (says Bishop Heber), I see but too many instances daily, and I am convinced it does us much harm in this country. We are not guilty of injustice, or wilful oppression, but we shut out the natives from our society, and a bullying, insolent manner is continually assumed in speaking to them." The exclusiveness of this species of hauteur is perhaps fully more remarkable with respect to that class of persons who have drawn their origin from the intercourse betwixt the English and natives. These Indo-British, as they are called, form a part of the population of Calcutta, and are a very interesting and increasing people. "Many of them (says Statham) are very opulent, and others can vie with the more cultivated of their European neighbours in literary attainments; notwithstanding this, there is a marked contempt shown them by Europeans generally. If a European lady should wed with an Indo-Briton, the doors of all the higher circles would be closed against her, however rich the man of her choice might be." This state of things will happily be modified by the provisions of the act of Parliament already narrated.

RURAL CHARACTERISTICS AND PRODUCTS.

In the large and fertile territory of Bengal, as well as in all other parts of India where the cultivation of the soil is pursued, the arts of the husbandman are, as may be expected, still on the rudest plan; and in every quarter there exists great room for improvement, which nothing could so well facilitate as the settlement of intelligent European families. In the inundated districts of Bengal, rice is the main crop which is raised, at least during the wet season; it grows to its greatest height while the lands are overflowed, and is frequently reaped by men in canoes, the ear only being cut off, and the stalk left. When the peasants go to market during the height of the flood, they take their families with them, lest the house should be washed off during their absence with the boats. Rice is the summer crop, requiring much heat and moisture; but during the cool dry season, from November to April, they sow and reap another harvest, consisting of wheat, barley, or different kinds of pulse: this is called the *dry crop*, because it is reared without flooding the lands; the rice being considered as the *wet crop*, for a contrary reason. There are, therefore, two seed-times and two harvests in this rich country. Besides these regular crops, many small grains are sown, which are limited to no particular season of the year, and which reward the industry of the Indian cultivator with a rich vegetation at all times.

INDIGO.

Besides the different kinds of grain, the farmers of Bengal raise a number of other products, of great value. Of these, one of the principal is indigo; this is a small plant, shrubby in its growth, but in its leaves and flowers very much like the common tares of this country; it is sown during the rains, and raised in rows or drills. The leaves only are useful, on which account it is cut repeatedly, without being allowed to flower, which would make it drier and less juicy. The leaves are steeped and beaten in a vat among water; after which, the liquid is strained through cloths, and set to evaporate in shallow troughs placed in the shade. This is soon effected in that warm dry climate; and the indigo is then found deposited in a crust at the bottom. The process requires much preparation and expense; and it has only succeeded well since the country has enjoyed peace, and there has been a prospect of employing large capitals with security. It now produces, however, a large return to the cultivators; and gives a new source of wealth to the country. It is cultivated along the whole course of the Ganges up to Delhi, and is an annual in the lower, but a triennial in the upper provinces. It succeeds best on overflowed grounds, and in dry seasons is apt to fail. The number of factories of indigo in the Bengal presidency is estimated at 300 or 400. A few of them belong to natives; but they are chiefly in the hands of Englishmen, who take leases of ten or twenty thousand acres of land in the name of native servants (not being allowed to hold it in their own) from a zemindar, for the purpose. They encourage the ryots (native cultivators) to raise crops of the plant, by making advances to them in money. They purchase the produce at a price agreed on, and erect works for extracting the dye from the plant; the whole of the operations being generally conducted by native labourers, under native superintendants. It is observed that the establishment of such factories raises the value of land, extends cultivation, and spreads a certain degree of improvement in the villages. The importation of Bengal indigo into Britain began about forty years ago, and has since increased to an amazing extent. Mr Crawfurd calculates that about 9,000,000 lbs. are annually exported from Calcutta, of which 7,000,000 lbs. come to Britain, and the rest goes to America, France, Germany, Sweden, &c. About L.1,680,000, he thinks, are expended for rent and labour in its production, and it realises in Europe a sum of L.3,000,000. In the countries named, Bengal indigo is silently obtaining a preference over every other.

SILK.

Silk is raised in great quantities in Bengal and Orissa, between the latitudes of 22° and 26°, and it has hitherto been very nearly a monopoly in the hands of the Company. It is chiefly produced by the native Indian worm, which affords four crops, or sometimes six in the year: the Italian worm, which was introduced half a century ago, yields only one crop a-year, but of a finer quality. The Indian silk, compared with the best European varieties, is "foul, uneven, and wants staple;" but its cheapness has brought it into extensive consumption. The Company have eleven factories, or "filatures," which form the centres of "circles," within which the cultivation of silk is carried on, each having a certain number of subordinate stations. The silk, in the raw state, is purchased from the ryots at the factories or subfactories, wound off the cocoons, and prepared for transmission to Europe. About 1,800,000 lbs. are annually brought to England, of which a very small quantity (one per cent.) is equal to the finest silk; the mass of it is decidedly inferior. There is strong ground to conclude that, under the new act, the production of silk in India will be greatly increased, and its price in Great Britain lowered.

COTTON.

Cotton has long been cultivated by the natives in all the three presidencies. It is universally of the kind called "short staple," and being coarse in quality, and badly cleaned, it fetches only two-thirds of the price of American short staple in the British market. The best quality comes from Bombay (the Guzerat); the next from Madras; and the worst from Bengal. The cultivation being entirely in the hands of the natives, is rudely conducted; and, in particular, pains are not taken to renew the plant constantly from the seed, as the Americans do with the most advantageous results. Experiments have been made under the sanction of the Company, and by private individuals, to introduce and cultivate finer species than those in use, but they have generally been failures. There is no doubt, however, that by the introduction of European capital and skill, the quality of Indian cotton may be much improved, and what is raised, sent to the market in a much cleaner and better condition. The exports of cotton from India to all countries amounted in 1827 to 68,000,000 lbs., of which only a third part came to Great Britain.

SUGAR.

The cultivation of the sugar-cane is pursued with great success in Bengal and other parts of India, but chiefly by the natives for domestic use. The process of bruising the canes is on a rude plan, and the sugar which is produced is from this or some other cause very inferior to the sugar of the West Indies. In no article of produce is there greater room for improvement than in this. The cultivation of the cane requires great care and skill, and the mechanism for extracting and preparing the sugar can only be erected at a great outlay of capital. It is anticipated that when Europeans are permitted to hold lands freely, and to embark capital on sugar plantations, sugar of good quality may be manufactured much cheaper than in the West Indies, where the price of labour is much higher.

THE BAMBOO AND OTHER PRODUCTS.

The bamboo, a species of cane or reed, is much cultivated in Bengal. It grows to the amazing height of forty feet; and though it arrives at perfection in two years, it has all the firmness of the hardest timber. It has joints like a reed, or like grass, and is, like them, quite hollow; yet it is so strong that the porters of the country use it for suspending the heaviest burden between the shoulders of two men while they are carrying it from place to place. It is used for beams and uprights in building houses; and being protected from damp by a kind of natural varnish, it will last in such situations for a hundred years. It serves also for making bridges, for the masts of small boats, and for innumerable other purposes; yet of this useful material, one acre of land will yield ten times as much as the same space will produce of other wood. There is none of the productions of India which puts so many conveniences, in regard to furniture, houses, boats, &c., within reach of the poorer classes, as the bamboo.

It would require a large space to mention even the names of the plants useful to man, which flourish in the luxuriant soil of Bengal. Cotton, tobacco, the opium poppy, rape (which is cultivated for the sake of its oil), cucumbers, vegetable marrow (as one of the gourd tribe is called), and innumerable other plants, always afford a plentiful harvest. Of fruit-trees, there are the mango, which is something like our peach, the date-tree, the vassia, the guava, the pomegranate, and others which it would be idle to enumerate.

Another production, which is peculiar to warm climates, and which grows in high perfection along the sea-coasts, is the cocoa-palm. This tree would of itself be almost sufficient for the subsistence of mankind in the countries where it grows, so various and useful are its products; indeed, there are some populous islands—the Maldives and Laccadives—on the coast of India, where little else is cultivated. This exceedingly valuable product being already described at length in our Journal, it requires no farther notice in this place.

MODE OF LIVING.

Animal food being rejected by many classes of Hindoos, the breeding of cattle is therefore not a source of much profit to the farmer, neither are sheep reared in any numbers, their flesh not being in request, while the wool is coarse and low-priced. To those of the natives who eat animal food, the fish of their numerous rivers afford a plentiful resource, many of the kinds being of excellent quality, and in such abundance that the poorest of the people can have them in as large quantities as they wish.

This natural abundance of food makes subsistence cheap, but does not much elevate the situation of the common people, because their wages are lowered in the same proportion. The usual hire of a plough with its yoke of oxen is not more than fourpence per day, and a farm labourer may be had to work regularly for five shillings a-month. The facility of finding natural substitutes for things which in other countries require skill and labour, gives many of the conveniencies of life an appearance of rudeness and imperfection which to us appears altogether savage. Much of the food of the people, for instance, requires no cooking; plantains, cocoa-nuts, dates, pumpkins, &c. being more palatable raw than dressed. Houses are made of bamboo or cajann stakes, without splitting, planing, or dressing of any kind; they are then woven together with small twigs equally unprepared; the whole is plastered over with mud from the nearest clay-hole, and then thatched with cocoa-nut leaves fresh from the tree. Oars for their boats are only bamboos, with a round board tied to the end; the masts are two or three of the same bamboos lashed together with strings. Drinking cups are made of a large nutshell, with one end rubbed off on a stone; a most palatable and wholesome drink is found in the juice of the cocoa-nut palm, which is received into an earthen jar as it drops from the point of a broken branch; and its only preparation is straining through a kind of natural sieve, which is found at the roots of every leaf on the tree. The common people wear little or no clothing; and when it comes to rain, their only umbrella is formed of a number of palm-tree leaves sewed together by the edges into a shape resembling a cradle cut across, which covers their head and back. This rude fashion of trying to find every thing ready made to their hands having once got admission among their ideas, infects their whole proceedings; every thing, both in farming and manufacture, is done on the principle of exerting as little skill and labour as may be, and letting nature do the rest; they only scratch the ground instead of ploughing it; they never apply any manure; their corn is thrashed by setting bullocks to tread upon it; the smith's anvil is the nearest stone, his bellows a rough goat-skin; a shoemaker tans the raw hide one day, and makes shoes of it the next, sitting the whole time at the door of his customer; the weaver's apparatus needs but the shadow of a tree for shelter—and it can be removed at an hour's notice to any other tree which is more convenient. Even their distillery needs only an earthen kettle, some cold water, and a few bamboo reeds for a worm; and with these they produce liquors as intoxicating and pernicious as any manufactured by the science of Europe.

This absence of skill in all the processes of industry, renders the labour of the working man of very slight value: hence, he never receives more than what is barely necessary for subsistence; and the whole mass of the people are consequently at the lowest ebb in regard to domestic accommodations or mental acquirements. Their celebrated countryman, Rammohun Roy, who died lately in this country, believed that many of them did not know whether the British or the Mahommedans be now masters of India. As to their houses, however, though they are only miserable huts, we must recollect that the people in warm climates are very little within doors. In cold countries, a man's house is every thing to him; he sleeps, eats, works, and spends many of his happiest hours there with his family; in India this is all reversed; the climate is here so warm and steady, that no one remains under a roof except by necessity, in time of night or in time of rain. Hence, except to people of rank, or in easy circumstances, the appearance and accommodations of the interior of the house are a matter of secondary consideration; and would scarcely be cared for, were it not for the women and children.

In the accounts of all travellers in India, it is mentioned that there is no possibility of travelling in almost any part of the country in safety without a guard and retinue of servants. The roads, if they can be called such, are hardly-discernible tracks, quite unfitted for wheel-carriages, and travellers must therefore ride on horseback, or on the backs of elephants, or be carried in palanquins—a species of litter supported on men's shoulders. There being also no inns in India, each traveller is obliged to carry tents and provisions for daily use. Throughout the whole regions of Upper and Southern India, and in some parts of Central India, robbery and theft prevail to a great extent, and armed attendants are necessary for protection.

Slavery prevails in Bengal and some other parts of India, but neither to a great extent nor on a severe principle. The slaves are mostly used in domestic labour, and are generally treated with kindness, both by Hindoos and Mahommedans. Although the British government does not countenance slavery, it would be found almost impossible to extirpate it, either by law or admonition, for it originates in the sale of children by parents during famines, or under circumstances of peculiar calamity. Such is sometimes the distress of the parents that they will dispose of their offspring for the merest trifle, not from want of affection, but most likely with a view to the saving of their lives. Selling children into slavery, therefore, prevents infanticide, or, what is as bad, death by starvation; and so long as no fund exists to relieve the famishing natives during times of exigency, it does not seem possible to prevent the disposal of children by their parents, especially since the laws of the Hindoos permit the practice. We may, however, naturally expect that, with the advance of civilisation and habits of providence, slavery will here, as elsewhere, cease. At present, slaves in India are frequently liberated by their owners from motives of piety.

ANIMALS.

India possesses a variety of animals, both in the brute and bird creation, found in no other region. Among the brute tribes the most conspicuous is the elephant, which affords amusement in the hunting, and which is of great service, when tamed, in carrying persons on its back in an ornamental and commodious seat fitted up for the purpose. The tiger is found in the low marshy regions or jungles, and is also made the object of hunting; but this ferocious animal is now becoming of rare appearance, except in the remote parts of the country. India abounds in monkies, and has some peculiar races of dogs. When English-bred dogs are taken to the country, they speedily degenerate. In the forests, deer of different kinds, and a race of antelopes, prevail. There are also various descriptions of oxen, among which is the white or sacred bull and cow. There are many splendid specimens of birds, as shining creepers, the ring-necked paroquet, lories, cockatoos, parrots, and other highly-coloured feathered animals. There are likewise vultures, bustards, peacocks, and nearly all the game birds and poultry of Britain. India and its islands possess many dangerous reptiles, as crocodiles, lizards, and poisonous serpents or snakes, all of which are more or less found about rivers and marshes, and render bathing in the waters by no means safe. India has also many remarkable insect tribes, one of which, the kermes, produces a fine scarlet dye. Fish, of an immense number of varieties, abound in all the streams and waters, and are frequently of exceeding brilliancy in colour.

CLIMATE.

The climate of India, though in some high districts salubrious and pleasant, is, on the whole, ill suited to the constitutions of Europeans. There are three seasons—the rainy, cold, and hot: the rainy in general extends from June till October; the cold from November till February; the hot from March till May. During the rains the climate is unhealthy. The temperature of the atmosphere ranges during the hot months from 72° to 105°. At Calcutta, the temperature varies throughout the year from 69° to 89°, but is more commonly about 82°. At Bombay, the temperature is generally somewhat higher; and at Madras it is higher still, the Carnatic being a dry and hot region. This general hotness of India, and the insalubrious character of the rainy season, produces not only discomfort, but renders Europeans liable to fevers, diseases of the liver, and other complaints not common in this country. To accommodate invalids, the East India Company have fitted up sanitory stations at certain parts of the country on the higher grounds, where the air is cool and agreeable; but these places cannot always be depended on by the enfeebled functionaries of the Company, and visits to England are often necessary for the preservation of life. In consequence of the heat of the climate, Europeans amply provide themselves with light cotton garments, which are universally worn as undress.

EAST INDIA MONEY.

The circulating medium of India consists of gold and silver coins, paper money, and cowries. The most common silver currency is the new coinage of Calcutta. Potdars, or money-changers, are a common class in every town, and sit generally in the open air with heaps of cowries placed before them. Cowries are small shells, which, not being depreciable by imitation, form a good medium for buying and selling among the lower classes. Their value varies in different places. The following is their value in Calcutta:—4 cowries 1 gunda; 20 gundas 1 pon; 32 pons 1 current rupee, or two shillings sterling (2560 cowries); 10 current rupees 1 pound sterling. The sicca rupee is 16 per cent. less in value than the current rupee, which is an imaginary coin. The Bombay rupee is valued at 2s. 3d.; a pagoda is 8s.

CALCUTTA.

Calcutta, the British capital of India, is situated about 100 miles from the sea, on the east bank of the Hooghley, a branch of the Ganges, in latitude 22° 23′ N., longitude 88° 28′ E. The length of the town is about six miles along the bank of the river. When seen from the south, on which side it is built round two sides of a great open plain, with the Ganges on the west, it presents the view of a very noble city, with tall and stately houses ornamented with Grecian pillars and spacious verandas. The esplanade between the town and Fort William leaves a grand opening, along the border of which is placed the new and splendid government house, erected by the Marquis Wellesley. Fort William, which was commenced by Lord Clive, is the largest and strongest fortress in India, but is considered too extensive to be easily defended; its garrison usually consists of two European regiments, with artillery, besides a supply of native troops. The public buildings of Calcutta, besides the government house, are a town hall, a court of justice, two churches of the established religion, and one for the Scotch Presbyterian worship, which is a very handsome edifice. There are also several chapels for other religious bodies, mosques, and pagodas—the latter generally decayed and ruinous, the religion of the people being chiefly conspicuous in their worship of the Ganges. Behind the elegant front lines of houses is ranged the native town, deep, black, and dingy, with various crooked streets, huts of earth baked in the sun, or of twisted bamboos, interspersed here and there with ruinous brick bazaars, pools of dirty water, cocoa-trees, and little gardens, with some fine large dirty houses, the residences of wealthy natives. "Fill up this outline," says Bishop Heber, in his valuable Correspondence, "with a crowd of people in the street, beyond any thing to be seen even in London, some dressed in tawdry silks and brocades, more in white cotton garments, and most of all black and naked, except a scanty covering round the waist, besides figures of religious mendicants with no clothing but their long hair and beards in elf locks, their faces painted white or yellow, their beads in one ghastly lean hand, and the other stretched out like a bird's claw to receive donations; marriage processions, with the bride in a covered chair, and the bridegroom on horseback, so swathed round with garlands as hardly to be seen; tradesmen sitting on the ground in the midst of their different commodities, and old men, lookers on, perched naked as monkeys on the flat roofs of the houses; carts drawn by oxen, and driven by wild-looking men with thick sticks, so unmercifully used as to undeceive perfectly all our notion of Brahminical humanity; attendants with silver maces, pressing through the crowd before the carriage of some great man or other; no women seen except of the lowest class, and even these with heavy silver ornaments on their dusky arms and ancles; while coaches, covered up close with red cloth, are seen conveying the inmates of the neighbouring seraglios to take what is called 'the air;' a constant creaking of cart wheels, which are never greased in India, a constant clamour of voices, and an almost constant thumping and jingling of drums, cymbals, &c., in honour of their deities; and add to all this a villanous smell of garlic, rancid cocoa-nut oil, sour butter, and stagnant ditches, and you will understand the sounds, sights, and smells of what is called the 'Black Town' of Calcutta. The singularity of this spectacle is best and least offensively enjoyed on a noble quay which Lord Hastings built along the shore of the river, where the vessels of all forms and sizes, Arab, Indian, Malay, American, English, the crowds of Brahmins and other Hindoos washing and saying their prayers; the lighted tapers, which, towards sunset, they throw in, and the broad bright stream which sweeps them by, guiltless of their impiety and unconscious of their homage, afford a scene such as no European and few Asiatic cities can at all parallel in interest and singularity."

In recent times, considerable improvements have been made in and about Calcutta, jungles being cleared away, streets drained, and stagnant water removed. Though the situation of Calcutta has not been well chosen, it is excellently adapted for commerce. At high water the river is here a full mile in breadth. The advantages possessed for inland navigation are considerable; foreign imports may be transported with great facility, on the Ganges and its tributaries, to the north-western quarters of Hindostan, while the valuable productions of the interior are received by the same channels. There is at all times a vast quantity of merchandise deposited at Calcutta, and the trade carried on is now very extensive. Besides a government bank, there are three private banks, which circulate to a considerable amount. There are several daily, twice-a-week, and weekly newspapers published. The religious, and charitable, and educational institutions, are numerous and of great service. Society in Calcutta is gay and splendid, and the British inhabitants among their own class are described as hospitable, though zealous of etiquette, and of an overbearing disposition. There are no hotels, or inns, or lodging-houses of any description—a want which appears perfectly amazing—and all strangers, male or female, must be provided with introductions to the houses of residents. The expenses of living are very considerable; and as there are now no more opportunities of acquiring wealth by the spoliation of native principalities, fortunes are much seldomer realised than formerly. There being also now fewer deaths, there are fewer chances of promotion. According to Mr Hamilton, "Without being attached to some department of service, or trained up to some mechanical trade, there is little hope of prosperity to a young man migrating on chance from Europe. Here all the inferior situations of clerks, overseers, &c. are necessarily occupied by the natives, and it is by these gradations in Europe that young men rise to opulence in the commercial world." The population of Calcutta is composed of about 14,000 Christians, 45,000 Mahommedans, and 120,000 Hindoos; but this is the amount only within the city proper. If the environs or suburbs be included, the population will amount to perhaps 600,000; and so densely peopled is the surrounding district, that within the circuit of twenty miles there is a population of nearly two and a half millions.

Serampoor, a Danish settlement, about twelve miles above Calcutta, is the head-quarters of the missionaries sent from Europe, and here a printing-press has been established, from which bibles in a great variety of languages have been issued. The missionaries also here conduct a college for the education of native Christians, Hindoos, or Mahommedans. The enterprise and judicious exertions of the missionary body at this place cannot be sufficiently commended.

MADRAS.

Madras, the seat of government of Southern India, is situated in the Carnatic, on the shore of the Bay of Bengal, in lat. 13° 5 N., long. 80° 21′ E. The shore is here low and dangerous to approach by vessels. On the beach stands Fort St George, a place of considerable strength, and which may be easily defended by a small garrison. A noble range of public edifices, including a custom-house and court-house, also adorn what is called the north beach. Madras differs in appearance from Calcutta. It has properly no European town, the settlers residing in their houses in the midst of gardens, and transacting business in the district appropriated to the residence of the natives. The principal church in Madras, St George's, is a beautiful edifice. There are many excellent charities here; and the school for male and female orphans, into which the philanthropic Dr Bell introduced the Lancastrian system of education, is superior to any thing of the kind in Calcutta. The society of Madras is more limited than that of Calcutta, but the style of living is similar. The roads in the vicinity are excellent, and afford most agreeable drives to the European residents. According to Heber, "the native Christians are numerous and increasing, but are, unfortunately, a good deal divided about castes." The Armenians are here numerous, and some of them wealthy. A Scotch Presbyterian church is now erected. The population of Madras and its suburbs has been stated at upwards of 400,000.

BOMBAY.

Bombay, the seat of government for the western parts of India, is a small rocky island, lying on the west coast of Hindostan, in lat. 18° 56′ N., long. 72° 57′ E. Bombay was originally some hilly rocky islets, but these, by the influence of the high tides, have been joined to each other; and now the island is composed principally of two unequal ranges of whinstone rocks, extending from five to eight miles in length, and at the distance of about three miles from each other. All the ground that can be cultivated is now laid out in agriculture, and the remainder is either barren or covered with the residences of Europeans and natives. These residences are on wet, low, and unhealthy grounds, even below high-water mark; and from this and other circumstances, Bombay is described as being the most insalubrious of the presidencies. The fort of Bombay is situated at the south-eastern extremity of the island, on a narrow neck of land. The chief advantage of Bombay is its deep tide water, which permits the most extensive system of maritime trade; excellent docks are erected for the accommodation of the shipping. Bombay is the seat of very extensive trade with the Persian Gulf on the north, as well as with the south of India. Cotton is the principal article of export. The population is stated at about 160,000, composed of Christians, Jews, Mahommedans, Hindoos, and Parsees.

DELHI,

once the capital of the Mogul empire, and still the residence of the tributary and fictitious sovereign of India, is situated in 28° 41′ N. in the province to which it gives its name, and at the distance of 976 miles from Calcutta. This once magnificent city is said to have, in former times, covered a space of twenty square miles; in the present day an immense number of its ancient streets, houses, temples, and other edifices, are in ruins, and the modern town, removed at some distance from the old, occupies a space of seven miles in circumference. It is seated on a rocky range of hills, and is surrounded by walls, recently improved and strengthened by the British. The city contains many large and good houses, mostly built of brick. There are a great number of mosques, with high minarets and gilded domes, and above all are seen the palace of the emperors, a very high and extensive cluster of Gothic towers and battlements, and the Jumna Musjeed, the largest and handsomest place of Mahommedan worship in Hindostan. The chief material of these public buildings is red granite, of an agreeable colour, inlaid in some of the ornamental parts with white marble. One of the principal characteristics of Delhi is thus described by Bishop Heber:—"We passed in our way to the Agra gate, along a very broad but irregular street, with a channel of water, cased with stone, conducted along its middle. This is part of the celebrated aqueduct constructed, in the first instance, by Ali Merdan Khân, a Persian nobleman in the service of the Emperor Shahjehan, then long neglected during the troubles of India, and the decay of the Mogul power, and within these few years repaired by the English government. It is conducted from the Jumna, immediately on leaving its mountains, and while its stream is yet pure and wholesome, for a distance of about 120 miles, and is a noble work, giving fertility to a very large extent of country near its banks, and absolutely the sole source of vegetation to the gardens of Delhi, besides furnishing its inhabitants with almost the only drinkable water within their reach. When it was first re-opened by Sir Charles Metcalfe in 1820, the whole population of the city went out in jubilee to meet its stream, throwing flowers, ghee, &c. into the water, and calling down all manner of blessings on the British government, who have indeed gone far, by this measure, to redeem themselves from the weight of, I fear, a good deal of impolicy."

The British Resident at Delhi exercises a most extensive authority, from his having the exclusive charge of the emperor and his family, his taking cognisance of all political events in the north-west of India, and his superintendence of many ex-kings and chiefs. The office is therefore always filled by one of the ablest and most experienced of the public functionaries of the Company. The population of Delhi is now computed not to exceed 200,000.

AGRA,

the capital of the province of the same name, is commodiously situated on the south-west side of the river Jumna, in lat. 27° 11′ N. The greater part of this once flourishing city is now in ruins. In the habitable part, the houses are several stories in height, and the streets remarkably narrow. There is a large and ancient fort, surrounded with high walls and towers of red stone, which command some noble views of the city and its environs. The principal sights, according to Heber, are the Motee Musjeed, a beautiful mosque of white marble, carved with exquisite simplicity and elegance; and the palace built by Akbar, in a great degree of the same material, and containing some noble rooms, now sadly disfigured and destroyed by neglect. Agra has been in some measure renovated by the British; and when made the seat of a presidency, will most likely be still further improved.

BENARES

is an ancient and highly venerated city in Hindostan, situated in lat. 25° 30′ N., on an elevated piece of ground on the banks of the Ganges, about half-way betwixt Agra and Calcutta. The streets of this holy city are extremely narrow, and the houses, which rise to the height of six stories, are in some cases united by galleries. The number of stone and brick houses from one to six stories high exceeds 12,000, and the mud houses to about 16,000, besides garden houses. The number of inhabitants is estimated at upwards of 600,000, exclusive of a large body of temporary residents who come hither on religious purposes from all parts of India. Benares may be called the University town of the Hindoos, as their laws and religion are here taught by Brahmins and learned men in various establishments for the purpose.

PORTUGUESE SETTLEMENTS.

The possessions of the Portuguese in India are now confined to Goa, and a small territory round it; Damaun, a seaport in the province of Guzerat; Diu, a small island near the southern extremity of the Guzerat peninsula; Dhelli, on the island of Timor; also Macao, in China; and establishments on Sumbhawa, Floris, and some others of the Eastern Isles. Goa is the only place here worthy of notice. It is situated on the west coast of India, in the province of Bejapoor, in lat. 15° 30′ N., 250 miles south-east of Bombay. During the period of Portuguese dominion in India, this was their splendid and populous capital, the head-quarters of their tyranny, the seat of their Inquisition. It is now a wilderness, of which the monasteries form the only tenanted portion, and a few miserable monks, half of them natives, are the only inhabitants. "Indeed (says Mr Hamilton) the city may be traversed from one extremity to the other without meeting a human being, or any other signs of former population, than pavements overgrown with grass, gardens and court-yards choked with underwood, and princely dwellings and venerable abbies mouldering rapidly to decay." There are still several churches in preservation, also the building once occupied by the Inquisition, which has been shut up for many years. Panjim, or New Goa, is situated five miles nearer the entrance to the harbour of Goa, and is now the seat of the Portuguese authorities, and of the business carried on. The territory in the neighbourhood of Goa, forty miles in length, by twenty in breadth, forms the possession of the Portuguese, and it was estimated, in 1808, that within this tract there were two hundred churches and chapels, and above two thousand priests.

EAST INDIA TRADE.

Before the trade to India was opened to private merchants in 1813, it was asserted that the extreme poverty of the natives, and the immutability of their habits, rendered it chimerical to expect a more extended consumption of British goods in Hindostan. But this prediction has been triumphantly disproved by the event. The declared value of the exports to India has increased five-fold since that time; and when the fall of price is taken into account, it may be safely affirmed that the increase in quantity is at least *eight-fold!* The change has operated to the advantage of both countries. It has reduced the price of Indian goods in Britain, and of British goods in India; and in the latter, as a consequence, articles of English manufacture are now spreading to every village. Calcutta, which formerly sent L.2,000,000 worth of piece goods to London every year, now receives the same amount from it. Though the progress of our manufactures has superseded several Indian articles in the English market, and thus destroyed certain branches of trade, the imports have scarcely diminished; and when the internal commerce of India, which has hitherto been almost entirely in the hands of the Company, is rendered as free as the external, there is a moral certainty that the imports will experience a great increase. The following table, showing the exports in the first year of free trade, and in 1828 (exclusive of the trade to China), well illustrates the effects of the change:—

Exports to India.		1814.	1828.
Woollen cloths, . .	pieces	12,500	33,400
Spelter, . .	cwts.	None.	84,000
Jewellery, . .	value	L.13,500	L.50,900
Machinery, .	do.	L.6,000	L.103,000
Iron, cast and wrought	cwts.	33,400	83,000
Hardware, . .	value	L.20,800	L.78,700
Cotton twist and yarn,	lbs.	None.	4,558,000
Muslins, plain, .	yds.	130,000	7,950,000
Do. printed, . .	do.	7,200	28,000
Calicoes, plain, .	yds.	82,600	22,461,000
Do. printed and dyed,	do.	507,600	12,381,000
British cotton manufactures—aggregate	value	L.109,400	L.1,621,000

It will be seen that the export of white calicoes has increased in fourteen years from 82,000 yards to 22,000,000!

The following table shows that the increase of the exports is entirely due to the activity of the private traders:—

Exports to India.	1814.	1821.	1828.
By the Company,	L.826,000	L.887,000	L.488,000
By private traders,	1,048,000	2,838,000	3,970,000

The following were the leading articles of export to India (exclusive of China), in 1832, with their declared value:—

Cotton manufactures . .	L.1,531,000
Cotton twist and yarn . .	309,000
Woollen manufactures . .	237,000
Copper, wrought and unwrought	364,000
Iron, wrought and unwrought	144,000
Hardware and cutlery . .	82,000
Wines	150,000
Beer and ale	87,000
Glass	101,000
Stationery	50,000
Books	27,000
Linen manufactures . .	49,000
Jewellery	33,000
Silk manufactures . . .	125,000
Apparel	32,000

Each of the other articles is under L.30,000.

Total value of the articles exported L.3,750,000.

The leading articles of importation from India (exclusive of China) in 1832, were the following:—

Imports from India.

		Quantity.	Value at Company's sale prices.
Indigo . .	lbs.	6,211,000	L.1,242,000
Raw silk . .	do.	1,842,000	1,180,000
Cotton wool . .	do.	35,210,000	807,000
Saltpetre . .	cwts.	229,000	413,000
Coffee . . .	lbs.	10,381,000	284,000
Sugar, raw . .	cwts.	175,000	200,000
Dyed cotton .	pieces	227,000	136,000
White calicoes and muslins . .	do.	79,000	40,000
Rice, not in husk .	cwts.	171,000	128,000
Pepper . .	lbs.	4,630,000	70,000
Tortoise shell . .	do.	30,000	77,000

Each of the other articles is under L.45,000.

About one-sixth of the goods brought from India have been till now imported by the Company, and five-sixths by private traders.

India now lies open to the enterprise of British capitalists, merchants, and manufacturers; and, judging from the foregoing statements, there can be little doubt but this great and magnificent region, with its hundred millions of inhabitants, will henceforward, by judicious management, afford a boundless scope for profitable adventure. The great advantages to be derived from the opening up of India to European traffic and civilised usages, will doubtless prove as beneficial to the natives as to the British. Already the country feels itself bettered in every respect by its subjugation. In the words of Pabrar, in his valuable work on the Resources of the British Empire—"Looking at its grand results as affecting the happiness of the human race, it must be confessed that never has a conquest turned out more advantageous and beneficial. All the immense Indian territories have been concentrated in a powerful confederation; a large river, immense deserts, and lofty mountains, constitute the strongest barriers against foreign invasion by land; while an extensive seacoast, and the mighty maritime power of Britain, defend it by sea. A great power, a central government, wisely and humanely presided over, and commanding all this confederation—all this immense amalgamation of states, has put an end to all the conflicting elements, and to all the civil wars waged by numberless and cruel tyrants, perpetually contending for empire; rapacity, tyranny, plunder, massacre, and savage cruelty, have entirely ceased."

Now that Europeans may purchase and hold lands, it may be anticipated that British capital and skill will speedily be directed to the cultivation of sugar, coffee, tobacco, and particularly cotton, all which produce, from the extraordinary cheapness of labour, may be increased to an incalculable extent, and with the most enlivening prospect of profit. Hitherto the system of jurisprudence established by the Company has been a vain mixture of Hindoo, Mahommedan, and English law, and by no means been calculated to preserve public tranquillity. Should the government proceed to modify and extend the system of administering the laws, at the same time relaxing the burden of taxation on land, and endeavouring to conciliate the natives by promoting those worthy of trust, much good might be anticipated. By these and other measures, suited to the genius of the people, a solid basis would be afforded for the investment of capital, and India would gradually improve both in its moral and physical condition. With the advancement of commercial intercourse, we might further expect the breaking down of a number of prejudices among the natives, and at length their reception of the principles of our beneficent faith. What a field is here offered for the speculations of the Christian and philanthropist!

WORDS FREQUENTLY USED IN REFERENCE TO INDIA, NOT EXPLAINED IN THE FOREGOING SHEET.

Adawlet, a court of justice.—*Bega*, a land measure, amounting in Bengal to about the third of an acre.—*Bungalow*, a dwelling formed of wood, bamboo, mats, and other light materials.—*Chokeydar*, a watchman.—*Choultry*, a place for the accommodation of travellers.—*Circar*, a large division of country.—*Coolies*, labourers, or porters.—*Coss*, a measure of distance not less than a mile, nor more than two miles.—*Crore*, ten millions.—*Cutwal*, a chief police officer.—*Dacoits*, robbers.—*Dewan*, a head officer of finance.—*Dewanny*, the privilege of exacting taxes in perpetuity.—*Durbar*, a court of audience.—*Gentoo*, a Portuguese term, signifying a Gentile.—*Ghaut*, a chain of hills, or pass among mountains.—*Hakim*, a governor.—*Howdah*, the seat elevated on the back of an elephant.—*Killadar*, the commander of a fort.—*Lack*, one hundred thousand.—*Lascar*, a native sailor.—*Lootie*, a plunderer.—*Musnud*, a throne.—*Nabob*, or *Nawaub*, a viceroy governor under the Mogul empire.—*Nizam*, an arranger.—*Nullah*, a small stream.—*Paddy*, rice in the husk.—*Pagoda*, a word of Europeans for a Hindoo temple.—*Perwana*, a licence.—*Pergunnah*, a certain number of villages, or tract of country.—*Peshwa*, a leader.—*Pundit*, a learned Brahmin.—*Puggies*, searchers for thieves.—*Raja*, a king or prince.—*Rajpoots*, literally, the offspring of kings, now meaning persons of distinction.—*Soubah*, a district of twenty-two circars.—*Subahdar*, the governor or viceroy of a soubah.—*Thugs*, robbers of Upper India.—*Tiffin*, a lunch, or mid-day meal.—*Vakeel*, an agent or ambassador.*

* For the most accurate and complete account of India, we beg to refer our readers to the East India Gazetteer, by Hamilton, 2 vols. 8vo. Much useful information, for those intending to proceed to India, will be found in the volumes of the Edinburgh Cabinet Library, on British India. Bishop Heber's Narrative, in 3 vols. 8vo. is too well known for its interesting details of Indian localities and manners to require any recommendation here.

EDINBURGH: Published by W. and R. CHAMBERS, 19, Waterloo Place; also by ORR and SMITH, Paternoster Row, London; and YOUNG and CUNNINGHAM, Dublin. Sold by John Macleod, Glasgow, and all other Booksellers.

No. 35. PRICE 1½d.

THE ART OF PRINTING.

REPRESENTATION OF THE STEAM-PRESS WHICH PRINTS "CHAMBERS'S JOURNAL," "INFORMATION FOR THE PEOPLE," AND "HISTORICAL NEWSPAPER," AT EDINBURGH.

[See Description on the Sixth and Seventh Pages of this Sheet.]

A. The printing cylinder, which takes the first impression from the types.
B. The cylinder which prints the second side.
C and D. Two drums, over and under which the sheet passes in its progress from one cylinder to the other.
E. The second form of types, after having been *once* inked, and about to pass under the second cylinder to receive the impression. (The first form cannot be seen, being under the board *f* between the cylinders.)
F. The ink-ductor and trough. A similar complete inking apparatus is at the other end.
G. The feeding or vibrating roller.
H. Two distributing rollers, for spreading the ink over
I. The inking-table.
K. Three inking-rollers.
L. The heap of paper, from which
M. The feeding-boy takes the sheets to lay them on tapes ready to be pushed into the machine.
N. A sheet of paper on the second cylinder, after having been printed on the first side.
O. Another sheet of paper, printed on both sides, just delivered upon the fly-board *f*, from which a boy takes and places the sheet upon a table.
P. The heap of printed paper.
Q. The receiving drum.
R. The belt from the engine which gives motion to the machine.
S T. Two large wheels which turn the cylinders.
U. The wheel which gives motion to the drums.
a a b. The tapes which conduct the sheets through the machine.
c. Stretching pullies for retaining the tapes at the proper degree of tension. (The corresponding set at the other end cannot be seen.)
d e. Pullies which guide the tapes in the margins of the paper.
g h i k m. Light copper rollers, round which the tapes pass after they quit hold of the paper.

ORIGIN AND HISTORY OF PRINTING.

PRINTING is the art of producing impressions from characters or figures, moveable and immoveable, on paper, or any other substance. There are several distinct branches of this important art—as the printing of books with moveable types or stereotype plates, the printing of copper plates and wood engravings, and the taking impressions from stone, called lithography. Our present object, however, is only to describe the art of printing books or sheets with moveable types, generally called *letter-press printing*, and which may undoubtedly be esteemed the greatest of all human inventions.

The art of printing is of comparatively modern origin: four hundred years have not yet elapsed since the first book was issued from the press; yet we have proofs that the principles upon which it was ultimately developed, existed amongst the ancient Chaldean nations. Entire and undecayed bricks of the famed city and tower of Babylon have been found stamped with various symbolical figures and hieroglyphic characters. These exceedingly interesting efforts of art in early times might at first readily be supposed as intended merely as decorative and ornamental, were it not that other reliques exist to suggest the probability of their being designed for a more useful purpose—historical, or otherwise. Some of the latter are solid clay figures, generally of a cylindrical form, whose shape and size forbid the idea of their having been employed in architecture, either for use or ornament, and which are inscribed, or rather stamped, with written characters, no less minute than regular. One of these precious remnants of antiquity, supposed to be upwards of 4000 years old, is preserved in the library of Trinity College, Cambridge. It may be described as being about seven inches high, and three in diameter at each end, increasing gradually in circumference in the middle, so as to resemble a wine cask. The characters impressed upon it run between regular lines from end to end of the figure—the space betwixt the lines increasing in the centre, and, on the whole, bearing the closest resemblance to the staves of a modern cask or barrel. There are evident marks of this figure having been cast in a mould, particularly a small blank space, about a quarter of an inch wide, which intercepts the foresaid vertical lines in the middle, or centre of the figure, and runs round its whole circumference, and where perhaps the printing mould had not joined. This rare piece of ancient learning and art, with other similar reliques, was presented to the College by the recently deceased General Sir John Malcolm, and is, of course, most carefully preserved. It must here be noticed, that the meaning of the characters impressed on these figures has never yet been discovered, and it is more than probable never will. It has long been a subject of disputation among philologists, whether these unknown characters were hieroglyphic or alphabetical, but the general, and as we should think the most probable opinion, is, that they are of the former description.

These exceedingly rude attempts at printing, as well as those of a much later date, it is well ascertained, were all executed by single blocks, which stamped off a whole subject or piece at once, and which were termed *typi fixi*. It is clear, therefore, that engraving in wood preceded, or rather was the direct original of the art of typography; and even to this day do the Chinese print their books in this manner, their endless vocabulary (amounting, as is conjectured, to about *eighty thousand* characters), as well as the peculiar structure of their language, rendering it utterly impracticable either to print their books with moveable types, or even to cast the latter separately. Their method of printing is as follows:—The work intended for the press is transcribed carefully upon sheets of thin transparent paper; each of these sheets is glued, with the face downwards, upon a thin tablet of hard wood; and the engraver then, with proper instruments, cuts away the wood in all those parts on which nothing is traced; thus leaving the transcribed characters in *relief*, and ready for printing. In this way, as many tablets are necessary as there are written pages. No press is used; but when the ink is laid on, and the paper carefully placed above it, a brush is passed over with the proper quantity of pressure. Du Hald, in his "Description de l'Empire de la China," published in 1736, says, that one man can thus, without fatigue, print ten thousand sheets per day; but such a statement is altogether preposterous. The Chinese chronicles state that the above mode of printing was discovered in China about 50 years before the Christian era, and the art of paper-making about 140 years afterwards; previous to which period, all their writings were transcribed or printed in volumes of silk cut into leaves of proper dimensions.

It is a curious enough circumstance, that, amongst the first attempts at printing by means of wood-engraving which can be traced to have been made in Europe, was the making of playing-cards for the amusement of Charles VI. of France. This was towards the latter end of the fourteenth century. Thereafter came prints from wood-blocks of human figures, single or in groups; the earliest existing specimen of which is in the possession of Earl Spencer, and dated 1423. It is by an unknown artist. These prints were at first without any text, or letter-press, as it is modernly termed; but after the groundwork of the art had been completed, its rise towards perfection was almost unparalleled in rapidity. Its professors composed historical subjects with a text or explanation subjoined. The pages were placed in pairs facing each other; and as only one side of the leaf was impressed, the blank pages came also opposite one another; which, being pasted together, gave the whole the appearance of a book printed in the modern fashion.

DISCOVERY BY GUTTENBERG.

The next step in the science of typography was that of forming every letter or character throughout a work separately, so as to be capable of re-arrangement, and forming all the succession of pages in a work, thereby avoiding the interminable labour of cutting new blocks of types for every page. And here, we cannot help remarking, it is curious that an idea seemingly so natural and simple should not have occurred to the Romans, who were unquestionably the most ingenious and scientific nation in ancient times. What renders this the more surprising, is the fact, which we learn from Virgil, that brands, with the letters of the owner's name, were in use in his time for the purpose of marking cattle. The credit of the discovery, however, was reserved for a German, John Guttenberg, who accomplished this important improvement about the year 1438. As this man was the first great improver of typography, to the study of which he exclusively devoted his whole time and attention, a short sketch of his life will only be a part of the history of the art. John Guttenberg, who is supposed to have been born at Mayence, or Mentz, in the beginning of the fifteenth century, settled at Strasburgh about the year 1424. In 1435, he entered into partnership with Andrew Drozheanis (or Dritzehen), John Riff, and Andrew Heelman, citizens of Strasburgh, binding himself thereby to disclose certain important secrets connected with the art of printing, by which they would attain opulence. The workshop was in the house of Dritzehen, who dying shortly after the work was commenced, Guttenberg immediately sent his servant, Lawrence Bieldich, to Nicholas, the brother of the deceased, and requested that no person might be admitted into the workshop, lest the secret should be discovered, and the *forms* (or fastened-together types) stolen. But they had already disappeared; and this fraud, as well as the claims of Nicholas Dritzehên to succeed to his brother's share, produced a lawsuit among the surviving partners. Five witnesses were examined; and from the evidence of Beildich, Guttenberg's servant, it was incontrovertibly proved that Guttenberg was the first who practised the art of printing with moveable types, and that, on the death of Andrew Dritzehen, he had expressly ordered the forms to be broken up, and the characters dispersed, lest any one should discover his secret. The result of this lawsuit, which occurred in 1439, was a dissolution of partnership; and Guttenberg, after having exhausted his means in the effort, proceeded, in 1445-6, to his native city of Mentz, where he resumed his typographic labours. Being ambitious of making his extraordinary invention known, and of value to himself, but being at the same time deficient in the means, he opened his mind to a wealthy goldsmith and worker in precious metals, named John Fust or Faust, and prevailed on him to advance large sums of money in order to make further and more complete trials of the art. Guttenberg being thus associated with Fust, the first regular printing establishment was begun, and the business of printing carried on in a style corresponding to the infancy of the art. After many smaller essays in trying the capabilities of his press and moveable types, Guttenberg had the hardihood to attempt an edition of the Bible, which he succeeded in printing complete, between the years 1450 and 1455. This celebrated Bible, which was the first important specimen of the art of printing, and which, judging from what it has led to, we should certainly esteem as the most extraordinary and praiseworthy of human productions, was executed with cut-metal types, on six hundred and thirty-seven leaves; and, from a copy still in existence in the Royal Library of Berlin, some of them appear to have been printed on vellum. The work was printed in the Latin language.

The execution of this—the first printed Bible—which has justly conferred undying honours on the illustrious Guttenberg, was, most unfortunately, the immediate cause of his ruin. The expenses incident to carrying on a fatiguing and elaborate process of workmanship, for a period of five years, being much more considerable than what were originally contemplated by Fust, he instituted a suit against poor Guttenberg, who, in consequence of the decision against him, was obliged to pay interest, and also a part of the capital that had been advanced. This suit was followed by a dissolution of partnership; and the whole of Guttenberg's apparatus fell into the hands of John Fust, who, from being the ostensible agent in the business of printing, and from the wonder expressed by the vulgar in seeing printed sheets, soon acquired the name of a magician, or one in compact with the devil; and under this character, with the appellation of Dr Faustus, he has for ages enjoyed an evil notoriety.

Besides the above-mentioned Bible, some other specimens of the work of Guttenberg have been discovered to be in existence. One in particular, which is worthy of notice, was found some years ago among a bundle of old papers in the archives of Mayence. It is an almanack for the year 1457, which served as wrapper for a register of accounts that year. This, says Hansard, would most likely be printed towards the close of 1456, and may consequently be deemed the most ancient specimen of typographic printing extant, with a certain date. That Guttenberg was a person of refined taste in the execution of his works, is sufficiently obvious. Adopting a very ancient custom, common in the written copies of the Scriptures and the missals of the church, he used a large ornamental letter at the commencement of books and chapters, finely embellished, and surrounded with a variety of figures as in a frame. The initial letter of the first psalm thus forms a beautiful specimen of the art of printing in its early progress. It is richly ornamented with foliage, flowers, a bird, and a greyhound, and is still more beautiful from being printed in a pale blue colour, while the embellishments are red, and of a transparent appearance. What became of Guttenberg immediately after the unsuccessful termination of his lawsuit with Fust, is not well known. Like the illustrious discoverer of the great Western Continent, he seems to have retired almost broken-hearted from the world, and to have spent most of the remainder of his days in obscurity. It is ascertained, however, that in the year 1465 he received an annual pension from the Elector Adolphus, but that he only enjoyed this small compensation for his extraordinary invention a period of three years, and died in the month of February 1468.

IMPROVEMENT BY SCHŒFFER.

It long formed a subject of contention amongst antiquaries and bibliomaniacs, by what means Guttenberg formed his types, but it is now pretty clearly ascertained that they were at first all individually cut by the hand. The mode of *casting* types in moulds has been very generally, and seemingly correctly, assigned to Guttenberg's successor, Schœffer. This individual was an industrious young man of inventive genius, an apprentice with Faust, who took him into partnership immediately after his rupture with Guttenberg, and who is supposed to have been initiated into the mysteries of the art by the latter. The first joint publication of Faust and Schœffer was a beautiful edition of the Psalms, which came out only about eighteen months after their going into partnership. Along with it appeared a declaration by them, claiming the merit of inventing the cut-metal types with which it was printed; but this pretension was evidently false; and, in fact, it afterwards appeared that the book had been four years in the press, and must, consequently, have been chiefly executed by Guttenberg. It is worthy of notice that the above publication was the very first to which the date, printer's name, and place of publication, were affixed.

To Schœffer, however, as said before, must be awarded the honour of completing Guttenberg's invention, by discovering the method of casting the characters in a *matrix*. In an account of Schœffer, given by Jo. Frid. Faustus of Aschaffenburg, from papers preserved in his family, we are informed that the artist privately prepared matrices for the whole alphabet; and when he showed his master (Faust) the letters cast from them, he was so well pleased that he gave his daughter, Christina, to him in marriage. Faust and Schœffer concealed the new improvement, by administering an oath of secrecy to all whom they entrusted, till the year 1462, when, by the dispersion of their servants into different countries at the sacking of Mentz, by the Archbishop Adolphus, the invention was publicly divulged, and the art was spread throughout Europe.

EARLY PROGRESS OF PRINTING.

Haerlem and Strasburgh were the first places to which the art of printing was transplanted from Mentz, and this at so early a date, that each of these places have their respective advocates as being the birth-place of it. From Haerlem, it passed into Rome in 1466, where its first professors were Conrad Sweinheim and Arnold Pannartz, who introduced the present Roman type in the following year, in printing Cicero's *Epistolæ familiares*. The Gothic character, from which our own *black-letter* was derived, was the next which was employed by the ancient printers; after which came the Italic; and so early as 1476, the first set of Greek characters was cast by the Italians—whether at Venice, Milan, or Florence, is a disputed point. In 1488, however, all previous attempts at the Greek character were eclipsed by a splendid edition of Homer's works, published at the last-named place, in folio, and printed by Demetrius, a native of Crete. To the Italians, too, belongs the honour of printing the first editions in the Hebrew language, and that almost contemporaneous with the Greek, at Soncino, a small town in the duchy of Milan.

In 1467, printing was set up in the city of Tours; at Reuthlingen and Venice in 1469; and, it is believed, at the same time in Paris. This city was the tenth town in Europe in which a printing press was established; it was set up by Ulrich Gering, a native of the canton of Lucerne, in the house of the Sorbonne, and in the year 1469. This Gering had been taught the art by Elias Helie von Lauffen, who introduced it into Switzerland, and commenced the operations of the Lucerne press, by publishing Marchesini's Biblical Lexicon Mamotrectus sive Primicerius, in the year 1470. The first work which issued from Gering's press, at the Sorbonne, was the "Epistolæ Gasparini Pergamensis; it was also published in the year 1470. Gering continued his labours until 1508, and died on the 23d of August 1510, bequeathing very considerable property for the benefit of young scholars and the poor of Paris. Strasburg was the next town which had the advantage of a press, and soon afterwards Lyons—the one in 1471, the other in 1473. In 1490, the art reached Constantinople; and here it may be remarked, in passing, that nothing can be more characteristic of the slothfulness and barbarous ignorance for which the Turkish nation enjoys so unenviable a pre-eminence, or rather, what may perhaps be alleged as the cause of such national degradation, is, that the art of printing has hitherto been most sedulously discouraged. It was introduced into Russia about the year 1560.

INTRODUCTION INTO ENGLAND.

Concerning the period and mode of introduction of the art of printing into England, little is known, but it is certain that it took place not long after its invention at Mentz. By many it is believed and affirmed to have been some time in the decade of 1450, during the reign of the unfortunate Henry VI. Another account—and that which had passed current with our historians and the world at large until the Restoration—assigned the credit of introducing it to a Mr William Caxton, a mercer and citizen of London, who, during his travels abroad, and his residence for many years in Holland, Flanders, and Germany, had thoroughly informed himself of the process, and upon his return, was induced, by the encouragement of many men of wealth and rank, to set up a press in Westminster Abbey, about the year 1471. Such was the tradition of our writers, till a little book, which had scarcely been before observed until the before-mentioned period (the Restoration), was taken notice of by the curious, with the date of its impression at Oxford, anno 1468. This book, copies of which are yet extant, is a small quarto of forty-one leaves, entitled "Expositio Sancti Jeronimi in Symbolum Apostolorum ad Papam Laurentium." At the same time (1664), a work was published by a Mr Atkins of London, entitled "Original and Growth of Printing in England;" in which an account is given of an ancient chronicle, said to have been found in the archbishop's palace at Lambeth, containing the particulars attending the first introduction of the art. By the latter, it would appear that it took place under the auspices of Thomas Bourchiers, Archbishop of Canterbury, during the reign of Henry VI. who sent R. Tourneur, master of the robes, and William Caxton, merchant, to Haerlem, who persuaded an under workman, named Corsellis, to come to England and set up a press at Oxford. It further mentions, that this transaction cost King Henry 1500 merks. But this single press was soon found insufficient for England; upon which the king set up another at St Alban's, and a third at Westminster; the latter being placed under the charge of William Caxton, in the year 1471.

It would be useless for us here to enter into the merits of the question concerning the authenticity of the above-mentioned chronicle, which at one time divided the literary world even to a violent degree. We will only observe, that the result of the disputation appears to be this:—The existence of the book before named establishes beyond a doubt that books were printed at Oxford by Corsellis, several years before Caxton set his press to work at Westminster, and therefore that that city has the honour of having been the first seat of the art in England; but Caxton was the first who introduced the printing with *moulded metal types*, the works by his predecessor having been executed merely with wooden ones. It is by our early writers not having attended sufficiently to this line of demarcation between the two stages of the art, that the misunderstanding has, as far as we can judge after much careful investigation, solely arisen. It is proper here to add, as a circumstance corroborative of the authenticity of the chronicle above mentioned, that in the second part of Shakspeare's Henry VI., there occurs a passage from which it might be inferred that printing had even then been for some time practised. This is where Jack Cade rails at Lord Treasurer Say for corrupting the morals of the community, by setting up a printing press, and encouraging the art.

After the art of printing had been thus introduced into Oxford and Westminster, it spread to St Alban's, Cambridge, Tavistock, Worcester, Canterbury, Ipswich, &c., in almost all cases by the encouragement of the churchmen of these places, and generally with the view of printing works of piety. About the year 1500, or probably somewhat earlier, Pynson was, by patent of Henry VII., invested with the office of king's printer, which may be regarded as the first instance of an appointment of this nature. At the close of the fifteenth and the commencement of the sixteenth century, London possessed a number of printers, but none whose name has been so celebrated as that of Wynken de Worde, a foreigner, and who had been instructed under Caxton. He improved the art considerably, and was the first printer in England who introduced the Roman letter—all previous printing, and much of a later date, being in the black or German letter.

FIRST PRINTED TESTAMENTS AND BIBLES.

Although at first countenanced by the clergy, the art of printing was soon looked upon with extreme jealousy by the church, which at length discovered that this invention was but too certainly calculated to revolutionise the whole fabric of society. The earliest efforts of the art, as we have seen, were directed to the multiplication of the Bible; but for a period of sixty or seventy years from the date of the invention, all the copies of the Scriptures which were printed were in the Latin or some other classic language, not understood by the people. But now a new era commenced. Certain printers began to issue the Bible in the English tongue, translated from the original, and this gave mighty offence to the church, or Romish hierarchy.

In 1526, Richard Grafton, a gentleman of liberal education, and who adopted the profession of printing, issued an edition of the New Testament in the English language, which drew down the wrath of the then Bishop of London. A proclamation was issued by this prelate prohibiting its use. "Understanding (says this document) that many children of iniquitie, maintaynors of Luther's sect, blynded through extreme wickedness, wandrying from the way of truth, and the Catholicke fayth, craftely have translated the New Testament inco our English tongue, entermedlying therewith many hereticall articles and erroneous opinions, pernicious and offensive, seducying the simple people," &c. The proclamation goes on to order all copies of the said New Testament to be brought to the bishop's vicar-general, to be burnt, under pain of excommunication, and incurring the suspicion of heresy. The penalty here set forth does not appear to have had any effect in prohibiting the use of the English Testament. As in the case of every attempt to shackle the press in ancient or modern times, the press was finally triumphant in the struggle. The success of the New Testament led to the publication, in 1535, of the whole Bible in the English language, being the translation of Miles Coverdale. But this noble undertaking was accomplished abroad. In 1539, England had the honour of executing an edition of the Bible in the English tongue, under the auspices of Cranmer and Henry VIII., and which was printed by Grafton and Edward Whitechurch. It would be needless to specify here the vicissitudes which the art of printing underwent in England from this period until recent times. For many years it had to struggle hard for a bare existence, and was from time to time placed under legal restrictions, seriously affecting both printers and the public. The eager desire for the acquisition of knowledge through the medium of printed books and sheets, which went on increasing throughout the eighteenth century, and the advancement of liberal sentiments in the legislature, at last silently, but efficiently and practically, secured what is called the "liberty of the press" in England; even although many of the absurd statutes in reference to the art of printing remained, and still remain, unrepealed.

INTRODUCTION INTO SCOTLAND AND IRELAND.

In the present day, we find letter-press printing pursued in almost every town in the realm. It was introduced into Scotland, and begun in Edinburgh, during the year 1507, only thirty years after Caxton had brought it into England. Since that period it has continued to be pursued with success in the Scottish metropolis, and, within the last thirty years, has there become the most distinguished craft in the city. Printing was not known in Ireland till about the year 1551, when a book in black-letter was issued from a press in Dublin; but till the year 1700, very little printing was executed in Ireland, and even since that period, the country has acquired no celebrity whatever in this department of the arts, although possessing some respectable printing establishments.

PROGRESS ON THE CONTINENT AND IN AMERICA.

The progress of printing on the Continent of Europe has been remarkably slow. Unless in the free states of Germany, where the art is pursued to an incalculable extent, the profession of the printer is almost every where under the severest restrictions, and little can be published without coming first under the scrutiny of censors appointed by the governments. The art is carried on in Paris perhaps with a greater degree of freedom than usual in other continental capitals, and from the presses in that city some exceedingly elegant works have been issued. But at Paris, as every where else, there is a general inferiority in the mechanism of the printing-office, when compared with that now in use in England and Scotland, except in those cases in which the presses employed have been imported from Great Britain.

While the art of printing has been by slow degrees creeping through the despotically governed states of Europe, and establishing itself at isolated spots in Oriental countries, every where creating distrust, and no where allowed to be exercised in furthering the great scheme of human improvement, it has been planted and widely ramified among the civilised inhabitants of North America. We are informed that the first printing-press established in the American colonies was one set up at Cambridge, in Massachusetts, in the year 1638, the era of the foundation of Harvard College of that place. It was only established by the exertions and joint contributions of different individuals in Europe and America; and there is no doubt but the mechanism and types were imported from England. The first work which issued from this press was the Freeman's Call, and the second, the Almanack for New England, both in 1639; the first book printed was the New England version of the Psalms, an octavo volume of 300 pages. In 1676, books began to be printed at Boston; in 1686, printing became known in Philadelphia; and, in 1693, in New York. In the year 1700, there were only four printing-presses in the colonies. Since that period, and especially since the revolution, which removed every thing like a censorship of the press, the number of printing-presses has greatly increased. The mechanism of the press has likewise been much improved in this country; and the Americans have copied the patent steam-press of Cowper of London, and now possess machines of this description. In 1800, the number of presses had increased to 500; in 1830, they amounted to 1200; and we learn that they are still increasing in number and extending their influence. A few years ago, the Cherokees, one of the tribes of native Indians, set up a press, and commenced a newspaper—a circumstance presenting us with an extraordinary instance of the growth of knowledge in America.

We shall now proceed to a description of the art in its various branches, though without entering into the more minute, and what would be tiresome, details of the profession.

OF THE TYPES.

Printers in early times made the letters which they used, but, in process of time, the necessity for a division of labour created a distinct trade of manufacturer of types, and it is only in rare instances in the present day that printers supply their own letter. The preparation of types requires much delicacy and skill. The first step in the process is the cutting of a punch or die, resembling the required letter. The punch is of hardened steel, with the figure of the letter cut upon its point. The letter is cut the reverse way. On this die being finished, it is struck into a piece of copper, about an inch and a quarter long, one-eighth of an inch deep, and of a width proportionate to the size of the type to be cast. This copper being so impressed with the representation of the letter, is called the matrix. The matrix is now fixed into a small instrument or frame, called the mould, which is composed of two parts. The external surface is of wood, the internal of steel. At the top is a shelving orifice, into which the metal is poured. The space within is of the size of the required body of the letter, and is made exceedingly true. The melted metal being poured into this space, sinks down to the bottom into the matrix, and instantly cooling, the mould is made to open with the instantaneous movement of a spring, and the type is cast out by the workman. This process of casting types is executed with great celerity. Of course, every separate letter in the alphabet, every figure, point, or mark, must have its own punch and matrix. In casting types, the founder stands at a table, and has beside him a small furnace and pot with heated metal, which he lifts with a small ladle. Type metal is a compound of lead and regulus of antimony, the latter giving hardness to the composition. The proper proportions of these metals is regulated by the size of the type, a greater quantity of antimony being employed for small than large letters.

When the type is cast from the mould, it is in a rough state, and as soon as a heap has accumulated on the caster's table, they are removed by a boy, who breaks off the superfluous tag of metal hanging at the end of each type. From the breaking-off-boy the types are removed to another place, where a boy is constantly engaged in rubbing or smoothing their edges upon a stone. Being now tolerably well cleaned, they are next removed to a table, and set up in long lines upon a frame, where they are polished and made ready for use. Whatever be the size of the types, they are all made of a uniform height, and must be perfectly square in their angles, otherwise it would be quite impossible to lock them together. A single irregular type would most likely derange a whole page. The height of a type is, or ought to be, exactly one inch; but founders, much to their discredit, do not act with uniformity in this particular, the letters of some founders being higher than those of others. But all the types of one class of any founder are always uniform in size and height; and to preserve their individuality, all the letters, points, &c. belonging to one class, are distinguished by one or more notches or nicks on the body of the type, which notches range evenly when the types are set. These nicks, as we shall immediately see, are also exceedingly useful in guiding the compositor. Types are likewise all equally grooved in the bottom to make them stand steadily.

The varieties of size of types in the present day amount to forty or fifty, enlarging by a progressive scale from the minutest used in printing pocket Bibles, to the largest which is seen in posting-bills on the streets. Printers have a distinct name for each size of letter, and use about twelve sizes in different descriptions of book-work; the smallest is called *Diamond*, and then follow, in gradation upwards, *Pearl*, *Ruby*, *Nonpareil*, *Minion*, *Brevier* (the type with which this sheet is printed), *Bourgeois*, *Long Primer*, *Small Pica*, *Pica*, and *English*. The larger sizes generally take their names thus—*Two-line Pica*, *Two-line English*, *Four*, *Six*, *Eight*, or *Ten-line Pica*, &c. Other nations have adopted different designations for their letters, principally from the names of their inventors; for instance, the French entitle Small Pica, *Philosophie*, from the first maker of the letter. All kinds of types are sold by weight by the founders, the price varying in amount according to the size of the letter. The smallest size, *Diamond*, costs about 12s. per pound; *Brevier*, about 3s. 6d.; *English*, about 2s.; and so in proportion for all intermediate sizes. Expensive as types thus are, their prices will not appear too high considering the immense outlay in cutting the punches and the general manufacture. In the *Diamond* size, 2800 go to a single pound weight of the letter *i*, and of the thinnest space about 5000.

A complete assortment of types is called a *Fount*, which may be regulated to any extent. Every type-founder has a scale showing the proportional quantity of each letter required for a fount; but it has to be remarked, that every language possesses its own scale. For the English language, the following is a type-founder's scale for the small letters of a fount of types of a particular size and weight:—

a	5500	h	6400	o	8000	v	1200
b	1600	i	8000	p	1700	w	2000
c	3000	j	400	q	500	x	400
d	4400	k	800	r	6200	y	2000
e	12000	l	4000	s	8000	z	200
f	2500	m	3000	t	9000		
g	1700	n	8000	u	3400		

It will be seen from this scale that the letter *e* is used much more frequently than any other character.

Types are nowhere manufactured so well as in Great Britain, and for their elegance and regularity of form, they have been much indebted to the late William Caslon, letter-founder in London. Mr Caslon was originally an engraver of ornamental devices on the barrels of fire-arms, and a maker of bookbinders' tools. The neatness with which he executed his work brought him into notice, and he was appointed to cut a fount of Arabic letters, for an edition of the New Testament. This occurred about the year 1720, and from this period he entered on a successful career as a letter-founder. Hitherto the types used in England had been mostly imported from Holland; but the decided superiority of Caslon's letters over those of all competitors at home and abroad, soon put a stop to the importation of foreign types; and were held in such estimation, as to be frequently sent to continental countries. From 1720 till 1780, few books were printed in England with the types of any other foundry, which still continues in existence in London.

The ingenuity and success of Caslon meet with a parallel in the case of the late Mr Alexander Wilson, type-founder in Glasgow. This person, by a strong effort of perseverance under difficulties, began to cut punches for types at his native town, St Andrews, about the year 1740, and there opened a letter-foundry—the first established in Scotland—in company with an equally enterprising individual named Bain. In 1744, Messrs Wilson and Bain removed with their foundry to the neighbourhood of Glasgow, in which city it still continues to flourish. Mr Wilson's style of letter was exceedingly elegant and neat, and these qualities led them to be employed in the printing of some beautiful editions of the Classics, by Messrs Robert and Andrew Foulis, the University printers. A branch of this Glasgow letter-foundry is now established in Edinburgh, under the firm of Wilsons and Sinclair. Besides this, the only other letter-foundry in Edinburgh is that of Messrs Miller and Company, type-founders to his Majesty for Scotland. The types manufactured by this house are unrivalled for neatness, beauty, and regularity, in which respects they compete with those of Wilson. They are largely employed in the printing of Bibles, newspapers, and other works in which a small type is required; and it is with letter from this extensive foundry that CHAMBERS'S JOURNAL and the present publication are executed.

The large letters, used in posting and hand bills, are manufactured chiefly at Sheffield. In this description of types very great improvements have also been made in recent times; and the varieties are becoming yearly more numerous and peculiar in character. The letter used in printing in North America is made principally at New York; and the style of both typography and presswork in that country is rapidly improving, and now almost competing with the products of the English press.

COMPOSING.

All the types in use in the printing-office are sorted in cases, or shallow boxes, with divisions. There are two kinds of cases—the *upper* and *lower case*; the latter lying nearest the compositor upon the frame for their support. In the upper case are placed all the capitals, small capitals, accented letters, figures, and characters used as references to notes. In the lower case lie all the small letters, points, and spaces to place betwixt the words. In the lower, no alphabetical arrangement is preserved; each letter has a larger or smaller box allotted to it, according as it is more or less frequently required; and all those letters most in request are placed at the nearest convenient distance to the compositor. By this ingenious and irregular division of the lower case, much time is saved to the compositor, who requires no label to direct him to the spot where lies the particular letter he wants. To a stranger in a printing-office, nothing appears so remarkable as the rapidity with which the compositor does his work; but habit very soon leads the hand rapidly and mechanically to the letter required. When Italic letters have to be introduced, they are taken from a separate pair of cases of the same fount.

The process of composing and forming types into pages may now be adverted to. Placing the copy or manuscript before him on the upper case, and standing in front of the lower case, the compositor holds in his left hand what is termed a composing-stick. Sometimes this instrument is of wood, with a certain space cut in it of a particular width of a line or column; but more commonly it is made of iron or brass, with a moveable side, which, by means of a screw, may be regulated to any width of line. In either case, the composing-stick is made perfectly true and square. One by one, the compositor lifts and puts the letters of each word and sentence, and appropriate points, into his stick, securing each with the thumb of his left hand, and placing them side by side from left to right along the line. When he places a letter in the stick, he does not require to look whether he is placing it with the face in its proper position. His object is accomplished by looking at what is called the *nick*, which must be placed outwards in his composing-stick. This is one of those beautiful contrivances for saving labour which experience has introduced into every art, and which are as valuable for diminishing the cost of production as the more elaborate inventions of machinery. When he arrives at the end of his line, the compositor has a task to perform in which the carefulness of the workman is greatly exhibited. The first letter and the last must be at the extremities of the line: there must be no spaces left in some instances, and no crowding in others, as we see in the best manuscripts. Each metal type is of a constant thickness, as far as regards that particular letter; though all the letters are not of the same thickness. The adjustments, therefore, to complete the line with a word, or at any rate with a syllable, must be made by varying the thickness of the spaces between each word. A good compositor is distinguished by uniformity of spacing: he will not allow the words to be very close together in some instances, and with a large gap between them in others. His duty is to equalise the spacing as much as he possibly can; and this is in some cases very troublesome. In composing poetry, or similar matter, where there is always a blank space at one of the ends of the line, spacing is very easily accomplished by filling up the blank with larger spaces, or *quadrats*. But whether prose or poetry, the matter of each line must be equally adjusted and *justified*, so as to correspond in point of compactness with the previously set lines. The process of composing is greatly facilitated by the compositor using a thin slip of brass, called a *setting-rule*, which he places in the composing-stick when he begins, and which, on a line being completed, he pulls out and places upon the front of the line so completed, in order that the types he sets may not come in contact with the types behind them, and smoothly glide into their places to the bottom of the composing stick.

When the workman has set up as many lines as his composing-stick will conveniently hold, he lifts them out into an elongated board, with a ledge on one or perhaps both sides, termed a *galley*, by grasping them with the fingers of each hand, and thus taking them up as if they were a solid piece of metal. The facility with which some compositors can lift what is called a *handful* of moveable type without deranging a single letter, is very remarkable. This sort of skill can only be attained by practice; and one of the severest mortifications which the printer's apprentice has to endure, is to toil for an hour in picking up about a thousand letters, and then see the fabric destroyed by his own unskilfulness, leaving him to mourn over his heap of broken type, technically called *pie*.

Letter by letter, and word by word, is the composing-stick filled; and by the same progression the galley is filled by the contents of successive sticks. When the compositor has set up as many lines as fill a page, he binds them tightly round with cord, and removes them from the galley. Sometimes, as in the case of newspaper and similar work, the *handfuls* of type are accumulated till they fill the galley, and are then removed in long columns. After the matter is thus so far prepared, it is the duty of the compositor to take an impression or *first proof* from the types, and then correct the errors he may have made. Proofs are usually taken by means of an old large press kept for the purpose. In the office of Messrs Chambers, in which the present sheet is composed, this lumbering piece of furniture is not required, all proofs of galleys and pages being taken by a small iron roller, which runs on raised ledges upon a neat metal table, on which the types are placed, and giving a sufficient impression to the compositor without any trouble. After the galley matter is corrected, and re-corrected by the compositor, it is divided into pages of the size wanted; and head-lines, or figures indicating the number of the page, being added, the pages are arranged upon a large firm table, and there securely fixed up in an iron frame or *chase*, by means of slips of wood and wedges, or *quoins*.

This process, which is called *imposing*, being completed, and the face of the types being levelled by a *plainer* and mallet, the *form*, as it is called, is proved and prepared for press. Proof-sheets being taken, they are subjected to the scrutiny both of a *reader* employed in this peculiar function in the office, and of the author. These having made their marks pointing out words and letters to be altered or corrected, the compositor once more goes over the form, correcting the errors by lifting out the letters with a bodkin, and, when revised, the sheet is pronounced ready for working. It may be explained that the imposing table at which all these corrections are made, is composed of smooth stone or marble, on the top, from the circumstance of materials of that nature not being liable to rust from the water which is often thrown upon the types while preparing them for the press, or in laying them out for distribution after working off.

It need scarcely be told that the size of books greatly varies; but the sizes are all reducible to a standard determined by the number of leaves into which a sheet of paper is folded. The most common size is *octavo*, each sheet of which contains eight leaves, or sixteen pages; the next is *duodecimo*, containing twelve leaves, or twenty-four pages in the sheet; and the next *octodecimo*, or eighteens, containing thirty-six pages in a sheet. There are many other sizes, such as the larger *quarto* (which is the size of the present sheet), the smaller *twenty-fours*, &c. The knowledge of placing pages of types in a form so as to produce, when printed, a regular series upon paper, is one of the branches of the art to be acquired by the young compositor.

PROGRESSIVE IMPROVEMENTS IN STYLE.

From what has been detailed, it will readily be supposed that the style of preparing pages of types for the press has been greatly improved since the invention of printing. When we examine old printed books, the difference of style of execution is very striking. The early printers were frequently governed by the wish to make their printed pages bear a resemblance to the old manuscript books formerly in use; and upon the whole, much less taste was displayed, in respect of neatness and accuracy, than might have been expected from the intelligent class of men who first cultivated the "divine art." The following particulars, relative to the early productions of the press, will show how the style of book-printing was gradually improved:—"With respect to their forms, they were generally either large or small folios, or at least quartoes: the lesser sizes were not in use. The leaves were without running title, direction-word, number of pages, or divisions into paragraphs. The character itself was a rude old Gothic mixed with Secretary, designed on purpose to imitate the handwriting of those times; the words are printed so close to one another, that it was difficult and tedious to be read, even by those who were used to manuscripts, and to this method; and often lead the inattentive reader into mistakes. Their orthography was various, and often arbitrary, disregarding method. They had very frequent abbreviations, which in time grew so numerous and difficult to be understood, that there was a necessity of writing a book to teach the manner of reading them. Their periods were distinguished by no other points than the double or single one—that is, the colon and full point; but they a little after introduced an oblique stroke, thus /, which answered the purpose of our comma. They used no capital letters to begin a sentence, or for proper names of men or places. They left blanks for the places of titles, initial letters, and other ornaments, in order to have them supplied by the illuminators, whose ingenious art, though in vogue before, and at that time, did not long survive the masterly improvements made by the printers in this branch of their art. Those ornaments were exquisitely fine, and curiously variegated with the most beautiful colours, and even with gold and silver; the margins, likewise, were frequently charged with variety of figures of saints, birds, beasts, monsters, flowers, &c., which had sometimes relation to the contents of the page, though often none at all. These embellishments were very costly; but for those that could not afford a great price, there were more inferior ornaments, which could be done at a much easier rate. The name of the printer, place of his residence, &c. &c. were either wholly neglected, or put at the end of the book, not without some pious ejaculation or doxology. The date was likewise omitted, or involved in some cramps circumstantial period, or else printed either at full length, or by numerical letters, and sometimes partly one and partly the other—thus, one thousand CCCC and lxxliii, &c.; but all of them at the end of the book. There was no variety of characters, no intermixture of Roman and Italic; they are of later invention; but their pages were continued in a Gothic letter of the same size throughout. They printed but few copies at once, for 200 or 300 were then esteemed a large impression; though, upon the encouragement received from the learned, they increased their numbers in proportion."

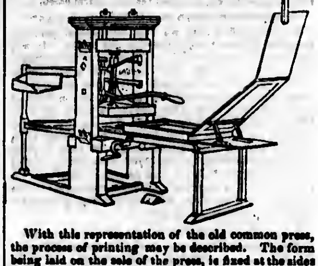
About 1469-70, alphabetical tables of the first words of each chapter were introduced, as a guide to the binder. Catch-words (now generally abolished) were first used at Venice, by Vindelinus de Spire. Early printed books had no signatures. Signatures are those letters of the alphabet which are put at the bottom of the right hand pages of sheets to distinguish their order. When the alphabet is finished, a second begins A a, or 2 A, instead of a single A; and when that is terminated, A a a, or 3 A, begin the third, and so on. In order to indicate more correctly the order of each sheet, printers add figures to the initial letter on the third, fifth, and seventh pages; the numbers of these figures, which do not pass the middle of the sheet, point out the size of the edition. Thus, A 2 on the third page, A 3 on the fifth, and A 4 on the seventh, show a work to be in 8vo; in the 12mo size, A 5 on the ninth page, and A 6 on the eleventh page, &c.; but it is now customary to give signatures only on the first and third pages of 8vo, and on the first, third, and fifth pages of 12mo.

In some modern French works, figures are substituted for letters, and the other leaves are marked by asterisks. The invention of signatures is ascribed by M. Marolles to John of Cologne, who printed at Venice in 1474; the Abbé Rive attributes it to John Koelhof, a printer at Cologne, and contemporary with the former, from whom we have a work dated in 1472. It is, however, of little consequence who was the originator, for, on the whole, signatures are rather a clumsy expedient, merely to direct the binder in folding the sheet, and are generally much too conspicuous upon the pages.

One of the chief improvements in the style of typography has been the dismissal of abbreviations and connected letters from the founts. Formerly, abbreviations were very common: the word *they* was indicated by the letter *y* and a small *e* above it; the conjunction *and* was indicated by &, which is a contraction of *et*. There were many of this species of abbreviations in printing both the English and Latin languages, and these were not more unseemly than the connected letters; such, for instance, as the junction of the letters c and *t* by a curve stroke from the top of one to the other. In recent times, all these connected letters have been disused, with the exception of *ff* and *fi*, because the head of the common *f* would press against the *l*, and be broke. Another very great improvement has been effected in the dismissal of the long *s*, in cases of two of this letter coming together.

PROCESS OF PRINTING.

The duties of the compositor do not involve the process of printing. When the forms are duly prepared in the composing-room, they are carried into the press-room, and come entirely under the charge of the pressmen. The earliest printing-presses were exceedingly rude, and seem to have resembled the common screw press, with a contrivance for running the form under the point of pressure. This must have been not only a laborious and slow operation, but one exceedingly defective, from the difficulty of regulating the impression, and the endangering of the face of the types. The defects in these original presses were at length remedied by an ingenious Dutch mechanic, Willem Jansen Blaew, who carried on the business of a mathematical instrument maker at Amsterdam. He contrived a press, in which the carriage holding the form was wound below the point of pressure, which was given by moving a handle attached to a screw hanging in a beam having a spring, which spring caused the screw to fly back as soon as the impression was given. This species of press, which was almost entirely formed of wood, continued in general use in every country in Europe, till the beginning of the present century. With certain lever powers attached to the screw and handle, it is here represented.



With this representation of the old common press, the process of printing may be described. The form being laid on the sole of the press, is fixed at the sides so as to render it immoveable from its position. There are two men employed: one puts ink on the form either by means of stuffed balls or by a composition roller—the other works the press. The latter lifts a blank sheet from a table at his side, and places it on what is called the *tympan*, which is composed of parchment and blanket stuff, fitted in a frame like a drum (and hence its name), and which, by means of hinges connecting it with the sole, folds down like a lid over the form. As the sheet, however, would fall off in the act of being brought down, a skeleton-like slender frame, called a *frisket*, is hinged to the upper extremity of the tympan, over which it is brought, to hold on the paper. Thus, the frisket being first folded down over the tympan, and the tympan next folded down over the form, the impression is ready to be taken. This is done by the left hand of the pressman winding the carriage below the *platten* or pressing surface, and the impression is performed by the right hand pulling the handle attached to the screw mechanism. The carriage is then wound back, the printed sheet lifted off and another put on the tympan, the form again inked, and so on successively. In the above engraving the press appears with the frisket and tympan sloping upwards, ready to receive the sheet, the frisket being sustained from falling backwards by a slip of wood depending from the ceiling. One of the greatest niceties connected with this art, is the printing of the sheet on the second side in such a manner that each page, nay, each line, shall fall exactly on the corresponding page and line on the side first printed. To produce this desirable effect, two iron points are fixed in the middle of the sides of the frame of the tympan, which make two small holes in the sheet during the first pressure. When the sheet is laid on to receive an impression from the second form, these holes are placed on the same points, so as to cause the two impressions to correspond. This is termed producing *register*; and unless good register is effected, the printing has a very indifferent appearance. Expert workmen perform these operations with surprising rapidity, though with considerable labour. The two men employed at a press take the process of pulling and inking for alternate quantities. After the forms are wrought off, they are washed in a solution of potash to remove the remains of the ink, which is of a thick oleaginous character, and then carried back to the composing-room to be distributed. This last operation is very speedily performed by the compositors.

To suit paper for printing, it is necessary to wet it some hours previous to its being used. This is done by dipping alternate quires in water, and afterwards pressing the mass with a heavy weight, till the whole is in a half dry state or of a damp consistency.

INK AND INKING ROLLERS.

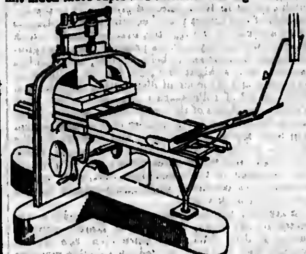
Much of the beauty of good printing depends on the quality of the ink, which it requires very considerable skill to manufacture. Among the old race of printers, little attention was paid to this department of the art; and it is only within the last thirty or forty years that the efforts of printing-ink manufacturers have been directed to the production of a material possessing the qualities of depth and durability of colour. It is now manufactured in London and Birmingham in a very superior manner, and from thence is supplied to printers all over the United Kingdom. Good printing-ink is made of genuine linseed oil, boiled to the consistency of a syrup, and then well mixed and ground with lamp-black. To be excellent, it must be stiff without strong adhesion, and keep soft and mellow, but dry quickly as soon as it is on the paper; above all, it must keep the colour, and not turn yellow after being printed with some time. It is made of different qualities, from 1s. 6d. to 5s. and upwards per pound weight.

One of the greatest of recent improvements in the art of printing is in the mode of inking the forms. From the days of Guttenberg, this had been done by stuffed cushions, or balls covered with skins, by which no regularity could be preserved, and no speed acquired. Earl Stanhope, when he invented his improvement on the press, attempted the plan of inking by means of rollers, but he could not discover any species of skin suitable for the purpose; all that this nobleman so anxiously desired, was at length achieved by the mere chance observation of a process in the Staffordshire potteries, where rollers formed of a composition were used. A Mr Forster, employed at a bookseller's printing-office at Weybridge, was the first who applied it to letter-press printing, by spreading it, in a melted state, upon coarse canvass; the inventors of printing machines soon caught the idea, and, by running the composition as a coat upon wooden cylinders, produced the perfect inking rollers. The composition is formed of treacle and glue, which, being heated and melted together, and poured into long iron moulds, produce a soft and pliable substance, nearly resembling soft India rubber, admirably adapted for distributing the ink over the surface of the types. The inking-roller is composed of a wooden centre covered with composition, is connected at each end with a handle, after the plan of a common garden-roller. The ink to be used is placed upon a metal table of an appropriate construction, and a portion being lifted by the roller, it is fully distributed over its surface, by rolling backward and forward on the smooth part of the table. The roller is then rolled once or twice over the face of the types, which is found a much better process than daubing them with the old-fashioned balls.

IMPROVED PRINTING-PRESSES.

It is exceedingly remarkable, that, notwithstanding the importance of the art of printing, the structure of the presses in universal use remained the same, without any improvement, till about the beginning of the present century. Before the introduction of presses upon an improved construction, the whole of the work of the printer was executed by the wooden press, of which we have given a representation above. But this press was liable to many objections. The surface communicating the impression, or *platten*, was generally only the size of half a sheet, and so after one portion of a form was pressed, the carriage had to be still farther wound in, and the remaining portion pressed. The consequence was, that, besides losing time, the impressions upon a single sheet were not always uniform, one part being perhaps harder pressed than the other. The clumsiness of the mechanism, the length of time occupied in working, and the labour to the pressman, afforded sufficient reasons for the attempt to improve the structure and general character of the press; nevertheless, as we have said, it was long before suggestions of this kind were carried into effect. The individual to whom the great honour is due of improving the printing-press, was the late Charles Earl of Stanhope, a nobleman who devoted much of his time to mechanical science, and who died greatly regretted in the year 1816.

Lord Stanhope's improvements did not go the length of altering the general form or construction of the press. He left the same plan to be pursued of winding the carriage below the *platten* by a handle and *rounce*, and of pulling the impression by the application of the right hand to the seat of power. What he accomplished was the constructing of the press with iron instead of wood, and that of a size sufficient to print the whole surface of a sheet, and of applying such a combined action of levers to the screw as to make the pull a great deal less laborious to the pressman; the mechanism altogether being such as to permit much more rapid and efficient working.



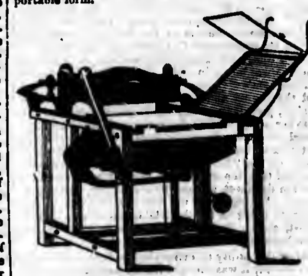
The *Stanhope press*, which is here represented, consists of a massive frame of iron, cast in one piece. This is the body of the press, in the upper part of which a nut is fixed for the reception of the great screw, and its point operates upon the upper end of a slider fitted into a dovetail groove formed between the two vertical bars of the frame. The slider has the platten firmly attached to the lower end of it; and, being accurately fitted between the side guides, the platten must rise and fall parallel to itself when the screw is turned. The weight of the platten and slider is counterbalanced by a heavy weight behind the press, suspended by a lever which acts upon the slider to lift it up, and keep it always bearing against the point of the screw.

There are two projecting pieces cast with the main frame, to support the carriage when the pull is made; to these, rails are screwed, and placed exactly horizontal for the carriage to run upon, when it is carried under the press to receive the impression, or drawn out to remove the printed sheet. The carriage is moved by a rounce or handle, with leather girths, very similar to the wooden press. Upon the axle of this handle a wheel is fixed, round which leather belts are passed, one extending to the back of the carriage to draw it in, and two others which pass round the wheel in an opposite direction to draw it out. By this means, when the handle is turned one way, it draws out the carriage; and by reversing the motion, it is carried in. There is likewise a check strap which limits the motion of the wheel, and, consequently, the action of the carriage. The principal improvement of Earl Stanhope's press consists in the mode of giving motion to the main screw of it, which is not done simply by a lever attached to the screw, but by a second lever. The main screw has a short lever fixed on the upper end of it, and this communicates by an iron bar or link to another lever of rather shorter radius, which is fixed upon the upper end of a second spindle, and to this the handle or lever by which the press is worked is fixed. Now, when the workman pulls this handle, he turns round the spindle, and, by the connection of the rod, the main screw turns with it, and causes the platten to descend with it and produce the pressure. But it is not simply this alone, for the power of the handle is transmitted to the screw in a ratio proportioned to the effect required at the different parts of the pull; thus, at first, when the pressman takes the handle, it lies in a direction parallel to the frame, or across the press; and the short lever (being nearly perpendicular thereto) is also nearly at right angles to the connecting rod; but the lever of the screw makes a considerable angle with the rod, which therefore acts upon a shorter radius to turn the screw; because the real power exerted by any action upon a lever is not to be considered as acting with the full length of the lever between its centres, but with the distance in a perpendicular, drawn from the line in which the action is applied to the centre of the lever.

The obvious excellence of the Stanhopian improvement in gaining power for the handle, led a number of printers to apply this species of lever power to the screw of the common press, but we believe not with marked success. The improvements of Lord Stanhope were speedily followed by the attempts of other individuals in Great Britain and America, to remedy the ancient defects in printing mechanism. So numerous, indeed, have these attempts been since the beginning of the present century, that it is quite out of our power to mention them in detail. With, we believe, one or two exceptions, all the modern improvers of the printing-press have confined their efforts chiefly to the process of communicating pressure to the platten, so as to modify labour, and procure greater rapidity of working. In these cases the screw has been generally dismissed, and power procured sometimes by the action of two or more inclined planes working against each other, in other instances by fulcrums and levers, and in others by the straightening of a joint. The latter is an exceedingly simple and beautiful form of power, and may easily be comprehended when we say, that it resembles the bending and straightening of the knee-joint of the leg: when the knee of the upright bar of the press is bent, the platten is drawn up; and when the knee is forced by a lever into a perpendicular position, the platten sinks, and the pressure is communicated. This may be considered the most efficient mode of compressing the platten yet discovered, and it would be difficult to rival it in the properties of simplicity and rapidity of execution. Nevertheless, such is the number and variety of improved presses in the present day, that it would not be easy to decide upon which has the best claims to the notice of printers. Among those which have gained a large share of approbation, may be mentioned the *Columbian press*, which is of American invention. This new press was brought to this country in 1818, by Mr George Clymer of Philadelphia, and made the object of a patent. The pressing power in this instance is procured by a long bar or handle acting upon a combination of exceedingly powerful levers above the platten, and by many workmen this press is greatly preferred to any other.

The various improved presses which we have noticed are, in most cases, made of at least three sizes, namely, *demy*, *royal*, and *super-royal*—that is, they are respectively able to print sheets of these sizes; and they accordingly vary in price from about L.50 to L.80 each. They are nearly all manufactured by the patentees in London. In the present day, the old wooden press of Blaew is entirely discarded from use in printing, and it is only to be seen in an obscure corner of the printing-office, reduced to the humble character of a proof-press.

The only instance worth mentioning, in which an improved press was made of quite a new construction, was in the case of the ingenious invention of Mr John Ruthven of Edinburgh. This mechanician contrived a press in which the types stand upon a fixed frame or table, while the pressing part or platten is brought over the form by being hurled forward on wheels. On being brought over the form, a depending hook or notch at each end of the platten is caught and pulled down by the combined action of levers beneath the table, and operated upon by the left hand of the pressman. This was an exceedingly meritorious invention, and many presses on this plan were manufactured and sold, but experience has evinced that the contrivance is only valuable when applied to small presses, not larger than foolscap size, and chiefly useful for executing jobs. Mr Ruthven makes his presses as small as quarto size; and as they stand on a table, and can be easily wrought by any gentleman, no better press could be recommended to the notice of the amateur printer. The following cut presents a correct representation of Mr Ruthven's press, which it will be perceived is of an exceedingly compact and portable form.



THE CHAPEL.

It is worth while to remark, that till the present day the phraseology used in relation to the mechanical details of the printer, possesses certain traces of the early connection of the art with men of learning. A number of the technical terms, as may be seen from the descriptions we have given, are a corruption of Latin words. We may instance *tympan*, from tympanum, a drum, and *stet*, which is used as a mark in correcting proof-sheets, and which is from the Latin word to stand. The name *brevier*, applied to a certain size of type, originated in that letter being first used in printing the Breviaries of the Romish church. An exceedingly old practice prevails among printers of calling their office a *Chapel*, and under this title the compositors, pressmen, and all others engaged in the office, have been in the habit of meeting together, and forming a species of lodge, in order to settle affairs connected with the internal arrangements of the office, or any disputes which may occur among members. The general improvement in every thing connected with printing establishments, and the advance of manners, have greatly modified the spirit which used to prevail in these confederacies; nevertheless, the appellation of *the chapel* remains, and is of traditionary interest. It has been supposed by many writers that the title of Chapel originated in Caxton's exercising the profession of a printer in one of the chapels in Westminster Abbey; and it is exceedingly probable that it has an origin of this nature, for printing was at first carried on in many places in England in connection with religious houses. Hence, in M'Creery's poem, entitled "The Press," the author has the following lines:—

> "Our art was hail'd from kingdoms far abroad,
> And cherish'd in the hallow'd house of God;
> From which we learn the homage it receiv'd,
> And how our sires its heavenly birth believ'd.
> Each printer hence, howe'er unblest his walls,
> E'en to this day his house a CHAPEL calls."

PRINTING BY MACHINES.

After all the ingenuity of Lord Stanhope and that of his successors had been lavished on the press, still the process of printing could not be executed but with considerable fatigue, and at a rate of speed seldom greater than that of throwing off 250 impressions, or 125 complete sheets, in an hour. It must appear obvious that this was a state of things quite incompatible with the advancement of knowledge, and the necessity for producing a large quantity of impressions in a short space of time, particularly as regarded newspapers. It became apparent that an entire revolution should be effected in the structure of the press; that the flat printing surface should be discarded, and cylinders brought into use. We have now to describe how this great new invention, applied to printing-machines, came to be adopted.

In 1790, Mr Nicholson, the editor of the Philosophical Journal, procured a patent for certain improvements in printing, which patent embodies almost every principle since so successfully applied to printing-machines; and although he did not carry his views into practical effect, little has been left for subsequent engineers to do, but to apply, in the most judicious manner, the principles he laid down in his patent. He may therefore be justly considered as the originator of the great modern improvements in printing machinery; for with him originated the ideas of taking the impressions from types by means of cylinders, and of inking the form with rollers instead of balls, which constitute the two essential parts of all effective modern printing-machines.

Whether Mr Nicholson's ideas were known to Mr König, a German, is now uncertain; but to him is due the distinguished merit of carrying steam-printing first into effect. Mr König, conceiving it possible to apply steam-power to produce accelerated speed with the common press, after various unavailing efforts to obtain assistance from the printers on the Continent, came to England. Arriving in London about 1804, he submitted his scheme to several printers there with no better success, until introduced to Mr Bensley senior, who, attracted by Mr König's plans, entered into arrangements with him. After persevering for some time in various attempts to accelerate the speed of the common press, and at the same time render the attendance of the man who inks the types unnecessary, his exertions resulted, to use his own words, "in discovering that they were only employing a horse to do what had been before done by a man." He in consequence gave up all idea of his projected improvements of the common press, and turned his attention to CYLINDRICAL PRINTING.

After continued experiments for some years, a small machine was made, in which the two leading features of Nicholson's invention were embraced (the cylinders and the inking-rollers), which he exhibited to Mr Walter, proprietor of the Times newspaper; and, on showing what further improvements were contemplated, an agreement was entered into for the erection of two machines for printing that journal. Accordingly, on the 28th November 1814, the public were apprised that the number of the Times of that date was the first ever printed by machinery, steam propelled. At this period but few persons knew of any attempts going on for the attainment of this object; whilst, among those connected with printing, it had often been talked of, but treated as chimerical.

After the utility of cylindrical printing had been thus proved, it was thought highly desirable that the principle should be applied to printing fine book-work, where accurate register is indispensable. This was, to a certain extent, attained, by using two large cylinders, the sheet of paper being conveyed from the bottom of the first cylinder (where it had received the first impression) by means of tapes, leading in a diagonal direction to the top of the second cylinder, round which the sheet was carried till the second side was printed. The first machine of this description was erected at Mr Bensley's office, where it continued at work for some years, till more modern machines superseded it.

So sanguine were the patentees (Mr König, Mr Bensley, and Mr R. Taylor) that no further improvement could be effected, that, in March 1817, they issued a prospectus, offering three kinds of machines at high prices, and requiring a considerable annual premium; but we believe these offers were not embraced.

In the course of 1818, Mr Napier, and Messrs Applegath and Cowper, took out patents for improvements in cylindrical printing machinery. Mr Napier's invention consisted principally in using grippers instead of tapes, as in König's, for seizing hold of and leading the sheet of paper round the cylinders—a contrivance which answers the purpose admirably. The cylinders, which are of a small circumference, are placed so, that, though revolving securely on their axles, and giving a sufficient strength of impression, they rise and fall alternately—rising to avoid touching the types at the part where there is no paper to be pressed, and falling to give the impression when the sheet is ready for receiving it. These cylinders are placed close together, and the machine occupies not more than half of the space of an ordinary book-printing machine. This press of Mr Napier may be kept in motion by manual labour, but steam-power is preferable. Ingeniously as this machine has been constructed, the principles upon which it works have made it give way in general estimation to those of Applegath and Cowper. These mechanicians' patent, which expired in 1832, referred principally to the application of two drums placed betwixt the cylinders, to insure accuracy in the register, over and under which the sheet was conveyed in its progress from one cylinder to the other, instead of being carried, as in König's machine, in a straight line from the one cylinder to the other; and the mode of distributing the ink upon tables instead of rollers—two principles which have secured to machines of this construction a decided preference for fine work. Machines of this construction have been made by Applegath and Cowper for the principal printing establishments in London, Paris, Edinburgh, and many other cities; and it is nearly upon the model of their machines that other manufacturers now construct their steam-presses for the execution of book-work.

In Ireland, the first steam printing-machine was erected by Mr Gunn, for Mr P. D. Hardy, printer, Dublin, in July 1833; and since then, the Dublin Evening Mail has been printed by a double machine of Mr Gunn's construction, which throws off that journal at the rate of about 2300 an hour.

In America, and on the Continent, machines were introduced shortly after their invention in England, and are now generally used, but principally for newspapers. Mr König established a manufactory for printing-machines at Frankfort-on-the-Maine, which is still carried on, we believe, successfully.

Printing-machines are now made of various kinds, adapted to the peculiar descriptions of work for which they are required. These descriptions of work may be classed under two distinct heads, namely, the printing of newspapers, one side at a time, and the printing of a better kind of sheets, or book-work, both sides at a time. There can be nothing more easy than to make a machine capable of first printing one side of a sheet of paper, and afterwards the second, by the removal of one form and the introduction of another; but this process will not produce *register*: the second side may or may not be on the back of the first, and the work is therefore of a very inferior appearance, though suitable enough for newspapers, in the working of which dispatch is alone required. This kind of press is therefore the best adapted to gain that end; for the first side of the paper may be printed deliberately, and the second side be made up to the last moment of time, and then thrown off. To produce a machine to print both sides at a time, and with perfect register, no small degree of mathematical accuracy, and no small share of ingenuity in the mechanician, are required. The great and important object to be attained in this kind of machine, is to cause the sheet, after it has received its first impression, to travel along the sides of the cylinders and drums at such a rate as to meet the types of the second side at the exact point which will cause the second side to fall with perfect accuracy upon the back of the first. To accomplish this exceedingly desirable end, the cylinders and drums must revolve at precisely the same speed as the carriage underneath; and, therefore, any inaccuracy in the turning of the axles, the cutting of the teeth of the wheels, or any other deficiency, however slight, will produce bad registered sheets, and create an enormous degree of vexation to the printer. With these explanatory remarks, we pass on to a notice of four different machines, calculated to produce register and non-register sheets, under various modifications and rates of speed.

1. A machine with one cylinder, called a single machine, generally used for printing newspapers; it throws off from 900 to 1200 an hour on one side, requiring two boys, one to lay on the paper, and another to receive it when printed.

2. A machine with two cylinders, called a double machine, but only printing from one form of types at the rate of from 1600 to 2200 an hour, requiring two boys to lay on the sheets, and two to take them off, exclusively used for newspapers. It consists of two small cylinders about ten inches in diameter, placed about five inches apart, and suspended from a beam at each end. A camb or eccentric causes the beams to vibrate, and with them the cylinders to rise and fall about one-half of an inch. The cylinders turn in opposite directions, and as the machine only prints one form at a time, that cylinder only which is turning in the same direction as the types, is permitted to rest upon the form, and take the impression, so that a sheet is printed by each cylinder alternately every time the type-carriage goes backwards or forwards. Two boys feed the paper into the machine, at two drums placed about three feet above the carriage, and the sheets are led down to the cylinders by tapes, which also convey it, after being printed, to the end of the machine, where two boys receive the sheets and lay them straight in a heap, ready to be again put through the machine when the second form is placed on the type-carriage to print the other side. There is a distinct and complete apparatus for inking the types at each end, similar in principle to that which will be found described in the account of the book-machine. In 1829, a machine of this description, made by Applegath and Cowper, was introduced into Scotland by Messrs Gray, the enterprising proprietors and publishers of the North British Advertiser.

3. A machine, similar to that used by the Times, with four printing cylinders, requiring the attendance of eight boys, and throwing off about 4000 sheets an hour. To attempt to describe this machine without diagrams, is difficult; but a general idea may be conveyed of its principle, by its being considered as two double machines placed in contact. There are four printing cylinders, about nine inches in diameter each, placed close together in pairs, but with a space of about seven inches between the centre ones, in which space there are two inking-rollers. Each pair of cylinders are secured to the ends of two strong beams, by means of adjustable connecting rods; to these beams a slight vibrating motion is given, by means of cambs, so as to cause the alternate cylinders to rise and fall about one-fourth of an inch. The type-carriage and inking-tables have a reciprocating motion, and the movements are so adjusted that those two alternate cylinders shall be depressed and press upon the types, whose motion coincides with the carriage, and, of course, the other two alternate cylinders are by the same means raised sufficiently to permit the types to pass free under them, till the carriage changes the direction of its motion, when the position of the cylinders is reversed, and the pair which formerly took the impression from the types are in their turn raised. Thus, every time the form of types moves backwards or forwards, two sheets of paper are printed. The paper is fed into the machine over four drums, placed in pairs over each other, at a considerable height above the machine, by four boys. The sheets are led down from the drums to their respective cylinders by means of broad tapes, and by other tapes they are conducted out to the ends of the machine, where they are received by four other boys, when printed, ready to be again passed through the machine to receive the impression on the second side.

This ingenious machine has only two inking apparatuses, one situated at each end. There are three pairs of inking-rollers, one pair at each end, close to the two outer cylinders, the remaining pair being placed between the two centre cylinders. The inking-tables are about three feet wide, and the motion of the carriage is sufficiently long to bring each table not only under its respective pair of inking-rollers, but also to enable each table alternately to ink the centre pair. Thus, the form is first inked by one of the outer pairs of rollers; the first cylinder is raised; in passing under the second, an impression is given, and, of course, the ink is taken from the form, but it immediately becomes inked anew by the centre pair of rollers; the third cylinder is raised; the form passes to the fourth cylinder, where another impression is taken; and the motion of the form being continued a little farther, it gets again inked from the outer pair of rollers at the opposite end of the machine from whence it started. In its return, the two cylinders which had just taken the impression are raised; the other two now print in their turn, the inking process going on as before; and two sheets are again thrown off.

The fourth kind of machine is called a book or perfecting machine, printing both sides of the sheet in register before it leaves the machine. The machine from which the engraving at the head of this article is taken, is one of this description, and bears a resemblance to that of Applegath and Cowper. It was planned and contrived by Mr Robert Gunn of Edinburgh, and made by the well-known engineers, Claud Girdwood and Company of Glasgow. It has now printed our Journal and other publications for some months, in a style which is hardly equalled, and certainly is not surpassed. We shall now proceed to describe it as intelligibly as the nature of the subject will permit, so as to convey to our readers a general idea of the principles upon which it is constructed. The machine is about fifteen feet long by five broad, and consists of a very strong cast-iron framework, secured together by two ends and three other cross pieces. To this frame all the parts of the machine are fixed. Parallel with the sides of the machine, and about two feet apart, are placed two rails the whole length of the frame, and upon these rails the type-carriages move backwards and forwards, small pullies being interposed between the rails and the type-carriages to diminish friction.

There are two type-carriages connected together, at such a distance apart that each form of types may be acted upon by its respective cylinder so as to produce the impression. The carriages are made perfectly level, and upon them the forms are placed, and secured by wedges.

The outer extremity of each type-carriage forms an iron table, upon which the ink is laid, and spread or distributed, and thence called the inking-tables. They are about half an inch lower than the surface of the types, so as to prevent their soiling the tapes when passing under the cylinders. To the type-carriages and inking-tables thus connected together, a reciprocating motion is given, by means of a short vertical spindle placed in the centre of the machine with a pinion at its upper end, which works into the teeth of a double rack, and above the pinion are a small stud and friction pulley. The rack is secured to the under side of the carriages by slides, which permit it to move freely only from side to side, being guided in its lateral movement by a set of levers which form a parallel motion. The object of this lateral motion of the rack is to allow it to move from the one side round to the other side of the pinion, and thus convert its continuous rotatory motion into a reciprocating one in the type-carriages. The stud and pulley on the top of the upright spindle are for the purpose of leading the rack round the pinion at the turns. The upright spindle is driven by a pair of bevelled wheels from the main shaft.

The two printing cylinders are nearly nine feet in circumference each, and are placed about two feet apart. They are accurately turned, so that the surfaces of the type-carriages and the cylinders may be perfectly parallel. The axis of each cylinder works in brass bearings in the upright framework, where, by means of screws, the degree of pressure with which the cylinders are allowed to rest upon the types, may be regulated to any degree of nicety. Over about two feet of the circumference of each cylinder which forms the printing surface, two folds of cloth, called blankets, are stretched by means of rollers placed inside the cylinder. The lower blanket is seldom changed, but the upper one on the second cylinder (which stands in the stead of what are called slip-sheets in hand-press printing) must be shifted as soon as the ink which it has absorbed from the printing on the first side of the sheet begins to set off, or soil the paper when receiving the second impression. This shifting is speedily effected, by unrolling a sufficient quantity of the cloth off one roller, and winding it up on the other, to present a clean portion to the printing surface. There are two narrow slits in each cylinder parallel with its axis, through which the blankets pass from the rollers inside, to the periphery of the cylinder.

The cylinders have a continuous rotatory motion towards each other, given by two large toothed wheels, whilst the type-carriages move backwards and forwards under them. The movements are so contrived that the type-carriages shall have gone and returned to the same point during the period that the cylinders have made one entire revolution; consequently, each successive impression is taken from the types by the same part of each cylinder, and thus, in order to bring the impression level, the same facility for patching or overlaying is afforded as at the hand-press.

The two drums placed between the cylinders are for the purpose of causing the sheet of paper to pass smoothly and accurately from one printing cylinder to the other, and do not *turn* the sheet, as represented by all the accounts of the machine which we have seen. The two drums, and the cylinder A, are connected together by toothed wheels, so as to cause the circumferences of the cylinders and drums to move together with one uniform velocity, and thereby prevent any sliding or shifting of the two systems of tapes over each other during their motion round the cylinders and drums; as, upon this, much of the perfection of the register depends.

The drum D has a very important function assigned to it, namely, making register. From various causes, such as the heat or moisture of the room, the state of the paper, or any inaccuracy in adjusting the forms, the register may become slightly irregular; and to obviate this, the second drum is suspended by a screw at each end, so as to permit it to move up or down to the extent of about an inch. Upon a little consideration, it will be obvious, that, if you increase or diminish the distance between the points where the two impressions are given, you accelerate or retard the sheet, while in its progress to receive the second impression, to the same extent; and as the raising or lowering of the drum has this effect, register is secured by turning its screws, and thus altering its position, as circumstances require. The lateral register can only be adjusted by placing the forms accurately on the type-carriages; but as it is not affected by the same causes as the register in the other direction, it very seldom requires alteration.

There are two complete inking apparatuses, one at each end of the machine; both are precisely similar, one being required to ink each form. We shall describe the one at the left end of the machine, which inks the second form:—About eight inches above the form is the ink-trough F, forming the bottom and back of a square box or receptacle for the ink: the front edge of the bottom being ground to fit very accurately to the surface of an iron roller, called the ductor, which forms the front of the trough, in which it slowly revolves inwards in fixed bearings at the ends. The trough is adjustable by means of three screws placed behind, which press the scraper so close to the ductor as to permit a stratum or film of ink, of the requisite thickness, to remain upon it. This film of ink is so thin, that from one to two inches in breadth, and of the length of the form, is requisite to ink the types for a single impression. The ink is taken from the ductor by a small composition roller G, called the feeding-roller; this roller is placed between the extremities of two levers or arms, fixed parallel upon a horizontal rod across the machine. By means of a crank motion from the cylinder shaft and adjustable connecting rods, a vibrating motion is given to the levers, so as to cause the feeding-roller to press for a short time against the ductor at one extremity of its movement, and to rest upon the inking-table at the other end of its vibration: in other words, this roller, by the motion of the press, is caused to rise at the proper time, and take down ink to the table, and in its descent meets the table exactly as it approaches. This may be reckoned the most beautiful and interesting part of the process of machine-printing. From the way in which the feeding-roller lays the ink, it is spread over the whole surface of the table by passing twice under the distributing-rollers before the table advances to the inking-rollers, which causes a degree of perfection in the distributing of the ink hitherto unattained.

To the ductor, a rotatory motion, which can be varied at pleasure, is given by means of a gut band which passes over two cones of pullies, one on the cylinder axle, and the other on the end of the ductor. By this arrangement, the quantity of ink which the feeding-roller receives can be varied at pleasure, by merely shifting the position of the band upon the cones.

Under the ductor are two distributing rollers, as they are technically called, placed diagonally across the machine *in opposite directions*, and resting in open bearings, which allow the rollers to rest with their weight upon the inking table as it passes under them. The result of this disposition of the rollers is a compound motion precisely similar to that of two cork-screws, but in opposite directions; the adhesion of the elastic surfaces of the rollers upon the table causing them to revolve upon their centres, whilst their diagonal position gives them a motion in the direction of their length. The ink is thereby spread equally over the surface of the table, ready to be taken by the inking-rollers. Close to the cylinders at K are three rollers, called inking-rollers, because they ink the types. They revolve in open bearings, and lie parallel to the cylinder.

Having described the inking apparatus in detail, we shall now explain its combined action. The inking process, then, consists of five parts:—There is the body of ink in the trough, from which the ductor takes a film of the requisite thickness.—From the ductor the ink is taken by the feeding-roller, and by it laid upon the table.—Over the surface of the table the ink is equally distributed by the compound motions of the distributing rollers.—When so spread, the reciprocating motion of the carriages brings the table under the inking-rollers, which thus receive the colour; and as the types also pass, in going and returning, under the inking-rollers, they become inked.

As the cylinders move in opposite directions, it must be obvious that that cylinder alone can print whose motion is coincident with the type-carriage at the time; and this occurs alternately, when the forms, after being inked, are passing inwards under their respective cylinders—the first form being printed when the type-carriages are moving from right to left of the engraving, and the second form when they are returning from left to right. As the forms, after the impressions are taken, have to return under the cylinders to be inked anew, a portion of each cylinder is turned down to a smaller radius, so as to allow the types to pass clear.

The apparatus for putting the paper into the machine is placed at one end, in front of the boy M. It consists of a series of broad tapes placed close together, passed over two small rollers about five feet apart. The ends of the tapes are secured to a wooden bar placed across, with its ends fastened to two endless leather belts. On an axis are fixed two large pullies, over which, and a roller (not shown in the drawing, but situated under the laying-on board) the two belts pass, and are secured. On the end of the axis with the pullies is a segment of a wheel with ten teeth, with a lever projecting from it. Another segment, with a projecting stud, is attached to the side of the large wheel, which in its revolution causes the stud first to act upon the lever, so as to throw the teeth of the two segments into gear, and by that means the series of endless tapes are made to move forwards about twelve inches, at first with a gradually accelerating motion, and soon at a uniform velocity, so that the sheet of paper, which lies upon the series of endless tapes, may not be displaced by a sudden jerk, and that it may be thrust into the machine with the same velocity as the cylinders.

To prevent the paper from slipping when going in, there are two projecting studs fixed to the tapes *behind* the sheet; up to these studs, and to a side guage, the boy places the paper. The instant the two segments become disengaged, the one with which the tapes are connected is drawn back by a gut band and balance-weight to its original position, ready for the next sheet.

We now come to treat of the tapes, which steadily lead the sheets of paper in their mazy course through the machine. They are about half an inch broad, made of strong materials, and are formed into two series of endless bands, arranged at certain distances apart, so as to fall into the interstices and margins of the forms, and are guided or retained in their proper positions by the moveable grooved guiding pullies *e*, *d*, and by the stretching pullies *c*, which are for the purpose of retaining the tapes at the proper degree of tension, being moveable, so as to correspond with the position of the other pullies. All the tapes meet together on the top of the receiving drum Q, at the point where the sheet is received into the machine; proceed in contact round the under part of the first cylinder, over the first drum, under the second, over and round the second cylinder to the point at which the printed sheet is thrown out, where they diverge; the one series *o o* then returns under the rollers *g* and *h*, over the stretching pullies *c* and the roller *i*, to the guiding pullies *d*, whence we traced them. The others, after quitting the point where the two series separated, pass upwards between the cylinders, over the guiding pullies *e*, down under the rollers *k* and *m*, over the stretching pullies (not seen, being concealed by the boy M), and up to the receiving drum Q, where the two series of tapes again meet.

The operation of printing is thus performed:—A boy M stands upon an elevated stool near the end of the machine, with a mass of damped paper lying on a board at his right hand. He takes a sheet off the heap, and lays it upon the broad tapes, placing it accurately to the guages: at the proper instant the sheet is pushed or drawn forward to where the two series of margin tapes meet, and being seized between them, is led round part of the receiving drum to the point where it and the cylinder nearly touch; it there leaves the drum, and embraces the first cylinder upon the printing blanket—the motion continuing, brings it to the lowest point of the cylinder at A, where it comes in contact with the first form of types moving in the same direction, and the impression is gradually taken line by line. As the sheet is printing, it moves upwards till it meets the first drum, which it passes over; then under the second drum; leaves that and comes upon the printing surface of the second cylinder, in an inverted position, that is, with the unprinted side of the sheet outermost, ready for the impression of the second form, which it receives at the lowest point of the cylinder, where it meets the second form of types, and is perfected. The sheet is by this time at the point where the two series of tapes diverge, and is there thrown out upon the fly-board placed between the cylinders, whence the sheets are taken by a boy, and laid in a heap upon a table before him.

The machine is put in motion by a belt from a steam-engine passing round a pulley on a horizontal shaft, which, by means of toothed wheels, gives motion to all the cylinders, drums, and type-carriages; the small rollers are turned by the tapes. The machine may be stopped at any instant by turning the handle of a lever, which shifts the belt from the fast to a loose pulley, without stopping the engine.

To produce an impression with a flat surface from a large form, requires a force of about from forty to fifty tons! and even with a cylinder, where a line only is impressed at a time, the pressure is little short of a ton. But, in the machine, to prevent any undue pressure of the cylinders upon the forms, there are wooden bearers, of the same height as the types, screwed upon the sides of the carriages under the ends of the cylinders; thus effectually shielding the types from the enormous and injurious pressure which a cylinder might, through accident or otherwise, be caused to exert.

Such is a description of the machine which is constantly employed in printing "CHAMBERS'S EDINBURGH JOURNAL," "HISTORICAL NEWSPAPER," and the present work, "INFORMATION FOR THE PEOPLE," and which it executes, as we have said, in a style not surpassed by any other species of press. In point of breadth of cylinder and type-carriage, this machine was originally intended to print a double sheet of these publications, or two separate sheets, and it still could do so if necessary. Hitherto it has printed only single sheets, but with so much greater rapidity than was previously calculated upon, and done its work so extremely well, that there has been found no occasion to make it produce two sheets at a time. The rate of speed at which it was calculated to print, was 750 sheets in the hour—the usual rate at which Cowper's best book-machines work; but it has been found that it will send forth with ease 800 an hour, or, if necessary, 900 an hour, or fifteen sheets in the minute, perfect and complete. From the time it was put up and fairly set to work, it has produced, in general, 8000 sheets per day, never "tiring" in its arduous labour, and never stopping unless during the night and on Sundays, or when it happens to outstrip our compositors in the execution of their department of the work. Prodigious as the quantity of printing is which this excellent machine executes, and great as is its rate of speed, not less astonishing is the smallness of the power employed in keeping it going, and the lightness of the duty of those who attend on its operations. It is placed at the end of a large well-lighted apartment on a ground floor, and the power is communicated to it by a belt proceeding by a hole cut in the wall from a small steam-engine, standing in a side-room. This engine is of no more than two-horse power, and is kept in motion by a boiler in a place adjacent. To regulate the engine, a man is employed, and the same person supplies the furnace with coal. Of this necessary article, about half a ton, or three shillings worth, is consumed daily: it will be recollected that coal is a cheap commodity in Mid-Lothian.

The printing-machine is under the superintendence of a steady person, well acquainted with the art of printing: it is his duty to place and displace the forms, to watch the impressions to see that the printing does not go out of register, to supply fresh bundles of paper; and take away the lots which have been printed; to regulate the darkness of the inking, to mend the tapes when any of them are accidentally broken, and, in short, to take complete cognisance of the whole process. The only other individuals engaged about the machine are the two boys, whose figures appear in the cut—the one doing nothing but laying on blank sheets, and the other as continuously taking them out when printed. These, therefore, form the complement of individuals employed in connexion with the process of steam-printing; but in the same apartment in which our machine works, other two men are engaged—one whose duty consists in damping and preparing the paper, carrying forms, &c.; and another, who is constantly engaged in counting off the printed sheets, and putting them in quires, preparatory to their being packed up, and sent off to the booksellers in the various parts of the country.

The nature and extent of the steam-press establishment which prints our sheets in Edinburgh, are now described; and it may be mentioned, that, on a similar, but more extensive scale, is the establishment of our agents in London, at which the editions of our works are printed for circulation in England. It will readily be supposed that the expense of erecting the machinery, which we have noticed, is by no means inconsiderable, even although printing-machines have fallen in price since the expiry of the patents. The machine of which we have given an engraving, cost upwards of L.300; but the erection of the steam-engine, the outlay for blanket stuff for the cylinders, and other accessories, amounted to at least L.300 additional. The cost of Cowper's printing machinery in London is considerably higher; this, however, some consider to be partly compensated by the exceeding accuracy and elegance of the workmanship.

Judging from the extraordinary perfection to which steam-printing has been brought within a very few years, it might reasonably appear that no farther improvements could be effected on this department of the printing art. But there is no discovered limit to human ingenuity. Every year is producing some curious if not valuable addition to printing machinery, and at present no one can foresee the termination to this as well as any other class of improvements. Besides those various descriptions of machines above alluded to, as being principally in use, there are others calculated to execute work of a more peculiar nature. Perhaps the most wonderful of these ingenious pieces of mechanism is a machine which has been made to print two colours by only one impression. The manner in which this apparently difficult duty is performed is singularly interesting. The printing cylinder, instead of revolving on its axle in a fixed socket, as in the other machines, is made to roll backwards and forwards, and the table for the types is stationary. The cylinder in retiring from giving the impression is followed by three inking-rollers, which, having received their ink from the distributing-plate, apply a fresh charge to the surface of the types. So far for one colour. When two colours, we shall suppose blue and red, are required to be printed, a portion of the form to be blue is placed on the table, and the other portion to be red is placed on a table directly underneath. This under form is inked by the advancing and retiring of rollers in the same manner as is the case with that above; being inked, the table heaves upwards, and the form or types are pushed into interstices left open for them in the upper form. Thus both surfaces are brought upon a level, and remain so till the cylinder effects the impression, when the lower instantly sinks. The sheet, when printed, is carried away by endless tapes, or cloth, and deposited on a table placed for the purpose. The forms used in this process are usually blocks or plates, dissected according to fancy, and the upper table not being solid, but composed of jointed brass susceptible of alteration, to permit the introduction of the under form, the printing of two colours at once is as simple as it is ingenious. On the same principle, three or more colours may be used, only by having additional tiers of inking rollers, distributing surfaces, and plates. We believe Sir William Congreve was the original inventor of the machine which has thus been applied to the purpose of printing in various colours. Hitherto, the work which has been executed by it has consisted chiefly of the stamp-duty marks for the Excise, and for bank-notes, fancy labels for druggists, and other similar jobs.

The only other peculiar machine which we may here notice, is one invented by Mr Cowper, intended to print from convex stereotype plates. The plates, instead of being fixed flat upon blocks, as will shortly be described, are fastened upon the cylinders, so as to give them a bent form, and the printing is effected with the face of the plate or type surface downwards; wherefore the paper is placed undermost instead of uppermost, as in all other printing. This mode of taking impressions is, however, more fanciful than useful, and is applied principally to the printing of religious tracts or other common work.

The introduction of printing machinery, either in adaptation to newspapers or books, has been effected more from the enterprise of certain individual printers, than from a general conviction among the members of the trade that it was an improvement upon the old process of printing. It was hardly, indeed, to be expected that printers, who had been so long accustomed to see the impression taken from types by means of flat surfaces, could all at once be reconciled to the use of cylinders instead. Accordingly, when they were first introduced, a prejudice existed, and still exists, with many in the business, that the face of the types is much more greatly injured by machines than by the ordinary press; whereas experience has demonstrated that this opinion is unfounded, because, in fact, the sharp angles of the letters are worn away by the paper being pressed by the soft elastic blanket into the interstices of the letters, and this is effected as completely when the impression is taken with a flat surface, as when a cylinder is used. The latter prints literally only a line at a time, and that minute portion of the circumference of a cylinder of nearly three feet in diameter, which presses upon the types, may, for all practical purposes, be safely considered a flat surface. From our own experience in both modes of printing, we would say that new types are much sooner worn down in their finer parts and acute angles by the pressure of cylinders than by that of the platten of a manual press; but then, on the other hand, such is the power—the searching pressure of cylinders, that a fount of types *will print well a great deal longer by a machine than by a hand-press.* We are confirmed in this belief by the opinion of different individuals who possess steam-printing machinery. The prejudice against cylindrical printing has led to very numerous and expensive attempts to apply steam-power to machines with flat printing surfaces. Some of these made by Napier have succeeded tolerably well, but they have never yet been found to equal, either in point of expedition, quality of work, or economy, the cylindrical machine. The last improvement in this description of machine was patented by a person in Newcastle, the leading feature of whose invention consists in placing the forms of types in a *vertical* position. We consider all attempts of this nature quite hopeless and fantastic.

Whatever may have been the prejudices of printers with regard to cylindrical printing, they have not been more strong than the dislike of the pressmen to the application of this greatest of all improvements in the art. It was believed by the operative printers generally, that machines would ruin their trade, and that henceforward they would perhaps spend their days in poverty and wretchedness. But the experience of a few years has proved how ill-founded these melancholy anticipations have been. It is now seen that manual and machine presses possess each peculiar characters, and do not trench upon the work of each other to an extent worth mentioning. The hand-press is much superior to the machine when the impression is limited to 750 or 1000 copies; it being hardly worth while to prepare the forms, to alter the tapes and blankets, and to set the machine a-going, for so small an impression. Hand-presses, therefore, will most likely always command the printing of books of limited impressions, and when particularly fine work is required. Presses wrought by men are, however, entirely unavailing when the impressions come to be thousands in number. This fact was strikingly developed in our own case. Before our steam-press was erected, we had sometimes the greatest possible difficulty to get our Journal printed. The impression for Scotland, which was 25,000 copies weekly, occupied two presses night and day for six days in the week, there being eight men employed, four acting as a relief during the night. Even by this incessant toil, our publication was frequently kept back so late as to prevent the dispatch of country parcels. It almost appeared that human nature could not stand up against such violent labour. No amount of wage seemed to be able to cause the workmen to remain sober. Notwithstanding the utmost attention of the master printers, the stereotype plates were damaged, and the paper wasted. On one occasion, we could not get the work printed at any price in Edinburgh, and were compelled to send it to Glasgow—a distance of 44 miles—to be executed. Such occurrences as these, and the dreadful harassment of mind which ensued, led us to think of removing the printing of our publications altogether to London. From this step, however, we were saved by Messrs Ballantyne and Company kindly undertaking to execute our printing with their machines; and with these our Journal was printed until our own machine was erected in October 1833. Those only who have experienced the same species of vexation which we had done, can understand the feeling of delight which animated us on first seeing this machine regularly at work, and both by the quantity and quality of its produce, affording a joyful prospect of future tranquillity.

We mention the above circumstance with the view of pointing out the utter inability of hand-presses, when large impressions, especially of periodicals, are required. Granting that they could, by calculation, execute the impressions in good time, it is too much to expect that human beings can, day after day, and week after week, exert their muscular strength to such a painful and body-killing extent. By the removal of our printing and that of others from hand-presses, it, moreover, does not appear that the quantity of work suitable for manual labour is lessened. The appetite for reading which sheets like the present create, leads to the reading, and, consequently, to the increased printing of books, and that in most instances by presses wrought with the hand.

By the erection of steam-presses, the three grand requisites, speediness of execution, quantity, and cheapness of labour, are procured to an extent demanded by the necessities of the age, and, without the aid of printing-machinery, the tide of knowledge and human improvement would be forced back greatly to the injury of society. Nothing, in our opinion, within the compass of British manufacturing industry, presents so stupendous a spectacle of moral power, working through the means of inert mechanism, as that which is exhibited by the action of the steam-press.

APPENDIX.—Stereotyping.

We may now offer a brief explanation of the process of stereotyping, which has been of immense service to literature. Stereotyping is the manufacturing of fictitious pages of types, and the invention is generally attributed to a Mr William Ged, of Edinburgh, about the year 1725. When the art was properly made known, it was hailed with acclamation by the printing and publishing world; but as experience developed its powers, it was found to be strictly applicable only to a particular kind of work.

When a page is intended to be stereotyped, the same process of putting up the types is gone through that we have already mentioned; instead, however, of being carried to the press, the page is plastered over with liquid stucco to the thickness of about half an inch, so that a level cake is formed on the surface of the types. As soon as the stucco hardens, which it does almost immediately, the cake is separated from the types, and, on being turned up, shows a complete hollow or mould-like representation of the faces of the types, and every thing else in the page. There being no longer any use for the types, they are carried off and distributed. As for the cake, it is put into an oven, and baked to a certain degree of heat and hardness, like a piece of pottery. It is next laid in a square iron pan, having a lid of the same metal, with holes at the corners. At the bottom of the pan there is a moveable plate, called the floating-plate; and upon this plate, which has a smooth accurate surface, the mould is placed with its face downwards. The lid being now placed and held tightly on by a screw, the pan, by the assistance of a crane and other mechanism, is immersed in a pot of molten lead, and being allowed to fill by means of the holes, it is at length taken out and put aside to cool. On opening the pan, a curious appearance is presented. The lead has run into the mould side of the cake, and formed a thin plate all over, exhibiting the perfect appearance of the faces of the types on which the stucco was plastered. Thus is procured a plate, or fictitious page of types, not thicker than the sixth of an inch. When the plate comes out of the pan, it is in a somewhat rude state, and has to be carefully pruned at the edges, its little specks picked clean, and, if necessary, one or more bad letters cut out, and replaced by soldering in the heads of moveable types. The plate is also planed upon the back by means of an ingenious rotatory cutting machine upon which it is fixed.

The stereotype plates, so prepared, are next taken to the printing-office, and made ready for press. This is done by placing them upon iron or wooden blocks, so that both plate and block make up the exact height of a page of real types. They are fixed to the blocks by the aid of small metal catches at the sides, head, and foot, which catches are held fast by slips of furniture properly wedged. Notwithstanding the great care taken in making the plates level and of a uniform thickness, it is seldom they are perfect; and to make them as accurate as possible for a fair impression, scraps of thin pasteboard or paper are placed betwixt them and the blocks at the thinnest parts. When the impression is completed, the plates are unfixed, packed up, and laid aside for future use. Now for the specific utility of stereotyping.

In all cases of common book-work it is best to print from types to the amount of the copies required, and then distribute the types; but in most cases of books published in parts, sheets, or numbers, stereotyping becomes absolutely necessary. It is easy to perceive the reason for this. When books are published in numbers, it often happens that many more copies are sold of one number than of another; and unless the types be kept up to complete sets in the hands of the publisher, or to print copies according to the increased demand, a serious loss is sustained. The manufacture of stereotype plates is, therefore, simply a means of keeping up fictitious types to answer future demands, at an expense greatly inferior to that of keeping the actual pages standing, or of putting the types up anew.

As this publication, as well as the Journal, is regularly stereotyped, there has, perhaps, hardly ever occurred such a remarkable instance of the value of this vast improvement in the typographic art. The very manner in which the work is effected furnishes matter for surprise. The types being put up on the premises of the publishers, are sent off in pages to a stereotype foundry, where two sets of plates are moulded, and the pages are then returned. One set of plates is kept for use in Edinburgh, and the other sent in a box by the royal mail or steam-vessel to London, where it is immediately subjected to a steam-press, and, in a few hours, made to produce twenty thousand or more printed sheets. By this wonderful process, the expense of setting up the types in London is avoided, and the publishers thereby permitted to extend the circulation of their works on the most liberal principles, and in a very quick manner, all over the empire, both to the benefit of the booksellers and the public. At the outset of the Journal, stereotyping most unfortunately was not resorted to; in consequence of this oversight, some of the numbers were put up in types four and five times, to print off additional supplies; and it has only been since the whole were regularly stereotyped, as well as printed with machinery, that the work has produced any profit commensurate with the exertions bestowed upon it, or been conducted with satisfaction to the parties concerned.

Edinburgh: Published by W. and R. Chambers, 19, Waterloo Place; also by Orr and Smith, Paternoster Row, London; and Young and Cunningham, Dublin. Sold by John Macleod, Glasgow, and all other Booksellers.

NATURAL PHILOSOPHY.

NATURAL PHILOSOPHY is a term of wide import and comprehensive meaning. It is not confined to one science alone, but includes many; all, indeed, which teach the nature and properties of actually existing substances, their motions, their connections with each other, and their influence on one another. It is sometimes also called *Physics*, from a Greek word which signifies *nature*. But that word has now a more circumscribed meaning, being, in common discourse, confined to that branch of natural philosophy connected with bodily health.

All those subjects of human investigation which are dignified with the appellation of sciences, may be divided into three grand classes. The first, which relate to *number* and *quantity*, and teach the properties of numbers and figures, are called *Mathematics;* the second, which relate to *matter*, and treat of the properties of the various bodies with which we are made acquainted by means of the senses, or by philosophical experiment, are called *Natural Philosophy;* and the third, which relate to *mind*, and investigate its nature, and the motives and rules of human actions, and the ends to which they ought to be directed—in other words, those sciences which treat of the moral nature of man, both as an individual and as a member of society, are called *Intellectual* or *Moral Philosophy*. With the first and third of these classes we have nothing to do at present, though to treat of them forms a part of the plan of this work; and therefore we will revert to them upon a future occasion. It is to the second class of sciences that our attention is for the present to be entirely devoted.

The sciences included in the general term Natural Philosophy may be divided into two great branches. The first and most important, and on that account sometimes called *Natural Philosophy*, but more properly *Mechanical Philosophy*, investigates the sensible motions of all bodies. The second investigates the constitution and qualities of all bodies, and is designated by various names, according to its different objects. Of the sciences composing this class, there are several to which the generic appellation of Natural History has been given. These are, *Botany*, which treats of the arrangement, classification, and habits of vegetable bodies; *Zoology* (a word derived from the Greek, and signifying to speak of animals), which teaches the arrangement, classification, habits, &c. of the lower animals; *Geology* (from two Greek words, signifying to speak of the earth), which investigates the nature of the strata of the earth, and the causes which produced them; to that department of the subject which treats of the waters of the earth, the name of *Hydrology* is sometimes given; *Meteorology*, which teaches the nature and causes of the phenomena which take place in the atmosphere; *Mineralogy*, which teaches the arrangement, the structure, and the nature of minerals, and treats of the earth composed of these masses; and *Crystallography*, the science which teaches the forms of crystals. Crystals are those bodies which, when they cohere into solid masses, assume a determinate figure or form. This science, which is of recent origin, is still in its infancy; for although the exact shape of almost every crystal may be determined, yet the laws by which a certain species of matter is made to assume it, are by no means very manifest. As far as experiment has gone, the intimate constitution of solid bodies appears to be very complicated, and little can be said to be known upon the subject, philosophically speaking. *Chemistry* is sometimes separated from natural philosophy, but, in accordance with the enlarged definition of the term which we have adopted, it forms a part of it. It unfolds the nature of the intimate particles, the atoms of bodies, their relations to each other, and the laws by which their combination and decomposition are affected. Here we have a very broad line of demarcation between it and that branch of the subject called mechanical philosophy. The latter treats of the relation of mass to mass, together with their sensible motions; and the other, of atom to atom, including all the phenomena resulting from their mutual attractions. Closely connected with both zoology and botany are those sciences which have, what we may term, the surname of *Physiology* given them: these are animal, vegetable, and comparative physiology; and to assist the memory of the reader, it may be mentioned, that they all have reference to a *living* object, or at least to one which had life. Physiology relates to the phenomena of life in general. Animal physiology, or anatomy, teaches the structure and functions of animals. Vegetable physiology, or anatomy, teaches the structure and functions of vegetables. And comparative physiology, or anatomy, teaches the structure and functions of the lower animals, as compared with the human frame, which is the most perfect of all. *Medicine* is another, and a most important branch of the subject. It teaches the nature of diseases, the causes, cures, and the means of preventing them.

It cannot be denied that such a distribution of the subject is necessarily imperfect, on account of one science becoming intimately and unavoidably blended with another. "Thus," says Lord Brougham, "chemistry shows the qualities of plants with relation to other substances, and to each other; and botany does not overlook those same qualities, though its chief object be arrangement. So, mineralogy, though principally conversant with classifying metals and earths, yet regards also their qualities in respect of heat and mixture. So, too, zoology, besides arranging animals, describes their structures, like comparative anatomy. In truth, all arrangement and classifying depends upon noting the things in which the objects agree and differ; and among those things in which animals, plants, and minerals agree, must be considered the anatomical qualities of the one, and the chemical qualities of the other. From hence, in a great measure, follows the second observation, namely, that the sciences mutually assist each other. Mechanical philosophy, in like manner, assists, though, in the present state of our knowledge, not very considerably, both chemistry and anatomy, especially the latter; and chemistry very greatly assists both physiology, medicine, and all the branches of natural history."

The first great head is Mechanical Philosophy, or what may be termed Natural Philosophy proper. It consists of various subdivisions, each constituting a science of great importance. At the head is placed *Dynamics*, from the Greek word signifying power or force, and it teaches the laws of motion in all its varieties. This science may be said to form the foundation of the other branches of mechanical philosophy, and should be looked upon as forming a portion of every other rather than a distinct and separate one of itself. When applied to the motions of the heavenly bodies, it forms the science of *Physical Astronomy;* and when to the calculation, production, and direction of motion, forms the science of *Mechanics*, or, more properly, *Practical Mechanics*. The term practical has been prefixed to distinguish this branch of the subject from that which comprehends every thing relating to motion and force. When forces act upon bodies so as to produce rest, that branch of mechanics which investigates the subject is termed *Statics*, from a Greek word signifying standing still. These divisions again branch out into distinct subdivisions, each having a name corresponding to the states of the bodies treated of, whether solid, fluid, or aëriform, and also according as we consider the equilibrium or motion of matter in the three states above named.

The application of dynamics to the pressure and motions of fluids, such as water, constitutes the science of *Hydrodynamics*, from the Greek words signifying water, and power or force. This science is again divided into two others; first, *Hydrostatics*, which treats of the equilibrium or the weight and pressure of liquids, from the Greek words for balancing of water; and, secondly, *Hydraulics*, which treats of their motion, from the Greek name for certain musical instruments played with *water* in *pipes*. When dynamics is applied to fluids, light and invisible, like atmospheric air, it constitutes the science of *Pneumatics*, from the Greek word signifying breath or air. Pneumatics relates to the equilibrium or movements of aërial fluids under all circumstances of pressure, density, and elasticity. With the pressure of air upon all bodies on the earth's surface, the ancients were entirely unacquainted. To Galileo and his pupil Torricelli we are indebted for this important discovery. Intimately connected with the last science is that branch of natural philosophy called *Acoustics*, which treats of the nature of sound, and the laws of its production and propagation. The science of sound was cultivated from the earliest ages; but although both Pythagoras and Aristotle were acquainted with the manner of its transmission through the air, and also investigated the nature of harmony, until Bacon and Galileo, Mersenne and Wallis, Newton, Lagrange, and Euler, showed its nature and laws, and submitted it to mathematical scrutiny, it can scarcely be said to have risen to the elevated station of a separate science. We keep out of view its application in the delightful art of music. Its progress has been constant and accelerated, and is now considered an important branch of experimental and mathematical science.

One of the most extensive and interesting branches of natural philosophy is the science of *Optics*, from the Greek word to see. It treats of the properties of light and of vision, as performed by the human eye. Closely connected with light is *heat*, the laws of which, together with the subjects of electricity and magnetism, fall within the jurisdiction of natural philosophy.

Such is a brief outline of the extensive range of sciences comprehended under the generic term of Natural Philosophy. Some of them, such as astronomy and mechanics, we have already treated of; and it is not our purpose to recapitulate here what was stated in the numbers of this work devoted to these branches of the subject. But, connected in a particular manner with these, there are certain topics, such as the properties of bodies, and the laws of matter and motion, which it was not found convenient to discuss to the full extent which their importance entitles them to in the articles above named. To these points, therefore, we propose to direct our attention at present. The other sciences, such as acoustics, pneumatics, hydrostatics, hydraulics, optics, &c. will be fully treated of in some future numbers of this work. The present article is therefore to be considered principally as an introduction to the study of natural philosophy.

PROPERTIES OF MATTER.

Matter, or that of which all bodies are composed, whose existence is made known to us by means of the senses, or by the test of philosophical experiment, is possessed of various properties, some of which are termed essential, because we cannot conceive of matter existing without them. There are others which do not appear to be essential to matter—that is, we could conceive of the existence of matter which was destitute of them, but which, nevertheless, are never found wanting in matter—they are called general or contingent properties; and there is a third class of properties which can, by certain methods, be conferred upon matter. These various properties we shall describe according to their relative importance.

IMPENETRABILITY.

By impenetrability, is meant the property which all bodies possess of occupying a certain portion of space, by virtue of which they exclude other bodies from existing in the same place at the same instant. There is clearly a difference here between the meaning of the word as it is employed scientifically, and as it is used in common language. In the usual sense we call any hard body, such as a stone, impenetrable, because it firmly resists our efforts to pierce it. But as it is understood philosophically (although we can condense, pierce, and remove the greater number of them), all bodies are alike impenetrable, because they equally possess the property of excluding other substances from the space which they occupy. When any body, such as the human hand, is plunged into water, the water is displaced so as to make room for the hand which has been immersed; for a liquid and a solid can no more occupy the same place at the same time than two solids. There are cases in which a condensation takes place, when two fluids are mixed together, so that a considerable deal less space is occupied by the two together than was occupied by them in a separate state. But this arises from a chemical combination having taken place; the particles of the substances, by the mysterious agency of chemical attraction, have been drawn closer together; thus the whole fluid occupies less space than it did formerly. In the same way, a sponge, by being compressed, has its particles brought nearer to each other, and of course it has less bulk than it had before it was squeezed. Indeed, the hand and the sponge together occupy the same space as the latter did singly. A nail, driven into a piece of wood or other soft material, under certain circumstances does not enlarge the general size of the body; but in penetrating it, it displaces its particles, and occupies the space which they occupied, and accordingly they are rendered more dense, or become more solidified than they were before, just in the same way as the particles of the sponge when compressed. In the one case, the particles are condensed from without, and the other from within. But these particles still occupy a certain quantity of space which cannot be occupied by other particles at the same time, for in every case in which the attempt is made, although this apparently seems to be effected, it will be found that the one has been removed to make way for the other.

EXTENSION OR MAGNITUDE.

All bodies which are observable by the senses are found to occupy a certain portion of space—that is, they possess extension or magnitude; and those which are so small as to elude investigation in this manner, are considered by the understanding to possess it. Indeed, the impenetrability of matter presupposes its extension or magnitude. It is impossible to conceive of matter, however minute may be the particle, without connecting with it the idea of its having a certain bulk, and filling a certain quantity of space. In common phraseology, we express this property of bodies by the word size; but the most appropriate term is volume. Thus, we say the volume of a terrestrial or celestial globe is so many cubic inches. When the *lines* and *surfaces* of a body are spoken of, the external limits of its magnitude are implied. Lines are the limits which separate the several surfaces of the same body. They are also called edges. Thus, the line which separates the top from one of the sides of a box is denominated an edge. The quantity of a surface is called its *area*, and the quantity of a line is termed its *length*. Thus, we say the area of a floor is so many yards, and the length of a rope is so many yards. Volume, area, and length, however, are sometimes expressed by the word magnitude. The dimensions of magnitude or extension are usually entitled length, breadth, and depth; and they vary of course very considerably in different bodies, according to their shape. Height and depth are the same dimension, considered in different points of view. When a body is measured downwards, it is said to be so many feet, &c. deep; when measured upwards, it is said to be so many feet, &c. high. Breadth and width express the same dimension.

FIGURE.

When we say that every body possesses figure, we mean that the extension of every body is bounded. The figure or the shape of a body is indicated by the limits of extension. If we place our hand upon a solid body, we become sensible of its impenetrability and extension, for it resists the entrance of the hand within its dimensions; and that this obstruction commences in certain places, and has certain limits, which limits determine its figure. Figure and volume are entirely independent of each other, and should be carefully distinguished. Bodies which have the same figure may possess very different volumes. For instance, an orange and the globe have the same figure, but not the same volume; and bodies may have the same volume, but possess different figures. Thus, two masses of matter may have the same volume, although the one be round and the other square. The figure of a body is its shape or form, the volume of a body is its size or dimensions. In general, nature assigns regular forms to her productions. Besides those which belong to living bodies, minerals also possess them, as we see in the great variety of crystals. Many of these are alike remarkable for the symmetry of their form and the transparency of their colour.

But further, with regard to figure in general: When the subject is attentively considered, some difficulties arise with regard to figure being essential to matter; and two questions might be asked, which at first sight appear rather embarrassing to answer. 1. Can we not suppose a mass of matter to increase in extension till it becomes infinitely large; and if so, how can we assign any bounds to it; for by these, figure is determined? and, 2. Has a fluid, such as water, any figure? In reference to the first question, we reply, that, although we can *conceive* of a mass of matter larger than any assignable quantity or being indefinitely large, yet our minds cannot *rest* for a moment in contemplation of such a mass of matter, without at the same instant conceiving of its extremities, and thus associating it with determinate dimensions. The human intellect is not capable of grasping at infinity; for the very means which we employ to enable us to speculate or reason upon the subject, lead us to conceive of finite size. Hence, all bodies which we either perceive or conceive, do in reality possess the property of figure. With regard to the second question, we reply, that the terms *figure* and *regular figure* are not to be confounded with each other; for although it would be absurd to say that fluids have any constant or regular figure, it would be equally erroneous to deny, that, at any given instant of time, they have a definite and actual figure. The cohesion, however, which exists amongst the particles of fluids is so much inferior to that of solids, that the figure of these bodies is liable to be disturbed by the slightest cause. But whenever one figure is destroyed, another must be assumed, however different it may be from the former; for without we admit this fact, we must admit the annihilation of matter, which is an absurdity, and not at all indicated by any thing which we observe in the world around us.

The three properties above described, viz. impenetrability, extension, and figure, are the most important of those which belong to matter. They may be considered as the principal tests of materiality; and where they can neither be detected by the senses, nor made demonstrable by reason, there can be no matter.

DIVISIBILITY OR SEPARABILITY.

The susceptibility of matter to be separated into parts, is a fact rendered familiar to us by every day's observation. The melting of sugar in a tea-cup, of salt in our soup, and a thousand other examples, have taken place before our eyes a thousand times. To the practical subdivision of matter there seems to be no assignable limit; and many of the instances of it which may be found in philosophical investigations, almost exceed credibility. The useful arts, also, furnish many striking examples; but it is in the organised world that the most astonishing proofs of the extreme divisibility of matter are to be found.

The blood which flows in the veins of animals is not as it seems, an uniformly red liquid. It consists of small red globules, floating in a transparent fluid called serum. In different species these globules differ both in figure and in magnitude. In man, and all animals which suckle their young, they are perfectly round or spherical. In birds and fishes they are of an oblong spheroidal form. In the human species, the diameter of the globules is about the 4000th of an inch. Hence it follows, that, in a drop of blood which would remain suspended from the point of a fine needle, there must be about a million of globules.

Small as these globules are, the animal kingdom presents beings whose whole bodies are still more minute. Animalcules have been discovered, whose magnitude is such, that a million of them does not exceed the bulk of a grain of sand; and yet, each of these creatures is composed of members as curiously organised as those of the largest species; they have life and spontaneous motion, and are endued with sense and instinct. In the liquids in which they live, they are observed to move with astonishing speed and activity; nor are their motions blind and fortuitous, but evidently governed by choice, and directed to an end. They use food and drink, from which they derive nutrition, and are therefore furnished with a digestive apparatus. They have great muscular power, and are furnished with limbs and muscles of strength and flexibility. They are susceptible of the same appetites, and obnoxious to the same passions; the gratification of which is attended with the same results as in our own species. Spallanzani observes, that certain animalcules devour others so voraciously, that they fatten and become indolent and sluggish by overfeeding. After a meal of this kind, if they be confined in distilled water, so as to be deprived of all food, their condition becomes reduced; they regain their spirit and activity, and amuse themselves in the pursuit of the more minute animals which are supplied to them; they swallow these without depriving them of life, for, by the aid of the microscope, the one has been observed moving within the body of the other. These singular appearances are not matters of idle and curious observation. They lead us to inquire what parts are necessary to produce such results. Must we not conclude that these creatures have heart, arteries, veins, muscles, sinews, tendons, nerves, circulating fluids, and all the concomitant apparatus of a living organised body; and, if so, how inconceivably minute must these parts be! If a globule of their blood bears the same proportion to their whole bulk, as a globule of our blood bears to our magnitude, what powers of calculation can give an adequate notion of its minuteness!—*Lardner*.

The transparent wings of certain insects are so attenuated in their structure, that 50,000 of them placed over each other would not form a pile a quarter of an inch in height.

In the manufacture of embroidery, it is necessary to obtain very fine gilt silver threads; to accomplish this, a cylindrical bar of silver, weighing three hundred ounces, is covered with about two ounces of gold; this gilt bar is then wire-drawn, until it is reduced to a thread so fine, that 3400 feet of it weigh less than an ounce. The wire is then flattened by passing it between rollers under a severe pressure—a process which increases its length, so that about 4000 feet shall weigh one ounce. Hence, one foot will weigh the 4000th part of an ounce. The proportion of the gold to the silver in the original bar was that of 2 to 300, or 1 to 150. Since the same proportion is preserved after the bar has been wire-drawn, it follows that the quantity of gold which covers one foot of the fine wire is the 150th part of the 4000th of an ounce; that is, the 720,000th part of an ounce.

The quantity of gold which covers an inch of this wire will be twelve times less than that which covers one foot. Hence, this quantity will be the 8,640,000th part of an ounce. If this inch be again divided into 100 equal parts, every part will be distinctly visible without the aid of microscopes. The gold which covers this small but visible portion is the 864,000,000th part of an ounce. But we may proceed even further: This portion of the wire may be viewed by a microscope which magnifies 500 times, so that the 500th part of it will thus become visible. In this manner, therefore, an ounce of gold may be divided into 432,000,000,000 parts. Each of these parts will possess all the characters and qualities which are found in the largest masses of the metal. It retains its solidity, texture, and colour; it resists the same agents, and enters into combination with the same substances. If the gilt wire be dipped in nitric acid, the silver within the coating will be dissolved, but the hollow tube of gold which surrounded it will still cohere and remain suspended.

Dr Wollaston succeeded in obtaining platinum wire, the diameter of which did not exceed the 3000th part of an inch. A quantity of this wire, equal in bulk to a common die used in games of chance, would extend from Paris to Rome. Newton determined the thickness of transparent substances by observing what colours they reflected. A soap bubble, which is a thin shell of water, and the matter of soap, reflects different colours from different parts of its surface. Immediately before the bubble bursts, a black spot may be observed near the top. At this part, the thickness has been proved not to exceed the 2,500,000th of an inch.

Amongst other instances of the divisibility of matter, we may notice the following:—The particles of light afford an admirable proof of the fineness and tenuity to which matter can be reduced. They descend from a distance which in some cases can scarcely be calculated, with extraordinary velocity; and whilst they strike upon the most delicate part of the human body, the [illegible]e, the blow is imperceptible. How inconceivably minute, therefore, must the atoms of light be! The effluvia given forth by a single grain of musk has been known to perfume a large apartment for twenty years, and yet at the expiry of that period there was no sensible diminution of the odoriferous matter. In the process of abrasion we have a striking illustration of the divisibility of matter. The particles of sand in the Arabian desert have, by their attrition, polished the hard rocks over which they have been drifted by the winds, during a long succession of ages. The toe of the bronze statue in the church of St Peter's at Rome, has been actually worn away by the kisses of ardent pilgrims! Yet how infinitely small must have been the quantity which attached itself to the lip of the devotee at each salutation!

Such are some of the remarkable phenomena connected with the divisibility of matter; and we are naturally led to inquire, is matter infinitely divisible, or are there certain constituent atoms which are incapable of farther division? The latter supposition is the one most generally admitted, yet there is no denying that it seems scarcely a legitimate inference. For however small a particle may be, we can easily conceive of one still smaller—for instance, by simply supposing that same particle halved. To the understanding, without reference to direct observation, it seems as absurd to assign limits to the divisibility of matter, as boundaries to space, which is considered infinite. Nevertheless, philosophers are of opinion, that, by a due consideration of phenomena, the existence of constituent material atoms is not only rendered probable, but almost morally certain, although we are unable by direct observation to prove the fact. The most remarkable of these phenomena is the formation of crystals, of which an account is given in the number of this work upon Chemistry. The details of the process of crystallisation give indications that the ultimate atoms of which the crystallised substances are composed, have a determinate figure. And it appears reasonable to presume that all bodies are composed of atoms; that the different qualities with which we find different substances endued, are a result of the figure and magnitude of these atoms; that the latter are indestructible and immutable by any natural process, and that although so minute as to elude the most refined analysis which human ingenuity has contrived to bring them under observation, yet as possessing magnitudes which they do not exceed.

POROSITY.

That the minute indestructible atoms of bodies are not in a state of actual contact, but are separated at some distance from each other, although that is imperceptible, is an unquestionable fact, notwithstanding that it appears at first sight unwarranted. In the article Chemistry, we have shown that the attraction subsisting amongst the particles of bodies is overcome by the repulsive agency of heat; that the latter exists even in the coldest bodies; and that, wherever it is present, it tends to keep the particles asunder. Hence it follows, that the volume of a body consists partly of material particles, and partly of interstitial spaces, which spaces are either an absolute void, or filled by some substance different from the body in question. These spaces are denominated *pores*, and the quality of having these is denominated porosity. The crossing of the constituent crystalline needles or plates in bodies also produces porosity. In some cases these are visible to the eye; in others they are brought within the sphere of observation by means of the microscope, and in all they can be proved to exist in some way or another. Owing to this circumstance, some bodies, such as water, become more bulky when rendered solid, than what they were when in the liquid state. The proportion of the quantity of matter to the volume, is called the *density*, which is always in an inverse ratio of the porosity.

The instances of porosity are numerous in every department of the material world, but those which are connected with animal and vegetable bodies are the most remarkable. Bone is a tissue of cells and partitions, and, when seen through a microscope, may be said to resemble a honeycomb. Wood appears as if it were a bundle of hollow tubes, like a pan pipe, for instance. If the end of a cylinder of straight wood be immersed in water, whilst the other is forcibly blown into, the air will be found to pass through the pores of the wood, and rise in bubbles through the water. A piece of wood, sunk to a great depth in the ocean, and exposed to the pressure there, has its pores filled with water, and becomes nearly as heavy as a stone. Thus, the boat of a whale-fishing ship, which had been dragged far under water by a whale, on being afterwards drawn up, was supposed to be bringing a piece of rock with it.

A piece of cork, in a strong close glass vessel nearly full of water, may be seen floating at the top; but if more water be then forcibly pumped into the vessel, the cork will be squeezed and reduced in size, until at last it becomes heavier than water, and sinks. On afterwards allowing water to escape, the cork will resume its bulk, and rise. A cork sunk two hundred feet under water will never rise again of itself.

A bottle of fresh water, corked, and let down thirty or forty feet into the sea, often comes up again with the water saltish, although the cork be still in its place; the explanation being, that the cork, when far down, is so squeezed as to allow the water to pass in or out by its sides, but on rising resumes its former size.*

The *compressibility* and *dilatability* of matter are qualities closely allied to porosity. By the former word is meant that quality in virtue of which a body allows its volume to be diminished without the quantity or mass of matter being diminished. It arises, of course, from the constituent particles being brought nearer to each other, and is effected in various ways; but the term compressibility is only applied to it when it is caused by the agency of mechanical force, as by pressure or percussion. All bodies are capable of being diminished in bulk, which is a conclusive proof of their porosity. But some of them have the power of resuming their former volume, when the force which diminished it is withdrawn. This quality is termed *elasticity*. All hard bodies, as steel, glass, ivory, &c. are elastic; and a great number of soft ones, as caoutchouc or India rubber, silk thread, a harp string, &c. The aëriform fluids, such as atmospheric air, are all exceedingly elastic; and so are liquids, such as water, but to a smaller extent. Elastic bodies vary much as to the extent to which they will yield without breaking, and as to the degree of perfection with which they regain their former state. A good sword may be bent until its ends meet, and resume its former straightness so perfectly as to appear as if it had never been disturbed. Other bodies, again, will retain something of a curvilinear shape. Marble and ivory are both very elastic. A billiard ball of the latter scarcely loses even its polish by long wear, although the parts which were struck yielded at every blow which they received. A marble chimney-piece, long supported by its ends, is found to have acquired a permanent bend. The elasticity of bodies is a quality of great utility, as is shown in time-pieces, such as watches, whose steel springs, although much and constantly bent, resume their original form when freed at the end of a century. Carriage-springs, gun-locks, &c. &c. are also instances of the usefulness of elasticity. Beds, sofas, couches, &c. derive their value from this property of matter as much as from their softness; indeed, their softness may be said to be derived from this quality. Air shows its elasticity at the greatest degree of rarefaction to which human ingenuity has as yet been able to carry it. A small quantity of air enclosed in a bladder, if freed from the pressure of the surrounding atmosphere by means of an air-pump, will, in virtue of its elasticity, raise a weight of several pounds. If a balloon were full while at the surface of the earth, it would infallibly burst when it ascended into the higher regions of the air. The density of the atmosphere, at the height of about $3\frac{1}{2}$ miles, is about one-half of what it is at the surface of the globe.

In recent times, the compressibility of water and other fluids has been determined by experiment. Mr Perkins, of London, found that a column of water an hundred times as heavy as the atmosphere (that is, exerting a pressure of 1500 lbs. upon every square inch) compresses water about [illegible] part of its whole magnitude.

Dilatability is the opposite of compressibility. It implies that quality of bodies by which they are enabled to be expanded in volume without being increased in the mass. The effect may be produced in several ways, for some bodies, as we have seen, have a natural tendency to dilate or expand after mechanical pressure is removed from them. But heat is the grand agent of nature, as well as art, in dilatation. This is manifested in an innumerable variety of natural phenomena, as well as philosophical experiments. As the subject, however, was treated of under Chemistry, it is unnecessary here to recapitulate the facts there brought under review. It may be stated generally, that the reduction of temperature, considered with reference to mechanics, is equivalent to compression, since it diminishes the volume without altering the mass; whilst an elevation of temperature is, on the same principle, equivalent to dilatability, since it enlarges the body without increasing the mass.

INERTIA.

In the number of this work devoted to Astronomy, we gave a general view of this property of matter, but it will here be necessary to enter more minutely into the subject.

From observation it must have early become evident to mankind that matter is incapable of spontaneous change of place. The history of the human mind, in its gradual progress from the savage to the civilised state, from the condition of ignorance to that of knowledge and philosophical superiority, is perhaps very similar to that of any individual mind, from the first dawn of reason, to the highest state of mental cultivation of which it is susceptible. One of the first inquiries of a child, when it sees either an object moving through the air, or upon the surface of the ground, is, How does it fly? how is it driven along? There is always a reference to some cause, some extraneous influence by which the state of rest of a body is broken, and it is enabled to shift from place to place. But this does not convey all the meaning which is implied in the word inertia. It expresses the resistance which matter makes to a change of state, whether that be motion or rest—in other words, that a body at rest would for ever remain so, were it not disturbed by some external cause; and that a body in motion would for ever continue to move on, were it not acted upon by external influence, and brought to a stand still. Every-day experience proves the truth of the first proposition, and many instances might be adduced of the stubbornness or obstinacy of matter, as its inertia is sometimes figuratively called, to yield to any impression given it, and its tendency to remain quiescent. When the sails of a ship are unfurled to the breeze, slowly and heavily at first she gets into motion, but gradually her speed increases as the force by which she is impelled overcomes the inertia of her mass. A great force is necessary at first to set a vehicle in motion, but when once this is effected, it goes onward with comparative ease, so that, in fact, a strong effort is necessary before it can be stopped. If a person be standing in it when it is suddenly set a-going, his feet are pulled forward, whilst his body, obeying the law of inertia, remains where it was, and he accordingly falls backwards. On the other hand, if the vehicle be suddenly stopped, and the individual be standing in the same position as formerly, the tendency which his body has to move forward—for it acquired the same motion as the carriage by which it was borne along—will cause him to fall in the opposite direction. Casualties of this description frequently occur to those on horseback, who are thrown over the necks of their steeds, or fall behind them, according as the animal stands still suddenly, or starts off unexpectedly. A man jumping from a coach at full speed will certainly fall prostrate on the ground, if he leaps down as if he were descending from a body at rest, to one which is in the same state; for when he makes the attempt, his body has the same motion as the coach; and when the feet arrive at the ground, the motion in the lower part is arrested, whilst it continues in the upper part; and thus he finds himself thrown from the perpendicular into the horizontal position. Dr Arnott mentions the following ingenious method which a traveller adopted to escape from a beast of prey:—"An African traveller saw himself followed by a tiger, from which he could not escape by running; but perceiving that the animal was watching an opportunity to seize him by the usual spring or leap, he artfully led it to where the plain terminated in a precipice covered by brushwood, and he had just time to transfer his hat and cloak to a bush, and to retreat a few paces, when the tiger sprung upon the bush, and, by the motal inertia of its body, was carried over the precipice and destroyed." Innumerable instances might be adduced illustrative of this law of nature. The following is a familiar one:—Upon the tip of the finger let a card be balanced, and a piece of money—say a shilling—laid upon it. Let the card then be smartly struck, and it will fly from beneath the coin, leaving it supported upon the digit. This arises from the inertia of the metal being greater than the friction of the card which passes from beneath it.

Coursing, or a hare-hunt, affords a striking illustration of inertia. In that cruel sport, the hare seems to possess an instinctive consciousness of the existence of this law of matter. When pursued by the greyhound, it does not run in a straight line to the cover, but in a zig-zag one, like the path of the lightning. The hare *doubles*, that is, suddenly changes the direction of its course, and turns back at an oblique angle with the direction in which she had been running. The greyhound, which is a far heavier body, unable to resist the tendency of its mass to persevere in the rapid motion which it has acquired, is impelled a considerable distance forward before it can check its speed and return to the pursuit. But, in the meantime, the hare has been enabled to shoot far ahead in the other direction; and although a hare is much less fleet than a greyhound, by this most scientific manœuvring it often escapes its pursuer. Those who have witnessed the perhaps still more cruel practice of horse-racing, may have observed that the horses shoot far past the winning-post before their speed can be arrested. This is also owing to the inertia of their bodies.

NATURAL PERMANENCY OF MOTION.

Although it seems to be an idea impressed upon our minds by every day's observation, that a body at rest would never move of itself, yet, that once set in motion, it has an equal tendency for ever to move in the direction in which the impulse is given, is by no means so apparent. The fact is, that motion is looked upon rather as unnatural to matter; and so late as the time of the celebrated Kepler, philosophers did not hesitate to affirm, as a maxim, "that matter is more inclined to rest than to motion." Hence, let us not be surprised that in the present day many receive with caution, and believe with diffidence, that the one quality is as natural to matter as the other. Reason, observation, and experience, prove to us that the same causes which destroy motion in one direction, are capable of producing as much motion in the opposite direction. Thus, if a wheel, spinning on its axis with a certain velocity, be stopped by a hand seizing one of the spokes, the effort which accomplishes this is exactly the same as, had the wheel been previously at rest, would have put it in motion, in the opposite direction, with the same velocity. If a carriage drawn by horses be in motion, the same exertion of power in the horses is necessary to stop it as would be necessary to *back* it if it were at rest. Admit this as a general principle, and it becomes evident that a body which can destroy or diminish its own motion, must also be capable of putting itself into motion from a state of rest, or of increasing any motion which it has received. But this latter is contrary to experience, and we must be compelled to admit that a body cannot diminish or destroy any motion which it has received. "Let us," says Dr Lardner, "inquire why we are more disposed to admit the inability to produce rather than destroy motion in itself. We see those motions which take place around us on the surface of the earth subject to gradual decay; and if not renewed from time to time, they at length cease. A stone rolled along the ground, a wheel revolving on its axis, the heaving of the deep after a storm, and all other motions produced on bodies by external causes, decay when the exciting cause is suspended; and if that cause do not renew its action, they ultimately cease.

But is there no exciting cause, on the other hand, which thus gradually deprives those bodies of their motion? and if that cause were removed, or its intensity diminished, would not the motion continue or be more slowly retarded? When a stone is rolled along the ground, the inequalities of its shape, as well as those of the ground, are impediments which retard and soon destroy its motion. Render the stone round, and the ground level, and the motion will be considerably prolonged. But still small asperities will remain on the stone and on the surface over which it rolls. Substitute for it a ball of highly-polished steel, moving on a highly-polished steel plane truly level, and the motion will continue without sensible diminution for a long period; but even here, and in every instance of motion produced by art, minute asperities must exist on the surfaces which move in contact with each other, which must resist, gradually diminish, and ultimately destroy, the motion.

Independently of the obstructions to the continuation of motion arising from friction, there is another impediment to which all motions on the surface of the earth are liable—the resistance of the air. How much this may affect the continuation of motion, appears by many familiar effects. On a calm day, carry an open umbrella with its concave side presented in the direction you are moving, and a powerful resistance will be opposed to your progress, which will increase with every increase of the speed with which you move."

Nature, in the organisation of animals, has made numerous provisions to facilitate their movements in the elements where they reside. Thus, fishes are sharp before and behind, and this shape enables them to dart more rapidly through the water. Birds have somewhat of a similar form, and thus their progress through the resisting air is facilitated. Every motion on the surface of the earth is retarded by the resistance of air and friction. But in the celestial spaces, we see motion freed from any such obstacles, and there it would appear to be eternal. The countless orbs with which the heavens are spangled, roll on with unerring regularity, and with a velocity which apparently has never diminished since these luminaries were projected from the Creator's hand into their appointed orbits. This alone, had we no other proof, is sufficient to correct the error or prejudice, that

* Arnott's Elements of Physics, vol. i. p. 34.

motion is always tending to rest. There is nothing with which we are acquainted in a state of absolute rest. The moon wheels round the earth, the earth round the sun, and the sun itself moves round its axis, as well as round the centre of gravity of the solar system. There is doubtless, also, in the great universe, a remote point to which, as to a magnet, he is turned, and with all his bright luminaries, his dazzling retinue of planets and comets, he is almost imperceptibly tending.

It is easy to perceive why we are not sensible of the motion of the earth: it evidently arises from every thing moving at the same rate as itself. The *common* motion, which belongs to all bodies, has no effect upon any new motion which may be given them. A man, for instance, who throws up a ball with the intention of catching it as it descends, can do so as easily on horseback as standing still upon the ground, on the deck of a ship as in the arena of a theatre. The ball evidently acquires the same forward motion as the person who throws it up; and, therefore, there is no more art necessary to catch it when both are rapidly moving, than the usual adroitness which is practised when the performer is standing still. Hence, leaping through a hoop upon horseback is by no means so miraculous a performance as it is generally supposed to be. The equestrian does not leap forward, for this would project him over the horse's ears; but merely jumps upwards, and allows his motal inertia to carry him through.

ACTION AND REACTION.

We now turn our attention to the effects of inertia or inactivity, as illustrated by cases in which two bodies at least are necessary. If in a straight line we place three bodies of equal weights—say A, B, and C—six inches apart from each other, and moving A towards B, which is in the middle, so as to strike it, both masses will move towards C after the impact. But the speed of A will only be half of that which it possessed before it touched B; and A, having thus lost half of its velocity, has given to B, which was before quiescent, just exactly that amount of motion. If B consisted of two masses, each of which was equal to A, in this case the velocity of the triple mass after impact would be one-third of the velocity from A to B. Thus, after collision, A loses two-thirds of its velocity, and B, which consists of two masses, each being equal to the former, each of these two receives one-third of A's motion; so that the whole motion received by B is two-thirds of the motion of A before impact, for by it exactly as much motion is received by B as is lost by A. A similar result to this will be obtained whatever proportion may subsist between the masses A and B. In general, therefore, when a mass A in motion impinges upon a mass B at rest, to find the motion of the united mass after impact, "divide the whole motion of A into as many equal parts as there are equal component masses in A and B together, and then B will receive by the impact as many parts of this motion as it has equal component masses."

But let us suppose the mass B to be moving instead of quiescent, and suppose it moves as well as A towards C, but with less velocity, so that A shall overtake it and impinge upon it: after the impact, the two masses will move towards C with a common velocity, the amount of which is half the sum of their velocities before impact. Thus, if A have the velocity 7, and B 5, the velocity of the united mass is 6, being the half of 12, the sum of 7 and 5. When A and B are not equal, the motion of the united mass may be thus ascertained:—Suppose A is divided into 10 component parts, and B into 8, each of which parts are equal in the mass, let then the velocity of A be 20, so that the motion of each of the parts being 20, the motion of the whole will be 10 multiplied by 20, or 200. In the same manner, let the velocity of B be 16, the motion of each part being 16, the whole motion of the eight parts will be 128. Then the sum of the whole motions towards C will be 328; and since none of this can be lost by the impact, nor any motion added to it, this must also be the whole motion of the united masses after impact. Being equally distributed amongst the thirty-six component parts of which the united masses consist, each part will have a thirty-sixth of the whole motion. Hence, 328 being divided by 36, we obtain the quotient 9.4, which is the velocity with which the whole moves. Such is the method of ascertaining the common velocity of two masses which impinge upon each other whilst moving in the same direction. It is not speed or velocity alone which determines the quantity of motion, but the masses moved must also be estimated.

In the foregoing case we have supposed the bodies moving in the same direction: let us now consider them as moving in opposite directions. Suppose A and B two equal bodies which move from two points, say two feet apart, and meet at C, equidistant from each of these two points, or exactly midway between them. In this case, the equal motions in opposite directions will destroy each other, and both masses will be reduced to a state of rest. The mass A loses all its motion in the direction A C, which is supposed to be transferred to B at the moment of impact. But B, having previously had an equal quantity of motion in the direction B C, will now have two equal motions impressed upon it, in directions immediately opposite, and these motions neutralising each other, the mass becomes quiescent. Thus, as in the former instances, the motion which is lost by one body is just transferred to another, consistently with the principle of "action and reaction." We shall further illustrate this part of the subject by a quotation from Dr Lardner:—"The masses A and B being still supposed equal, let them move towards C with different velocities. Let A move with the velocity 10, and B with the velocity 6. Of the 10 parts of motion with which A is endued, 6 being transferred to B, will destroy the equal velocity 6, which B has in the direction B C. The bodies will then move together in the direction C B, the four remaining parts of A's motion being equally distributed between them. Each body, therefore, will have two parts of A's original motion, and 2 therefore will be their common velocity after impact. In this case, A loses 8 of the 10 parts of its motion in the direction A C. On the other hand, B loses the entire of its 6 parts of motion in the direction B C, and receives 2 parts in the direction A C. This is equivalent to receiving 8 parts of A's motion in the direction A C. Thus, according to the law of 'action and reaction,' B receives exactly what A loses. Finally, suppose that both the masses and velocities of A and B are unequal. Let the mass of A be 8, and its velocity 9; and let the mass of B be 6, and its velocity 5; the quantity of motion of A will be 72, and that of B, in the opposite direction, will be 30. Of the 72 parts of motion which A has in the direction A C, 30 being transferred to B, will destroy all its 30 parts of motion in the direction B C, and the two masses will move in the direction C B, with the remaining 42 parts of motion, which will be equally distributed among their 14 component masses. Each component part will, therefore, receive three parts of motion: and accordingly 3 will be the common velocity of the united mass after impact.

When two masses, moving in opposite directions, impinge and move together, their common velocity after impact may be found by the following rule:—Multiply the numbers expressing the masses by those which express the velocities respectively, and subtract the lesser product from the greater; divide the remainder by the sum of the numbers expressing the masses, and the quotient will be the common velocity; the direction will be that of the mass which has the greater quantity of motion."

The force of a body in motion depends, therefore, upon the mass and upon the velocity; and hence it follows, that any body, however small, may be made to move with a force equal to another body, however great, provided the former receives a degree of velocity great enough to compensate for the superiority which the latter possesses on account of its mass.—See this further illustrated under *Attraction*.

LAWS OF MOTION.

Newton, in his Principia, gives the consequences of the property of inertia above explained, under the form of three propositions which are entitled the "laws of motion." They have been already given in the number of this work upon Astronomy, but must be here recapitulated, in order to illustrate what follows:—

1. Every body must persevere in its state of rest, or of uniform motion in a straight line, unless it be compelled to change that state by forces impressed upon it.

2. Every change of motion must be proportional to the impressed force, and must be in the direction of that straight line in which the force is impressed.

3. Action must always be equal and contrary to reaction; or the actions of two bodies upon each other must be equal, and directed towards contrary sides.

Inertia and force having already been defined, the first law becomes self-evident, or is an identical proposition. The second will be explained when we come to treat of the composition and resolution of force. The third has been so far rendered intelligible, and will be further illustrated as we proceed.

The fact already mentioned, that the force with which a body moves is estimated by the velocity of the motion and the mass, or weight of the thing moved, we have frequent practical illustration of. If to two balls, the one weighing one pound and the other two pounds, we communicate the same degree of force, the lighter body will move with twice the speed of the heavier one. Yet, although the velocities are different, they strike another body with exactly the same force, and are capable of overcoming the same resistance. Bodies may be regarded as reservoirs of force or motion, always ready to return as much as they have received. Momentum is the name given to the motion in a body, with reference to the production by it of new motions, or the overcoming of resistances, and is but another term for the *quantity of motion*.

A cannon-ball, according to the quantity of motion in it, may have only the force or momentum that will bruise a plank; or it may have enough to penetrate a tree, or even to shoot its rapid way through a block of the hardest stone.

A block of wood, floating against a man's leg with moderate velocity, would be little felt; but a loaded barge, coming at the same rate, and pressing it against the quay, might break the bones; a large ship, again, although moving no faster, would crush his body against any fixed obstacle; and an island of ice, opposed in its approach to another, even a first-rate man-of-war, would destroy it, as meeting barges destroy an egg-shell.

A hailstone falling, strikes rudely; a stone rolled from a height as of old, the besieged against the besiegers, carries death with it to many; an avalanche, breaking from its hold on a mountain steep, may sweep away a village.

To meeting bodies of equal mass the shock is the same, whether the motion be shared between them or be all in one; if their size be different, the shock is greatest to the smaller body.

If a running man come against a man who is standing, both receive a certain shock. If both be running at the same rate in opposite directions, the shock is doubled. In some such cases as when swift skaters have met, the shock has proved fatal.

The meeting of fists of boxers not unfrequently dislocate or break bones.

A man's skull is fractured more certainly by its being dashed against a tree or beam while he is on a galloping horse, than by the blow of a similar beam shot at him with the velocity of a horse.

When two ships in opposite courses meet at sea, although each may be sailing at a moderate rate, the destruction is often as complete to both as if with a double velocity they had struck against a rock. Many melancholy instances of this kind are on record. In the darkness of night, a large ship has met one smaller and weaker, and, in the lapse of a few seconds, have followed the shock of the encounter, the scream of the surprised victims, and the horrible silence, when the waves had again closed over them and their vessel for ever. In November 1825, on the coast of Scotland, the Comet steam-boat was thus destroyed, and carried to the bottom with her about seventy passengers, into whose ears the drowning water rushed, before the sounds of arrested music and joy had died away. —*Arnott.*

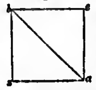
COMPOSITION AND RESOLUTION OF FORCE.

Force may be defined to be that which produces motion or pressure. If two equal forces act upon the same point of a body, in exactly opposite directions, the body acted upon will remain at rest. Such forces are the simplest examples of equilibrium, and the truth of this principle is self-evident. If, however, one of the forces be greater than the other, the body acted upon will move in the direction given to it by the superior force. Thus, then, we may infer, that when a body is driven in immediately opposite directions by two unequal forces, it is affected in exactly the same manner as if it were driven by a single force, equal to the difference between the two forces, and acting in the direction of the greater force.

This single force, whose action is equivalent to the combined action of two or more forces, is called their *resultant*, and the process by which a single force equivalent in its effect to two or more other forces is found, is called the *composition of force*. On the other hand, two or more forces may be found whose combined effects are equivalent to that of a given force; the process by which these are determined is called the *resolution of force*, and the two or more forces which are equivalent to the single force, are called its *components*.

We have only considered the simple instance in which the directions of the forces are in the same straight line; but let us now examine the more complex case, in which two forces act on the same point in different directions. This we shall illustrate by the following figure.

Fig. 1.



Let *b* be the original place of a ship, *e* is the east wind, and *s* the south wind. By the operation of these two aëriform forces, the vessel will at every instant be moved a little south and a little east, and will, in reality, go in a south-east direction; that is, in the diagonal or middle line *b a*, which shows the true course of any body set in motion in the above manner. The figure is called the *parallelogram of forces*, and is an important help to the understanding of many facts in natural philosophy. The minute examination of the subject belongs to technical mathematics, but the general truths are perfectly intelligible to the mathematics of common sense.

When two forces act upon a body, like the wind and tide in the last example, the result is the same, whether they act together or one after the other. For instance, if the wind drive a vessel one mile south, as from *b* to *s*, fig. 1, and, immediately afterwards, the tide drive it one mile east, as from *s* to *a*, the vessel will be in the same place at last, viz., at *a*, as if she had been driven at once south-east in the line *b a*, by the simultaneous action of the two. Therefore, by drawing the lines *b s* and *b e*, to represent the force and direction of the two causes of motion, and by then adding one of them, or an equivalent, to the end of the other, as *s a* to *b e*, or *e a* to *b s*, the square or parallelogram is sketched, of which the middle line, or *diagonal*, as it is called, shows the resulting direction of the forces, and the true course of the body obeying them.

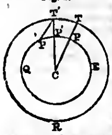
What is thus true of the effect of continued forces like wind and tide, is true, also, of momentary impulses; like the blows of clubs simultaneously striking a ball, or of two billiard balls striking a third.

In the case above supposed, the forces are equal, but if one be greater than the other, the figure becomes oblong; and in cases where the forces cross each other obliquely, it takes various shapes, but in every case the diagonal shows the *result*. Where various forces cross each other so obliquely as to be represented by lines drawn in almost opposite directions, would form a parallelogram having scarcely any breadth; that is to say, the diagonal would become next to nothing; thus proving that opposing forces neutralise or destroy each other. When forces cross so acutely as to advance nearly parallel to each other, the *resultant* is longer than either of the constituents; when, however, they cross obliquely, the *resultant* is less than either of them. But in all cases where the two forces are equal, with whatever obliquity they cross each other, the resulting direction must be midway between them. A boat impelled by oars goes straight, although the direction in which the oars act is constantly changing; because the changing obliquity of the force is the same on both sides. Similar observation will apply to almost every body impelled by instruments projecting from its sides, and acting against a fluid. The motions of fishes, the act of swimming, the flight of birds, are all instances of the same kind.

An instance of the composition of motion is afforded when a stone is let fall from the mast of a ship in full sail. As the vessel is sailing forward when the stone is let fall, it might be expected that during its descent it would reach the deck behind the mast. But it is found to fall at the foot of the mast just as it would have done had the ship been at rest. To account for this, let *b s*, fig. 1, be the position of the mast of the ship when the stone is dropped. The mast is moving forwards with the vessel in the direction *b e*, so that in the time which the body would take to fall to the deck, the top of the mast would move from *b* to *e*. But the stone having the same motion as the mast, it is affected by two motions, that of the vessel expressed by *b e*, and its descending motion as expressed by *b s*. Hence, by the composition of motion, it will be found at the opposite angle *a* of the parallelogram at the end of the fall. During the fall, however, the mast has advanced with the vessel to *e a*, so that the body falls exactly at the foot of the mast.

"An instance of the composition of motion," says Dr Lardner, "which is worthy of some attention, as it affords a proof of the diurnal motion of the earth, is derived from observing the descent of a body from a very high tower. To render the explanation of this more simple, we shall suppose the tower to be on the equator of the earth. Let E P Q, fig. 2, be a section of the earth through the equator, and let P T be the tower. Let us suppose that the earth moves on its axis in the direction E P Q. The foot P of the tower will, therefore, in one day, move over the circle E P Q, while the top T moves over the greater circle T T′ R. Hence it is evident that the top of the tower moves with greater speed than the foot, and therefore in the same time moves through a greater space. Now, suppose a body placed at the top: it participates in the motion which the top of the tower has in common with the earth. If it be disengaged, it also receives the descending motion T P. Let us suppose that the body will take five seconds to fall from T to P, and that in the same time the top T is moved by the rotation of the earth from T to T′, the foot being moved from P to P′. The falling body is therefore endowed with two motions, one expressed by T T′, and the other by T P. The combined effect of these will be found in the usual way by the parallelogram. Take T *p* equal to T T′, the body will move from T to *p* in the time of the fall, and will meet the ground at *p*. But since T T′ is greater than P P′, it follows that the point *p* must be at a distance from P′ equal to the excess of T T′ above P P′. Hence the body will not fall exactly at the foot of the tower, but at a certain distance from it, in the direction of the earth's motion; that is, eastward. This is found, by experiment, to be actually the case; and the distance from the foot of the tower at which the body is observed to fall, agrees with that which is computed from the motion of the earth, to as great a degree of exactness as could be expected from the nature of the experiment.

Fig. 2.



The properties of compounded motions cause some of the equestrian feats exhibited at public spectacles to be performed by a kind of exertion very different from that the spectators generally attribute to the performer. For example, the horseman standing on the saddle, leaps over a garter extended over the horse at right angles to his motion; the horse passing under the garter, the rider lights upon the saddle at the opposite side. The exertion of the performer in this case is not that which he would use were he to leap from the ground over a garter at the same height. In the latter case, he would make an exertion to rise, and, at the same time, to project his body forward. In the case, however, of the horseman, he merely makes that exertion which is necessary to rise directly upwards to a sufficient height to clear the garter. The motion which he has in common with the horse, compounded with the elevation acquired by his muscular power, accomplishes the leap."

If a billiard ball strike the cushion of the table obliquely, it will be reflected from it in a certain direction, forming an angle with the direction in which the latter was struck. It is technically termed the angle of incidence; the other is called the angle of reflection. If bodies were perfectly elastic, these angles would always be equal to each other (as in the case where light is reflected from a polished surface); but this not being the case, the angle of incidence is less than the angle of reflection; and with the same obliquity of incidence the more imperfect the elasticity is, the less will be the angle of reflection.

Motion is sometimes called *absolute* or *relative*. The latter is easily explained. If, whilst a vessel is passing through the waters, a man on deck walks from one extremity to the other, he has a relative motion, which is measured by the space upon the deck over which he treads in a given time. But he is also impelled through the deep along with the vessel in another direction. If it so happen that, as he passes from stem to stern, his motion in one direction be exactly equal to the ship in the opposite direction, the man will be relatively to the surface of the sea, and that of the earth, at rest. Thus relatively to the vessel he is in motion, whilst relatively to the earth he may be considered as at rest. This, however, is not absolute rest; for the surface itself is moving by the diurnal rotation of the earth upon its axis, as well as by the annual motion in its orbit round the sun. These motions and others connected with the earth, must be all compounded by the theorem of the parallelogram of forces, before we can obtain the *absolute state* of the body with regard to the motion or rest.

ATTRACTION.

In the numbers of this work devoted to Astronomy and Chemistry, the various kinds of attraction were pointed out; but in this place it will be necessary to enter more fully into the subject, particularly that part of it pertaining to terrestrial gravity.

Although, from the law of inertia, matter is incapable of itself of changing its state, yet wherever we cast our eyes over the wide panorama of creation, we find that state to be in constant but regular fluctuation. There is not in the universe such a thing as absolute rest, or even of absolute uniform and rectilinear motion. There are in nature a series of forces in continual operation, whose existence is demonstrated by their observed effects, but whose nature, seat, and mode of operation, are entirely unknown to us: these are called by the general name of *attractions*. These forces may be primarily distributed into two classes. In the first are comprised all those attractions which exist between the molecules or constituent particles of bodies; and in the second, those which exist between the bodies themselves, or between masses of matter. Those belonging to the first class have been treated of at sufficient length in the article Chemistry. Those of the second class, connected with magnetism and electricity, have been treated of in the article devoted to Electricity and Galvanism. These attractions are only naturally manifested between bodies of particular kinds, or are made to develope themselves by certain artificial processes. But there is an attraction exhibited by bodies of every description and under all circumstances; an attraction which is totally independent of the nature of the constituent parts of bodies, and depends for its intensity only upon the mutual size and distance of the masses. This attraction is called the attraction of gravitation.

GRAVITATION.

In explaining this important law of nature, we shall avail ourselves of the description given of it in two popular works upon Mechanics; namely, that of Dr Lardner, and that contained in the Library of Useful Knowledge.

The earth is a mass of matter, nearly, but not exactly, of a globular form, the diameter being about eight thousand miles. This enormous mass possesses the property of attracting towards its centre all smaller bodies placed near its surface; so that, if they be perfectly free to move, and opposed by no obstacle, they will move in straight lines towards the centre of the globe, and will continue so to move, until they reach the surface. If the part of the surface which they meet be solid, or even a liquid specifically heavier than the descending bodies, their further approach to the centre will be obstructed; but in that case the attraction towards the centre will be manifested by the force with which the bodies press upon the resisting surface. If the bodies thus supposed to have met the surface in their approach towards the centre happen to meet a liquid, as the sea, and be specifically heavier than it, they will still continue to approach the centre, moving through the liquid, until, in fine, they be stopped either by a liquid heavier than themselves, or a hard surface. All lines which are drawn from points without a globe to its centre, are evidently perpendicular to its surface; and hence, bodies, in moving towards the centre of the earth, attracted by its influence, move perpendicularly to its surface; and when their progress is obstructed by that surface, they press on it perpendicularly with a force equal to that with which they are attracted towards the centre.

This attraction, which the earth exerts upon all bodies placed near its surface, is called *terrestrial gravity*; and the force with which any body drawn towards the centre is pressed upon an horizontal plane, is called the *weight* of that body. It must be very obvious that the common effects of falling bodies, and of pressures produced by weight, are perfectly accounted for in the preceding observations. This attraction is by no means peculiar to the earth, but is common to all material substances, whatever be their form, quantity, or position. In this respect, the force of gravity differs from magnetism, and other attractions which are only resident in substances of particular species. If the earth were a large magnet, those peculiar substances only which are affected by the loadstone would have weight, or would fall to the surface when unsupported. All other bodies would rest indifferently in any position in which they might happen to be placed, and would move upwards just as readily as downwards. But every material substance is susceptible of the attraction of gravity; and what is more, it is susceptible of this in the exact proportion of its mass. Thus, if the mass of the earth were doubled, it would exert a double attraction on all bodies placed near it; and, consequently, the weights of all bodies would in that case be doubled. If its mass were tripled, the weights of all bodies would be tripled, and so on. In general, therefore, the attraction of the earth for a body in its vicinity, is proportional to its mass.

We have stated that gravity is an attraction common to all material substances; if so, then it may be asked, Why do not the various bodies placed near the earth's surface attract the earth towards them? If a body be disengaged at any height from the surface, it will be drawn by the attraction of the earth, and will, consequently, descend in a straight line perpendicular to the surface. But since the body attracts the earth, why does not the surface *ascend* towards the body, being drawn by the attraction of the body on the earth; in which case, the surface of the earth and the body would meet at some place intermediate between their first positions? We answer, that in fact this very effect takes place. The surface of the earth *does* approach the descending body; and that descending body not only attracts the mass of the earth towards it, but attracts it with exactly as much force as that by which the earth attracts the descending body. Why, then, it will be asked, is not the rapid approach of the earth to meet the descending body perceptible? To explain this, we must go into some farther details relative to the Composition of Force, and repeat the doctrine of Action and Reaction.

If two bodies, A and B, be moving with the same velocity, the forces with which they move will be equal, provided their masses or quantities of matter be equal, but not otherwise. If the mass of A be greater than the mass of B, its force will be greater in the same proportion. This will be very evident if we consider the forces with which they would strike any obstacle opposed to them. If B be a musket-ball, and A be a cannon-ball of one hundred times the weight, both being projected with the same speed, A will strike any obstacle with one hundred times the force with which B would strike it. In general, then, when the velocities with which bodies are moved are the same, their forces are proportional to their masses or quantities of matter.

Now, let us suppose that the masses of the bodies A and B are equal, but that they move with unequal velocities; that is, that they move through different spaces in the same time. Let the space described in one second by the body A be *a*, and let the space described in the same time by the body B be *b*, these spaces are called the velocities of the bodies. The equal bodies thus moving with different velocities, will move with different forces. It is evident that the body which has the greater velocity will have the greater force, and that also in the same proportion as its velocity is greater. If two equal bullets be successively projected from the same gun, but with different charges of powder, that which is projected by the stronger charge will strike the mark with a proportionally greater force. But in this case, the only difference in the motions of the bullets, is, that one has a greater velocity than the other. Hence we perceive, that, "when equal masses are in motion, their forces are proportional to their velocities."

We have thus separately considered the cases in which unequal masses are moved with equal velocities, and in which equal masses are moved with unequal velocities; and we have seen that the forces are, in the one case, proportional to the masses, and in the other, to the velocities. Now, if unequal masses be moved with unequal velocities, it is natural to expect that we should, in comparing the forces, take into account both the velocities and the masses. It appears that the moving force of a body may be increased or diminished, by increasing or diminishing either its mass or its velocity, or both. In fact, if the number representing the mass be multiplied by the number representing the velocity, the product thus obtained will represent the moving force. Thus, if the masses of two bodies, A and B, be in the ratio of the numbers 8 and 5, and the velocities of these bodies be in the ratio of the numbers 7 and 3, their moving forces are as the product of 8 and 7 to the product of 5 and 3; that is, as 56 to 15. It appears, therefore, that in this instance the force of A bears a much higher ratio to the force of B than either the mass of A bears to the mass of B, or the velocity of A to the velocity of B; the reason of which is, that the mass and velocity conspire in imparting to A a superior moving force. In general, then, we conclude that the moving forces of bodies are proportional to the products of their masses and their velocities.

Since, then, the moving force of a body depends conjointly on its mass and its velocity, it necessarily follows that, if, while we increase its velocity in any proportion, we diminish its mass in the same proportion, its moving force will be the same; for it will lose as much force by the diminution of its mass as it gains by the increase of its velocity. In like manner, if, when we increase its mass, we diminish in the same proportion its velocity, the moving force will be unaltered; for as much will be lost by the diminished velocity as will be gained by the increased mass.

To return to the case of the earth, and a body near its surface: They attract each other with equal forces; and, therefore, in their consequent approach to each other, the earth must have a velocity as many times less than that of the falling body, as the mass of the earth is greater than that of the falling body. Since all bodies which can be submitted to these circumstances, must be infinitely smaller than the earth, the space through which the earth approaches them in their fall must be infinitely smaller than the space which they fall through.

To take a very improbable and extreme case: Suppose a ball of earth, of a diameter equal to the tenth part of a mile, were to be placed at an height above the surface equal to the tenth part of a mile, let us consider what space the earth would move through to meet it. The earth's diameter being about 8000 miles, and spheres being as the cubes of their diameters, the mass of the earth would have to the mass of the ball the ratio of 512,000,000,000,000 to 1; consequently, if the tenth part of a mile were divided into 512 millions of millions of equal parts, one of these parts would be pretty near the space through which the earth would move towards the falling body. In the tenth part of a mile there are somewhat less than 6400 inches; if this were divided into 512 millions of millions of parts, each part would be the eighty millionth part of an inch; it is, therefore, through a space less than this that the earth would move, under the circumstances which we have supposed.

It is therefore quite evident, that, with respect to falling bodies, the earth is to be considered at rest.

We have stated that bodies attract each other in proportion to their quantities of matter. Hence, the earth attracts different bodies with different forces. A piece of lead contains a considerably greater quantity of matter in the same bulk than a piece of cork, and accordingly we find that the earth attracts it with a proportionally greater force; in other words, it has greater weight. It is for this reason that *weight* is justly assumed as the measure or exponent of the quantity of matter in any substance, whatever, in other respects, be the species or qualities of that substance.

But it is not *alone* the masses of bodies which determine their mutual attractions. Their distances from each other affect this force. It is found that the force of attraction decreases as the distance is increased, but in a still greater proportion. Thus, for example, a body placed upon the surface of the earth, at the distance of 4000 from its centre, is attracted by a certain force towards that centre. At double that distance, or at 4000 above the surface, it would only be attracted with the fourth part of that force, and it would in fact lose three-fourths of its weight.

The earth being globular, or nearly so, it follows that the lines in which its attraction acts converge towards its centre, and that at different parts of the earth the lines in which falling bodies descend are not parallel, but are such as, if continued, would intersect at the centre. In considering, however, the action of gravity on bodies, at places not far distant on the surface of the earth, we may assume, without sensible error, that the directions in which it acts are parallel, and that they are all perpendicular to the same horizontal plane. A distance as great as one mile will only produce a deviation from parallelism amounting to less than one minute, or the sixtieth part of a degree.

Although the intensity of terrestrial gravity increases as the distance decreases, and although the motion of a falling body as it approaches the earth is accelerated, yet the height through which we are enabled to observe its descent, bears so small a proportion to the whole distance from the centre of the earth, that the change of intensity cannot be practically estimated. The increase can be proved to be one part in 4000, a very insignificant quantity. In explaining the laws of falling bodies, therefore, we shall assume, that, in their entire descent, they are urged by a force of uniform intensity.

The force of gravity is not exactly the same at every part of the earth's surface; it is greatest at the poles, and least at the equator. But the cause of this will be explained when we come to speak of centrifugal force, and the motion of pendulums. However, the attraction of the earth at any given place acts upon a body at all times with the same degree of force; and since it acts separately and equally on every particle of matter without reference to the kind of body which is thus operated upon, it follows that, whatever be the species of matter of which bodies are composed, or the magnitude of their masses, they should all descend to the earth with the same velocity. Yet common observation does not verify this fact. For instance, when a bird is shot in the air, the body of the animal descends rapidly downwards, whilst the feathers that may have been torn from it flicker about, and are a long time in reaching the surface of the ground. What are termed light substances, such as thistle-down, paper, &c., fall slowly and irregularly, whilst denser substances, such as stones and metals, fall rapidly. And we are not without instances in which the earth, instead of attracting, seems to repel bodies; thus, vapour, balloons, &c., actually ascend. But these are easily explained when we consider that the earth is surrounded to the height of about fifty miles by an atmosphere composed of a thin aëriform fluid. Through this elastic medium light bodies ascend, just as a cork rises in a vessel of water, to the bottom of which it has been forcibly pressed; because bulk for bulk the balloon and the cork are lighter than the element in which they move. By another application of the same principle, we perceive the reason why a ball of cotton and another of lead, both of the same size, fall to the ground with different degrees of velocity. It is evident that the resistance of the air is in proportion to the volume of a body; hence it obstructs the fall of both the above-named substances in a like degree. But the cotton being attracted in a less degree than the lead in proportion to its bulk, yet having the same resistance to overcome, is more slow in penetrating the atmosphere, and does not reach the earth so soon as the lead. It can be shown by direct experiment, that light and heavy bodies would fall to the ground at the same rate, were there no atmosphere. If by means of an air-pump we extract the air from a tall glass vessel, and having, by means of a wire passing air-tight through the top of the vessel, disengaged a feather and a piece of metal at the same instant, they will be found to descend with the same speed, and strike the bottom at the same moment. Under *Pneumatics*, the phenomena connected with aëriform fluids will be resumed.

ACCELERATED MOTION AND ACCELERATED FORCE.

It must have been observed by every one, that the velocity with which a body moves is increased as it approaches the ground. Owing to the inertia of matter, any force continuing to act on a mass which is free to obey it, produces in the mass a quickening or accelerated motion; because the force which set the body into motion in the first instant continues to impel it from the principle of inertia, whilst accession of force, which it continues to receive at every successive moment, increases the motion. Hence, a falling body under the influence of attraction is as it were a reservoir, receiving at every instant fresh velocity and momentum. A ball dropped from the hand can be caught again in the first instant; but after a little delay, it will be pursued in vain. An arrow impelled into the sky may be perceived as its point "upon the curl hangs pausing;" at that instant a bird of heaven might seize the harmless messenger of death with its bill; and even for some time after it has begun to descend, the eye can readily follow it, but as it nears the earth, its velocity becomes so great that we frequently lose sight of it altogether. When the lightning stroke detaches a fragment of rock from the brow of a hill, the ponderous mass moves slowly at first; but when once fairly launched, it acquires fresh velocity and momentum at every instant, and, bounding from steep to steep with impetuous speed, drives every obstacle before it. The falls of Niagara afford an illustration of the same truth, upon nature's most magnificent scale. At first "the broad column which rolls on and shows,

> "More like the fountain of an infant sea
> Torn from the womb of mountains by the throes
> Of a new world,"—(BYRON),

bends heavily and slowly over the precipice; then becoming a thinner and thinner sheet as it descends, at last, enveloped in an atmosphere of foam and mist, it flashes into the phlegethon below,

> "Rivalling the lightning's flash in ruin and in *speed*."

Thus, then, it is clear that a new impulse is given to a body every instant of its fall, by which means it acquires additional velocity; and its final velocity is composed of the aggregation of all the small increments of additional speed which are so communicated. As we are at present to consider the force of attraction invariable, it follows that the velocity communicated to the body at each moment of time will be the same, and, therefore, that the whole quantity of velocity which obtains at the end of any given time, is proportional to the length of that time. Thus, if during one second of time a certain velocity be produced in a body, when it has fallen two seconds it will have acquired twice that velocity, and so on. Such is the fundamental principle or characteristic of *uniformly accelerated motion.*

Besides the time of the fall of a body, and the velocity at each instant, the spaces through which it moves in given intervals of time, counted either from the commencement of the fall, or from any proposed epoch of the descent, are equally important objects of inquiry. The space is moved through with varying speed, but as the velocity increases uniformly with the time, the average speed is obtained by ascertaining that which the body had in the middle of the interval which elapsed between the beginning and the end of the fall; and thus the space through which the body has actually fallen is that through which it would move in the same time with this average velocity uniformly continued. The fact is, that the velocity of the body, after half the whole period of the descent, is half the final velocity. Hence it follows, that between the three quantities, the height, the time, and the final velocity, which enter into the investigation of the phenomena of falling bodies, there are two fixed relations:—First, the time counted from the beginning of the fall, and the final velocity, are proportional the one to the other; so that as one increases, so does the other. Secondly, the height being equal to half the space which would be moved through in the *time* of the fall, with the *final velocity*, must have a fixed proportion to these two quantities, viz. the time and the final velocity, or must be proportional to the product of the two numbers which express them. Dr Lardner ingeniously illustrates this doctrine as follows:—

"But since the time is always proportional to the final velocity, they may be expressed by equal numbers, and the product of equal numbers is the square of either of them. Hence, the product of the numbers expressing the time and final velocity is equivalent to the square of the number expressing the time, or to the square of the number expressing the final velocity. Hence we infer that the height is always proportional to the square of the time of the fall, or to the square of the final velocity.

The use of a few mathematical characters will render these results more distinct, even to students not conversant with mathematical science. Let S express the height from which the body falls, V the final velocity, and T the time of the fall, and let the square of any of these quantities, or rather of their numerical expressions, be signified by placing the figure 2 over them—thus, T^2 or V^2. The sign × between two numbers signifies that they are to be multiplied together. These being premised, the results of the reasoning in which we have been just engaged, may be expressed as follows:—

V	increases proportionally with	T	[1]
S	. . . .	V × T	[2]
S	. . . .	T^2	[3]
S	. . . .	V^2	[4]

The theorems [3] and [4] follow from [1] and [2]; for since by [1] T is proportional to V, it may be put for V in [2], and by this substitution V × T becomes T × T, or T^2. In the same manner, and for the same reason, V may be put for T, by which V × T becomes V × V, or V^2.

By these formularies, if the height through which a body falls freely in one second be known, the height through which it will fall in any proposed time may be computed. For since the height is proportional to the square of the time, the height through which it will fall in *two* seconds will be *four* times that which it falls through in *one* second. In *three* seconds it will fall through *nine* times that space; in *four* seconds, *sixteen* times; in *five* seconds, *twenty-five* times, and so on. The following, therefore, is a general rule to find the height through which a body will fall in any given time:—Reduce the given time to seconds, take the square of the number of seconds in it, and multiply the height through which a body falls in one second by that number; the result will be the height sought.

The following table exhibits the heights and corresponding times as far as 10 seconds:—

Time	1	2	3	4	5	6	7	8	9	10
Height	1	4	9	16	25	36	49	64	81	100

Each unit in the numbers of the first row expresses a second of time, and each unit in those of the second row expresses the height through which a body falls freely in a second.

If a body fall continually for several successive seconds, the spaces which it falls through in each succeeding second have a remarkable relation among each other, which may be easily deduced from the preceding table. Taking the space moved through in the first second still as our unit, four times that space will be moved through in the first two seconds. Subtract from this 1, the space moved through in the first second, and the remainder 3 is the space through which the body falls in the *second* second. In like manner, if 4, the height fallen through in the first two seconds, be subtracted from 9, the height fallen through in the first three seconds, the remainder 5 will be the space fallen through in the third second. To find the space fallen through in the fourth second, subtract 9, the space fallen through in the first three seconds, from 16, the space fallen through in the first four seconds, and the result is 7, and so on. It thus appears, that, if the space fallen through in the first second be called 1, the spaces described in the second, third, fourth, fifth, &c. seconds, will be expressed by the odd numbers respectively, 3, 5, 7, 9, &c. This places in a striking point of view the accelerated motion of a falling body, the spaces moved through in each succeeding second being continually increased.

If velocity be estimated by the space through which the body would move uniformly in one second, then the final velocity of a body falling for one second will be 2; for with that final velocity the body would in one second move through twice the height through which it has fallen.

Since the final velocity increases in the same proportion as the time, it follows, that, after two seconds, it is twice its amount after one, and after three seconds thrice that, and so on. Thus, the following table exhibits the final velocities corresponding to the times of descent:—

Time	1	2	3	4	5	6	7	8	9	10
Final velocity	2	4	6	8	10	12	14	16	18	20

The numbers in the second row express the spaces through which a body with the final velocity would move in one second, the unit being, as usual, the space through which a body falls freely in one second.

A body falling freely by the force of gravity, descends in one second of time through a height of about 16 feet; in two seconds, it would therefore fall through four times that space, or 64 feet; in three seconds, through 9 times the height, or 144 feet; and in four seconds, through 256 feet. In order, therefore, to be enabled to observe the phenomena for only four seconds, we should command an height of at least 256 feet. But further, the velocity at the end of the first second would be at the rate of 32 feet per second; at the end of the second second, it would be 64 feet per second; and towards the end of the fall, it would be about 120 feet per second. It is evident that this great degree of rapidity would be a serious impediment to accurate observation, even though we should be able to command the requisite height."

MR ATTWOOD'S MACHINE.

But this difficulty was obviated by Mr Attwood, a natural philosopher of the last century, who constructed a machine of a very simple nature, by which the law theoretically deduced was experimentally proved. Into the groove of a wheel turning on its axle with very little friction, he inserted a fine silken cord, to the ends of which were attached two equal cylindrical weights. When both were placed at exactly the same distance from the ground, of course they balanced each other and remained at rest. When, however, to one of the weights a small additional weight was added, the equilibrium was destroyed; the loaded weight began to descend, whilst the other one rose. Under these circumstances, the descent of the loaded weight is a motion of the same kind as the descent of a body in the air falling by the force of gravitation; that is, it increases according to the same laws, though at a diminished rate. To render this plain, suppose that the loaded weight descends from a state of rest through one inch in a second, it will descend through four inches in two seconds, through nine in three, and so on. Thus, in twenty seconds it would descend through 400 inches, or 33 feet 4 inches, a height which could easily be commanded.

RETARDED MOTION.

With respect to a falling body, we have observed that its velocity is increased in proportion as it continues to descend. But in regard to a body which is projected upwards, the reverse of this takes place. Whatever is thrown perpendicularly into the air, loses a part of its velocity at every instant, on account of the force of gravity acting upon it as a drag weight, so to speak, which finally compels it to change its course, and return to the earth from whence it arose. Any body thus sent upwards, say a musket-ball, would have, but for the resistance of the air, at corresponding points of the ascent and descent, an equal velocity; and, on reaching the ground, it would have acquired exactly the velocity with which it departed.

We have seen that a body falls four times as far in two seconds as it does in one, although the velocity at the end of two seconds is only doubled. In the same manner, a body shot upwards with double velocity rises four times as far as if shot with a single velocity; if shot with triple velocity, it rises nine times as far, and so on.

An upward jet of water is small below where it issues from the orifice of a pipe with a high degree of velocity, but it becomes more bulky as the fluid loses its velocity in ascending, and at the top it often spreads laterally like a palm tree, so that any light round solid will continue supported and playing upon its summit. The same circumstance takes place when air is forcibly blown through a hollow tube held perpendicularly. The rise of a pendulum from the bottom of its arc, is an exact copy, reversed, of its previous descent to that point. To this subject we shall turn our attention after we have described one of the most important phenomena of nature, namely,

CENTRIFUGAL FORCE.

Centrifugal force will be easily understood, after the description which has been given of the inertia of matter. By this law, when a body is set in motion, its tendency is to continue for ever to move in the direction in which the impulse is given, unless it be deflected from it by an efficient force.

A body moving in a circle, then, or curve, is constrained to do what is contrary to its inertia. A person on first approaching the subject might suppose that a body, which for a time has been constrained to move in a circle, should naturally do so when set at liberty. But on reflecting that a circle is as if made up of an infinite number of straight lines, and that the body moving in it has its motion bent at every step of the progress, the reason is seen why constant force becomes necessary to keep it there; a force just equal to the inertia with which the body tends, at every point of the circle, to pursue the straight line, called a tangent, of which that point is the commencement. The force required to keep the body in the bent course is called *centripetal* or centre-seeking force; while the inertia of the body tending outwards, that is, to move in a straight line, is called the *centrifugal* or centre-flying force. An apparatus, called a *whirling table*, has been constructed for the purpose of exhibiting experimental illustrations of the laws of centrifugal force. By this machine we are enabled to place any proposed weights at any given distances from centres round which they are whirled, either with the same angular velocity, or with velocities having a certain proportion. Threads attached to the whirling weights are carried to the centres round which they respectively revolve, and there, passing over pullies, are connected with weights which may be varied at pleasure. When the whirling weights fly from their respective centres by reason of their centrifugal force, they draw up the weights attached to the other ends of the threads, and the amount of the centrifugal force is estimated by the weights which it is capable of raising.

With this instrument, the following experiments may be exhibited:—

Exp. 1. Equal weights whirled with the same velocity at equal distances from the centre, raise the same weight, and therefore have the same centrifugal force.

Exp. 2. Equal weights whirled with the same angular velocity, at distances from the centre in the proportion of one to two, will raise weights in the same proportion; therefore, the centrifugal forces are in that proportion.

Exp. 3. Equal weights whirled at equal distances with angular velocities, which are as one to two, will raise weights as one to four; that is, as the squares of the angular velocities: therefore, the centrifugal forces are in that proportion.

Exp. 4. Equal weights whirled at distances which are as two to three, with angular velocities, which are as one to two, will raise weights which are as two to twelve; that is, as the products of the distances two and three, and the squares one and four, of the angular velocities: hence, the centrifugal forces are in this proportion.

The centrifugal force must also increase as the mass of the body moved increases; for, like attraction, each particle of the moving body is separately and equally affected by it: hence, a double mass, moving at the same distance and with the same velocity, will have a double force. The following experiment verifies this:—

Exp. 5. If weights which are as one to two be whirled at equal distances with the same velocity, they will raise weights which are as one to two.—(*Lardner.*)

The consideration of centrifugal force proves, that, if a body be observed to move in a curvilinear path, some efficient cause must exist which prevents it from flying off, and which compels it to revolve round the centre. If the body be connected with the centre by a thread, cord, or rod, then the effect of the centrifugal force is to give tension to the thread, &c. If an unyielding curved surface be placed on the convex side of the path, then the force will produce pressure on this surface. But if a body is observed to move in a curve without any visible material connection with its centre, and without any obstruction on the convex side of its path to resist its retreat, as is the case with the motions of the planets round the sun, and the satellites round the planets, it is usual to assign the cause to the attraction of the body in the centre. The sun is the centre of our system, and it is customary to say that the attraction of the sun, neutralising the effects of the centrifugal force of the planets, retains them in their orbits.—(*See our article on Astronomy.*)—This phraseology, however, is scarcely correct, inasmuch as we are totally ignorant of the proximate cause of that tendency which the planets have of moving towards the central orb of their several systems. But to enter into an examination of subtleties so refined as these, would be out of place here.

Examples of centrifugal force present themselves to us wherever we look over the wide expanse of nature's works, or the ingenious inventions of man. Dr Arnott, in his able work on Natural Philosophy, enumerates a great number, of which the following are the most striking:—

A sling cord is always tight while the stone is whirling, and its tension is of course the measure both of the centripetal and centrifugal force.

In a corn-mill, the grain being admitted between the stone through an opening in the centre of the upper one, is then kept turning round between them, and is, by its centrifugal force, always tending and travelling outwards until it escapes as flour from the circumference.

A tumbler of water placed in a sling, may be made to vibrate like a pendulum with gradually increasing oscillation, and at last to describe the whole circle, and continue revolving about the hand without spilling a drop; the water, by its inertia of straightness or centrifugal force, tending more away from the centre of motion towards the bottom of the tumbler, even when that is uppermost, than towards the earth by gravity.

In the same manner as solid bodies laid on a whirling table are thrown off, so water in a vessel which is caused to spin round in any way, as on the centre of a horizontal wheel, instead of lying at the bottom, is raised all round against the sides of the vessel.

A man or a horse turning a corner at speed, leans much inwards, or towards the corner, to counteract the centrifugal force, that would throw him away from it.

In skaiting with great velocity, this leaning inwards at the turns becomes very remarkable, and gives occasion to the fine variety of attitudes displayed by the expert; and if the skaiter, in running, finds his body inclined to one side, and in danger of falling, he merely makes his skait describe a slight curve towards that side, and the tendency of his body to move straightly, or its centrifugal force refusing to follow in the curve, restores the perpendicularity. Skaiting becomes to the intelligent man an intellectual as well as a sensitive or bodily treat, from its exemplifying so pleasingly the laws of motion.

The reason also why a spinning-top stands, will be understood here:—While the top is quite upright, the extremity of its peg, being directly under its centre, supports it steadily; and although turning so rapidly, has no tendency to move from the place. But if the top incline at all, the *side* of the peg, instead of the *point*, comes in contact with the floor; and the peg then becomes as a little roller, advancing quickly, and describing a curve somewhat as a skaiter does, until it come directly under the body of the top as before. It thus appears that the very fact of the top inclining, causes the point to shift its place, and not to rest until it come again directly under the centre of the top. It is remarkable, that, even in philosophical treatises of authority, the standing of a top is still vaguely attributed to *centrifugal force*; and some persons believe that a top spinning in a weighing-scale would be found lighter than when at rest; and others most erroneously hold that the centrifugal force of the whirling, which, of course, acts directly away from the axis, and quite equally in all directions, yet becomes, when the top inclines, greater upwards than downwards, so as to counteract the gravity of the top. The way in which centrifugal force helps to maintain the spinning of a top, is, that, when the body inclines, or begins to fall in one direction, the motion in that direction continues until the point describing its curve has forced itself under the body again.

By reason of centrifugal force, also, it is easier to do feats of horsemanship in a small ring, as at our theatres, than if the animal were running on a straight road. We see the man and horse always inclining inwards, to counteract centrifugal force; and if the rider tend to fall inwards, he has merely to quicken the pace; if to fall outwards, he has to slacken it, and all is right again.

A ball of soft clay, with a spindle fixed through its centre, if made to turn quickly, soon ceases to be a perfect ball. It bulges out in the middle, where the centrifugal force is great, and becomes flattened towards the ends, or where the spindle issues.

This change of form is exactly what has happened to the ball—our earth. It has bulged out seventeen miles at the equator, in consequence of its daily rotation, and is flattened at the poles in a corresponding degree. A mass of lead that weighs one thousand pounds at our pole, weighs about five pounds less at the equator, by reason of the centrifugal force. This is the most remarkable and important manifestation of this law, and the manner of proving it will be afterwards described.

In the planets Jupiter and Saturn, of which the rotation is much quicker than of our earth, the middle or equator bulges out still more, even so as to offend an eye which expects a perfect sphere.

If the rotation of our earth were seventeen times faster than it is, the bodies or matter at the equator would have centrifugal force equal to their gravity, and a little more velocity would cause them to fly off altogether, or to rise and form a ring round the earth like that which surrounds Saturn. Saturn's double ring seems to have been formed in this way, and is now supported chiefly by the centrifugal force of the parts. Were it to crumble to pieces, the pieces might still revolve as so many little satellites. The true satellites are only more distant masses sustained in the same manner. And our earth, and the other primary planets, have the same relation to the sun that these satellites have to Saturn; all being sustained by an admirable balance between centrifugal force and gravity.

Amongst the numerous subjects connected with mechanical philosophy, the *centre of gravity* is one of the most important. But an explanation of it having already been given in the number of this work upon Mechanics, it is unnecessary to repeat what was there stated.

ON THE AXIS.

The line round which a body having rotatory motion revolves, is called an axis. In this case every point of the body must move in a circle whose centre lies in the axis, and whose radius is the distance of the point from the axis. Whilst the body revolves, the axis itself is sometimes moveable, and not unfrequently in a state of motion. We have an example of this upon a grand scale in the revolutions of the earth and planets; one on a humbler scale in the spinning of a top. We are, however, to investigate only those cases in which the axis is immoveable. Instances of this description are innumerable. Wheel-work of every kind, the moving parts of watches and clocks, turning lathes, mill-work, doors and lids on hinges, are all obvious examples. In some cases, as in most of the wheels of watches and clocks, &c., the body always turns in the same direction. In others, such as in pendulums of clocks, balance-wheels of chronometers, &c., the motion is alternate or reciprocal, its direction being at intervals reversed. When the alternation is constant and regular, it is called *oscillation* or *vibration*, as in pendulums and balance-wheels.

Bodies moveable on an axle of rotation are submitted to different kinds of forces. They are generally distinguished by the duration of their action into instantaneous and continued forces. If the body which sustains an action of the former kind be quiescent and free, it will move in the direction in which the impulse is given with a uniform motion. If, however, the force impressed upon it be incapable of setting it in motion, then it receives a shock, the effect of which is called *percussion*. A continued force produces a continued effect. If the body be free and previously quiescent, this effect is a continual increase of velocity. If the body be so restrained that the applied force cannot put it in motion, the effect is a continued pressure on the points or lines which sustain it.

A solid body which is moveable upon a fixed axis, is susceptible of no motion, except one of rotation upon the axis. If it be submitted to the action of instantaneous forces, one or other of the following effects must ensue: 1. The axis may resist the forces, and prevent any motion. 2. The axis may modify the effect of the forces sustaining a corresponding percussion, and the body receiving a motion of rotation. 3. The forces applied may be such as would cause the body to spin round the axis even were it not fixed, in which case the body will receive a motion of rotation, but the axis will suffer no percussion.

What has been just observed of the effect of instantaneous forces is likewise applicable to continued ones. 1. The axis may entirely resist the effect of such forces, in which case it will suffer a pressure which may be estimated by the rules for the composition of force. 2. It may modify the effect of the applied forces, in which case it must also sustain a pressure, and the body must receive a motion of rotation which is subject to constant variation, owing to the incessant action of the forces. 3. The forces may be such as would communicate to the body the same rotatory motion if the axis were not fixed. In this case the forces will produce no pressure on the axis.

A simple and elementary exposition of the mechanical properties of a fixed axis is a matter of considerable difficulty, and cannot be fully entered into here. The complete mathematical developement of the theory long puzzled the most acute geometers, and it was only at a comparatively recent period that it was fairly analysed. A body moves round its axis in two ways: 1. By having pivots at two points, which rest in sockets, so that, when the body is moved, it must revolve round the right line, joining the pivots as an axis; 2. A thin cylindrical rod may pass through the body, on which it may turn in the same manner as a wheel upon its axle. When force is applied to produce rotation, its power is estimated, not by the force alone, but by multiplying the force by the distance of its direction from the axis. The product is called the *moment* of the force round the axis. The distance of the direction of a force from the axis is sometimes called the *leverage* of the force. The *moment* of a force is, therefore, found by multiplying the force by its leverage, and the energy of a given force to turn a body round an axis is proportional to the leverage of that force.

When a body revolves on a fixed axis, the parts of its mass are whirled in circles round the axis, and have, accordingly, centrifugal forces proportional to their distances from the axis. If the component parts of the mass were not united together by cohesive forces of energies greater than these centrifugal forces, they would be separated, and fly off from the axis; but their cohesion prevents this, and causes the effects of the different centrifugal forces, which affect the different parts of the mass, to be transmitted so as to modify each other, and finally to produce one or more forces mechanically equivalent to the whole, and which are exerted upon the axis, and resisted by it. Dr Lardner explains these effects as follows:—

"It is obvious that any number of equal parts of the mass, which are uniformly arranged in a circle round the axis, have equal centrifugal forces acting from the centre of the circle in every direction. These mutually neutralise each other, and therefore exert no force on the axis. The same may be said of all parts of the mass which are regularly and equally distributed on every side of the axis.

Also, if equal masses be placed at equal distances on opposite sides of the axis, their centrifugal forces will destroy each other. Hence it appears that the pressure which the axis of rotation sustains from the centrifugal forces of the revolving mass, arises from the unequal distribution of the matter around it.

From this reasoning it will be easily perceived, that, in the following examples, the axis of rotation will sustain no pressure.

A globe revolving on any of its diameters, the density being the same at equal distances from the centre.

A spheroid or a cylinder revolving on its axis, the density being equal at equal distances from the axis.

A cube revolving on an axis which passes through the centre of two opposite bases, being of uniform density.

A circular plate of uniform thickness and density revolving on one of its diameters as an axis.

In all these examples, it will be observed that the axis of rotation passes through the centre of gravity. The general theorem, of which they are only particular instances, is, "if a body revolve on a principal axis, passing through the centre of gravity, the axis will sustain no pressure from the centrifugal force of the revolving mass." This is a property in which the principal axes through the centre of gravity are unique. There is no other axis on which a body could revolve without pressure.

But we cannot enter further into this interesting subject.

ON THE PENDULUM.

If a body be placed upon a horizontal axis, which does not pass through its centre of gravity, it will remain in permanent equilibrium only when the centre of gravity is immediately below the axis. When this point is removed to any other situation, the body will oscillate or move from side to side, until the resistance of the air, together with friction, brings it to rest. Such a body is a pendulum. The swinging motion which it receives is called *oscillation* or *vibration*. A common pendulum consists of a ball suspended by a rod from a fixed point, and made to spring backwards and forwards, or to vibrate under this point.

Galileo having observed the hanging chandeliers of lofty ceilings to continue vibrating long and with singular uniformity, after any accidental cause of disturbance, was led to investigate the laws of the phenomenon; and out of what, in some shape or other, had been before men's eyes, but uselessly, from the beginning of the world, his powerful genius extracted the most important results. Independently of the light which the theory of the pendulum has thrown on various branches of physics, the instrument itself, with a few wheels attached, to record its vibrations, has now become the perfect time-keeper, regulating many of the affairs of men. The pendulum is strictly an object of mathematical study; but we shall attempt to give a general idea of its important characteristics in common language.

1. The *times of the vibrations* of a pendulum are very nearly equal, whether it be moving much or little; that is to say, whether the arc described by it be large or small. This remarkable property is what makes it a time-keeper. The reason that a large vibration is performed in the same time as a small one; in other words, that the pendulum always moves faster in proportion as its journey is longer—is, that in proportion as the arc described is more extended, the steeper are its beginning and ending, and the more rapidly, therefore, the pendulum falls down at first, sweeps along the intermediate space, and stops at last. It is evident, for instance, that the portion of the arc most distant from the centre of gravity is much more steep than that which is nearest it. A pendulum made to vibrate in the curve called a *cycloid*, which, in the central part, very nearly coincides with a circular arc, but towards the extremities rises a little more steeply, has its beats perfectly *isochronous*, or in equal times, under all circumstances. This remarkable law was one of the earliest discoveries of Galileo.

A common clock is merely a pendulum, with wheelwork attached to it, to record the number of the vibrations, and with a weight or spring having force enough to counteract the retarding effects of friction and the resistance of the air. The wheels show how many swings or beats of the pendulum have taken place, because at every beat a tooth of the last wheel is allowed to pass. Now, if this wheel has sixty teeth, as is common, it will just turn round once for sixty beats of the pendulum, or seconds; and a hand fixed on its axis projecting through the dial-plate, will be the second hand of the clock. The other wheels are so connected with this first, and the numbers of teeth on them so proportioned, that one turns sixty times slower than the first, to fit its axis to carry a minute hand, and another by moving twelve times slower still, is fitted to carry an hour hand.

2. The *length of a pendulum* influences the time of its vibration. Long pendulums vibrate more slowly than short ones, because, in corresponding arcs or paths, the bob or ball of the long pendulum has a greater journey to perform, without having a steeper line of descent. The ball of the long pendulum may be considered as having rolled twice as far down a given slope as the ball of the short pendulum. Now, as a body falls four times as far, either directly or on any uniform slope, in two seconds as in one, a pendulum must be four times as long, to beat once in two seconds, as to beat every second. A pendulum of a little more than thirty-nine inches beats seconds; one of four times that length is required to beat double seconds, and one of one-fourth the length to beat half seconds. As the smallest change in the length of a pendulum alters the rate of going of the clock, a pendulum which beats seconds constitutes an easily found and correct standard of measure. To counteract the dilatation or contraction of pendulums from the changing heat of the seasons, various ingenious contrivances have been employed. One of the best of these is a *gridiron pendulum*, as it is called, from consisting of various rods of metal. It renders the different dilatability by heat of two metals composing it, the cause of unchanged length in the whole.—*Arnott.*

An idea of it may be thus formed. Suppose a rod three feet in length; the first and the last foot to be steel, and the middle one to be brass; then let the rod be bent so that the brass portion of it be placed on each side of the steel ends, one of which to be attached to the point of suspension, and the other to the metallic bob or ball. Brass expands with heat twice as much as steel; and the instrument is so contrived that the different dilatability of the two metals is made to compensate each other, and thus keep the pendulum always of the same length. There is another, and a most ingenious one, the invention of Mr George Graham, called the *mercurial pendulum*. In this one the metal mercury, which is always fluid at ordinary temperatures, is used instead of a metallic ball. Suppose a long hollow tube, which contains at the bottom an inch of mercury. Now, when the pendulum is exposed to an increase of temperature, the tube is lengthened, and of course the clock would move slow; but the quicksilver has also been expanded or raised in the tube, and thus has raised the centre of oscillation; thereby really shortening the pendulum, and that to the exact amount of the expansion of the tube. By this ingenious contrivance the pendulum is made to remain unchanged, which has been proved by the test of experiment.

In investigating the laws which regulate the times of vibration, two elements are to be determined: first, the exact time of a single vibration; and, second, the exact distance of the centre of oscillation from the point of suspension. The former is determined by ascertaining the number of oscillations which a pendulum makes in an hour, by means of a good chronometer. The entire time which the pendulum swings being divided by the number of oscillations made during that time, the exact time of one oscillation will be obtained. The distance of the centre of oscillation from the point of suspension is a matter of easy calculation. The time of vibration of one pendulum of known length being thus obtained, the following problems are easily solved: "First, to find the length of a pendulum which shall vibrate in a given time; and, second, to find the time of vibration of a pendulum of a given length." The former is thus obtained. The time of vibration of the known pendulum is to the time of vibration of the required pendulum, as the square root of the length of the known pendulum is to the square root of the length of the required pendulum. This length is therefore ascertainable by the ordinary rules of arithmetic. The latter problem may be solved as follows:—The length of the known pendulum is to the length of the proposed pendulum, as the square of the time of vibration of the known pendulum is to the square of the time of the proposed pendulum. The latter is therefore found by arithmetic.

As the rate of a pendulum has a known relation to the intensity of the earth's attraction, we are enabled by this instrument not only to detect certain variations in that attraction in various parts of the earth, but also to discover the actual amount of the attraction at any given place.

To compare the force of gravity in different parts of the earth, it is only necessary to swing the same pendulum in the places under consideration, and to observe the rapidity of its vibrations. The proportion of the force of gravity in the several places will be that of the squares of the velocity of the vibration. Observations to this effect have been made at several places, by Biot, Kater, Sabine, and others.

The earth being a mass of matter of a form nearly spherical, revolving with considerable velocity on an axis, its component parts are affected by a centrifugal force; in virtue of which, they have a tendency to fly off in a direction perpendicular to the axis. This tendency increases in the same proportion as the distance of any part from the axis increases; and, consequently, those parts of the earth which are nearer the equator, are more strongly affected by this influence than those near the pole. It has been already explained that the figure of the earth is affected by this cause, and that it has acquired a spheroidal form. The centrifugal force, acting in opposition to the earth's attraction, diminishes its affects; and, consequently, where this force is more efficient, a pendulum will vibrate more slowly. By these means the rate of vibration of a pendulum becomes an indication of the amount of the centrifugal force. But this latter varies in proportion to the distance of the place from the earth's axis; and thus the rate of a pendulum indicates the relation of the distances of different parts of the earth's surface from its axis. The figure of the earth may be thus ascertained, and that which theory assigns to it, it may be practically proved to have.

This, however, is not the only method by which the figure of the earth may be determined. The meridians being sections of the earth through its axis, if their figure were exactly determined, that of the earth would be known. Measurements of arcs of meridians on a large scale have been executed, and are still being made in various parts of the earth, with a view to determine the curvature of a meridian at different latitudes. This method is independent of every hypothesis concerning the density and internal structure of the earth, and is considered by some to be susceptible of more accuracy than that which depends on the observations of pendulums.

With respect to the other parts of Mechanical Philosophy, the most important of them have been discussed already in the number on Mechanics. Upon the laws of mechanics, the construction of machinery, so important for the comfort of mankind, depends. A machine is an instrument by which force or motion may be transmitted and modified as to its quantity and direction. The most simple machines are the mechanic powers; and their various combinations give rise to those beautiful and intricate pieces of mechanism which have given man so unlimited a sovereignty over uninformed matter.

The other sciences, besides Mechanics, which are included under Natural Philosophy, such as Hydrostatics, Optics, &c., both on account of their interest and importance, will be afterwards treated of at large in the present work.

INFORMATION FOR THE PEOPLE.

CONDUCTED BY WILLIAM AND ROBERT CHAMBERS, EDITORS OF "CHAMBERS'S JOURNAL" AND "HISTORICAL NEWSPAPER."

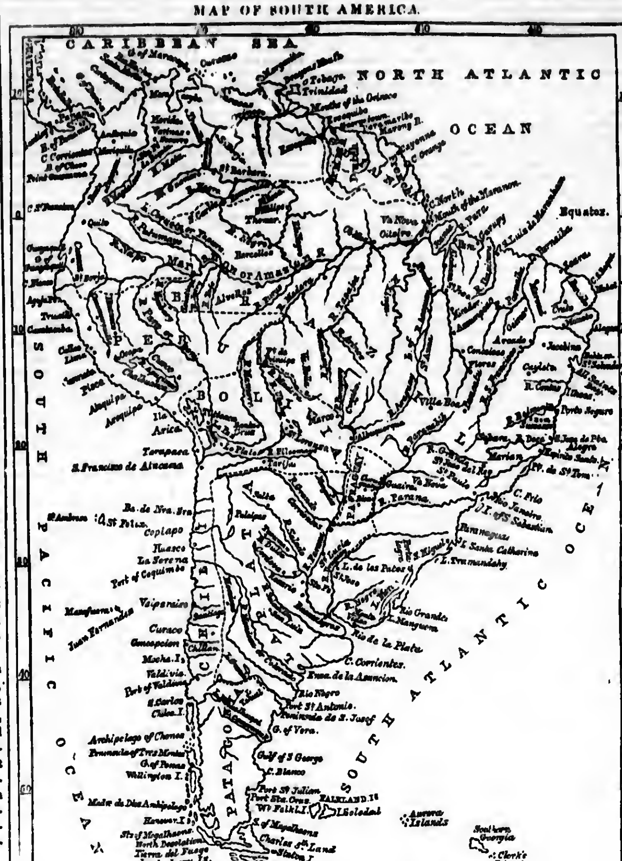
No. 37. PRICE 1½d.

SOUTH AMERICA.

To give a brief, and at the same time lucid, history of this immense portion of the globe, is a task attended with no small difficulty. The innumerable and unprecedented revolutions which have taken place in almost every province of this great territory, especially during the last quarter of a century, attended as these have been by changes equally of the laws, rulers, and geographical limits of each, render it difficult to assign the positive condition of either in any of these respects, at the present moment; and it is more than probable that, even while we are writing, some one or other of them may be undergoing a complete remodelling in all its relations. In some of them, the form of government has been changed three times within these twelve years; in others, civil war has scarcely ever ceased; in all of them we have seen one party chasing another from power with fearful rapidity, the victors murdering or proscribing the vanquished. Of the hundred most conspicuous politicians who have taken the lead in the various states, within the short period mentioned, we doubt if ten have escaped death, excepting those who have sought refuge in foreign countries. The military chiefs, as they served all parties in turn, have probably fared rather better. The number of revolutions occurring severally in the states—we mean of changes in which one party displaced another by violence, without any reference to constitutional forms—has certainly not been less on an average than one every two years, giving an aggregate of thirty in twelve years! As for insurrections, there must have been at least twice as many, since, on a fair calculation, not more than one half of them succeeded; but, in point of fact, the larger states have scarcely enjoyed one month's internal peace. Of the bloody war with Spain, which lasted sixteen years, it was fondly hoped that the evils and sufferings flowing from it would soon be effaced by the benignant influence of freedom and unfettered industry. But at this moment, so far as we can judge, each state is no nearer a permanent settlement, and has no better prospect of peace, order, and security, than on the day when it drove the last Spanish royalist from its shores.

From what we have said, our readers will at once allow the difficulties attending our task. We have, however, been careful in collecting the very latest information on every point, and we believe, that, with the aid of the accompanying map, the reader will be enabled to acquire a pretty correct idea of the present condition of the South American Continent. But for the reasons above stated, as well as from our having, in a late Information (on the West Indies), given a short sketch of the character and history of the aborigines, we will confine our account of the past history of the country within as brief limits as possible.

MAP OF SOUTH AMERICA.



BOUNDARIES AND DIVISIONS.

South America extends from the Isthmus of Panama, or Darien—which connects it with the northern portion of the American continent—on the north, to the Straits of Magellan, on the south; or, more properly speaking, perhaps, to Cape Horn, although the latter be disjoined from the mainland. It is triangular in form, and is washed by the Atlantic on the north-east, and by the Pacific Ocean on the south and west. Its length from north to south is calculated at about 4600 miles, and its greatest breadth at 3200; covering an area of upwards of 6,500,000 square English miles, three-fourths of which lie within the region of the tropics, and the other fourth in the temperate zone. This immense tract of country may be divided into nine great departments; viz. Colombia, Paraguay, Banda Oriental, Brazil, Peru, Bolivia, Guiana, Chili, and Buenos Ayres (or the united provinces of La Plata). These various portions, however, although they may be described as having been at one time unique provinces, have for the most part been long and often broken up into smaller ones, which will come to be noticed afterwards, in treating of them separately. The whole continent, again, may be said to be separated into two portions by the hand of nature, which has raised that huge chain of mountains, or *cordilleras*—the Andes—which run from the Straits of Magellan to the Isthmus of Darien, parallel to the shores of the Pacific. Nature may also be said to have separated it into five distinct physical regions:—1. The low flat country lying between the foot of the Andes and the Pacific Ocean, averaging from 30 to 150 miles in breadth. 2. The valley of the Orinoco, enclosed by the Andes and their branches, consisting of huge plains, or *steppes*, called by the natives *llanos*. The heat is so intense in these plains during the summer, that the ground is split into great rents or fissures. 3. The basin of the Amazon (or Maranon), which embraces nearly a third of the whole continent, or two millions of square miles, and the soil of which is every where overrun with vegetation. 4. The great plain of the Plata and its tributaries, consisting of numerous varieties of soil and climate. 5. The elevated country of Brazil, very woody towards the Atlantic, and opening into fertile plains in the interior. We shall speak more fully of the climate and productions of these regions, when we come to discuss those subjects separately.

DISCOVERY AND HISTORY.

There seems little doubt that Columbus, during his second voyage of discovery in the tropical seas, in 1493, had seen the continent of South America; and that it was it which, not conjecturing the existence of an ocean to the south, he mistook for a portion of India, and for this reason assigned the name of the *West Indies* to the various islands he discovered in the Caribbean Sea. According to Mr Southey, it was Vicente Yanez Pinzon, a Spaniard, and a distinguished associate of Columbus, who first, in the year 1500, discovered the coast of Brazil. It does not appear, however, that Pinzon paused to investigate the coast or interior, but instantly returned to report the intelligence to the court of Spain. Scarcely had he departed, when a Portuguese navigator, named Pedro Alvarez de Cabral, while on an expedition to discover a passage to India by Cape Horn, stood so far to the west that he unexpectedly found himself on the coast of Brazil; and after running along this unknown land, he anchored in the fine bay now called after him "Cabralia." Here he landed, and took possession in the name of his sovereign. A messenger was instantly dispatched in one of the vessels to Portugal with the intelligence, and King Emanuel forthwith sent out three other ships under the celebrated Americo Vespucci (whose name was, with so much injustice to the merits of Columbus, afterwards bestowed on the whole of the New World), who, after his return, was again sent back in 1504, when the first settlement was made. This was not effected without fatal opposition, as three of the crew, who were sent ashore to converse with the natives who lined the beach, were instantly murdered, roasted, and eaten, before the eyes of their comrades. This circumstance, together with the idea entertained that the country was only productive of wood, parrots, and monkeys, deterred the Portuguese from making any other serious attempt to establish a colony until 1549. In that year, an expedition was sent out under Thomas de Souca, to which some Jesuits were attached, who managed so well in conciliating the natives, that the latter gave them no farther disturbance; and the city of St Salvador (Bahia) was then founded, which, up to 1771, continued to be the capital of Brazil.

In the meantime, the whole of the north-east coast had been explored, and numerous little settlements effected by various adventurers from Spain and Portugal, which were then the only maritime nations that distinguished themselves in this way. The wealth of the country in gold and precious stones was soon discovered; and as the real value of them was unknown to the natives, their visitors or invaders were enabled to load themselves with riches. Up to the year 15[illegible], however, the knowledge of the Pacific Ocean had remained unknown to these adventurers, and, consequently, all the rich countries which lie along its shores. In that year, a Spaniard, named Vasco Nunez de Balboa, having attached to him a troop of 150 of his countrymen, founded a colony in the Isthmus of Darien, where a simple Indian, perceiving the fondness of the Spaniards for gold, offered to show them a country where that metal was used for the meanest vessels. He accordingly led them into the interior, whence they got a sight of the Great Pacific Ocean, and of the wealthy and populous city of Peru. Balboa did not venture to proceed, but returned to Darien, where he found a new governor, Pedrarius, had got appointed in his place, who, instigated by avarice and jealousy, put him to death. Although the existence of the rich countries to the west of the Andes had thus become known, no one was daring enough to attempt a hostile expedition against the warlike tribes which obstructed the way to them by land, and the navigable routes by Cape Horn and the Straits of Magellan had not then been discovered. The connection between the Atlantic and Pacific was at last found out in 1520, by Magellan, or Magelhaens, a Portuguese navigator, by the discovery of the straits now named after him. This event was of course the signal for new and ardent adventurers, but all failed in their attempts to reach this new world of promise, until the year 1525, when the famous, or rather infamous, Francis Pizarro, having associated himself with two others, fitted out an expedition for the purpose. Having proceeded first to Darien, they sailed thence, in November 1525, with about eighty men and four horses. Owing to ignorance of navigation, they suffered severe loss in coasting along, but Pizarro persevered; and having sufficiently satisfied himself respecting the immense wealth of the cities and soil, he returned to Spain for reinforcements. The presents he brought to the king at once procured him these, with a commission as governor and captain-general of the new-found territories, and the right of appropriating to himself a large share of the profits of the expedition. He accordingly sailed with three ships, carrying 185 soldiers, thirty-seven horses, several pieces of ordnance, ammunition, stores, &c. On landing, they found a civil war raging, of which Pizarro did not fail to take advantage, and his conduct will render his name for ever a byword of treachery, rapacity, and cruelty. Having extorted immense sums, under promise of assistance, from the reigning Inca, Atahualpa, a day was appointed for delivering up the treasure in a large square surrounded by a high wall, into which Pizarro had introduced his artillery and soldiers. When the good Inca had entered, and the square was filled with his followers to the number, it is said, of 7000 or 8000, Pizarro opened his artillery upon them, and slaughtered every man, with the exception of the Inca, who was reserved for further use. Pizarro offered to release him upon his paying an enormous ransom, being, it is said, no less than a whole house filled with gold. By spoiling the temples, and other means, the ransom was soon made up, and no sooner delivered, than the unfortunate captive was put to death—being allowed to choose strangulation, instead of burning, as a reward for becoming a Christian! The news of their success brought a great accession of strength from Europe to the invaders; and Pizarro, in order to consolidate his empire, founded, in 1535, the city of Lima, intending it as the future capital of his dominions. The joint chiefs of the expedition, alarmed at his proceedings, attempted to resist, but he soon subdued them, and ordered Almagro, an old man in his 75th year, who had been his companion in his first expedition, to be strangled. The son of the victim, however, organised a conspiracy four years afterwards, broke into the palace at Lima, and succeeded in destroying the monster. It is needless to trace this part of our subject farther in this place, as it will afterwards fall to be treated of under the head of Peru.

The province of Buenos Ayres was first coasted along by Americo Vespucci in the year 1501, but he was driven off that latitude by tempestuous weather. In 1516, the entrance of the great river La Plata was first discovered by Juan Diaz de Solis, who communicated his own name to the stream. Fearful of venturing too far up the river in his little squadron of three ships, as the navigation seemed both dangerous and difficult, he sailed along its northern shore in his long-boat, and seeing some savages on the beach, who by their gestures and signs seemed to invite him on shore, he imprudently landed with a few men, when the whole were instantly killed and devoured by the Indians, before their companions' faces. A party of the Portuguese, settled in Brazil, afterwards attempted an overland march to the new territory, but these were also all massacred on the banks of the Paraguay. At last Charles V. sent Sebastian Cabot, in 1526, to sail round the then recently discovered Straits of Magellan; but that commander having anchored in the La Plata, then called Rio de Solis, he received such flattering accounts of the riches and beauty of the country, that he abandoned his original purpose, and proceeded up the river. In ascending, he and his officers ran into mistakes respecting the main stream, amidst the immense number of large tributaries that poured into it. In proceeding up the Paraguay, he was attacked by the natives, who killed twenty-five of his men, and compelled him to return. Having, however, obtained some gold and silver from the Indians in barter, he transmitted it to the emperor, who highly approved of Cabot's conduct, and sent out another armament of nearly 3000 men under Mendoza. So fierce and obstinate, however, was the resistance of the natives, that this expedition likewise failed to establish a peaceable or safe settlement. A continual struggle was in this way kept up, till, in 1586, a number of Jesuits went out to convert the savage Indians; and such was the effect of their labours, proceeding fearlessly throughout every part of the interior, that they succeeded in paving the way to an ultimate reconciliation, making thousands of converts, forming them into industrious communities called *reductions*, and, in sober fact, actually reducing them to the condition of civilised societies. These worthy men, however, got little thanks for their labours from the Spanish settlers, who accused them to the home government of stirring up the natives to sedition; but the proofs of their beneficial labours were too strong to be confuted.

The history of Chili furnishes one of those exceptions to the dogma which assigns to civilisation alone, intelligence, patriotism, and other virtues of a high moral standing. Looking to their civil, domestic, and political institutions, it is clear they possess a far higher degree of independence and energy of character than any of the other aboriginal natives of America. To keep even a partial possession of Chili cost the Spaniards more blood and treasure than all their other settlements put together. One portion of the natives, indeed—the Araucanians—who refused to entertain any terms whatever with the great conquerors, have maintained their independence unimpaired for upwards of three hundred years, and now live under a government of their own, which, singular to say, is highly aristocratic, but at the same time affording perfect security to the liberty of the people. Previous to the conquest of Peru by the Spaniards, some of the northern parts of Chili were subject to the Incas, who of course surrendered to the conquerors their authority over these provinces. The Chilians at first were disposed to acknowledge the supremacy of the Spaniards, but the oppressive conduct of the latter soon roused them to resistance, and they quickly expelled the invaders. Pizarro afterwards sent General Valdivia against them, who succeeded in conciliating the northern portions of the nation, and he founded the city of Santiago in 1541. He then proceeded against the southern portion, where he founded the city of Conception, but was attacked by the Araucanians, who drove them from their territories. The cities of Villanca, Valdivia, Imperial, and other towns founded from time to time by the Spaniards, were regularly assaulted and taken by this brave people, who continued their resistance until their invaders were glad to sue for peace. The Dutch sent over an armament with the professed object of assisting to expel the Spaniards, but the Chilians soon saw the selfishness of their motives, and turned them adrift. The treaty of peace concluded betwixt the Spaniards and Chilians, lasted till the year 1655, when hostilities again broke out, and lasted for ten years; but the Araucanians were indomitable, and a second peace was concluded, which remained uninterrupted until 1770, when the Araucanians again took up arms upon an attempt being made to compel them to live in towns and villages. At length peace was restored upon one condition—that the Araucanians should henceforth have a resident minister at Santiago—a provision which sufficiently shows their power and importance. By this time the other parts of Chili had acknowledged the supremacy of the Spaniards, and all parts of the nation appears to have remained undisturbed until the general revolutionary movements in 1810—of which more hereafter.

At the time that the Spaniards and Portuguese were thus gradually possessing themselves of the great South American continent, neither France nor England had begun to display a similar spirit of enterprise; and when the spirit of colonising at length manifested itself, their views were directed rather to the northern portion of the same continent. The only purpose, indeed, for which the English maritime adventurers of the age of Elizabeth visited the South Seas, was plunder; and these—embracing the names of men which have been recorded as the brightest ornaments of our naval annals—were loaded with honours and rewards just in proportion to the extent of their robberies.

It is a curious fact, that, amongst the first adventurers to the southern continent from Britain, was an expedition which proceeded from the port of Leith. The place of settlement was the Isthmus of Darien, and, had the enterprise not been opposed and ruined by the mean and selfish policy of a few narrow-minded monopolists, it would have proved one of the most useful and important to Great Britain that ever was projected. Of the rise, progress, and catastrophe of this well-planned but ill-fated undertaking, Sir John Dalrymple, in his Memoirs of Great Britain, has given a most interesting, and indeed affecting, account. A Mr Paterson, a Scots clergyman, was the projector; the celebrated Fletcher of Salton patronised his plan; through his influence the Scots ministry adopted it, and in a short time nearly a million sterling was collected in England, Scotland, and Holland—of which L.400,000 was subscribed in Scotland alone, *being one-half of the cash then in the country*. Two expeditions, amounting together to 2500 men, successively sailed from Leith for the projected settlement; but "the jealousy of trade," says Sir John, "which has done more mischief to England than all other causes put together, created an alarm in England, and both houses concurred in an address to the king against the establishment, as detrimental to the interests of the East India Company." The consequence was, that the English, Dutch, and Americans, were prohibited by King William III. from all correspondence with the colony; the second expedition sailed; but when they arrived, they found that the whole of their predecessors were gone—either dead from starvation, or, as it afterwards turned out, or having left the colony in despair. Their successors shared the same fate. Cut off from all supplies, interdicted all communication with the West Indies or British America, and besieged by the Spaniards both by sea and land, this ill-fated colony was obliged to capitulate to the enemy.

Having now given a short sketch of the original history of the principal South American colonies, we shall next proceed to detail briefly the means by which the downfall of the Spanish power was effected in America; for it would be as impossible as unnecessary to attempt to trace the history of the various settlements from their establishment down to modern times. The horrible cruelties of the Spaniards—the continual and ineffectual efforts of the oppressed to cast off their yoke—the well-known history of the descents of the Buccaneers—these are the materials which would supply an account of the intermediate space. The particulars of the changes effected by the revolution in each colony shall, however, be given afterwards, separately, under their various heads. We are compelled to this partial repetition by the circumstance of the revolution having broken out simultaneously in all the Spanish settlements, while those of other nations, which had previously been wrested from the Spaniards, remained perfectly tranquil.

Previous to the revolution, the Spanish possessions in South America* formed five distinct governments, all constructed on the same plan, and independent of each other. Three of these were vice-royalties; viz. Peru, La Plata, and New Grenada (the latter being afterwards one of the three component states of Colombia); and two were captain-generalships, Chili and Venezuela (the latter being also afterwards merged in the republic of Colombia). The government was vested in the viceroy or captain-general, who was held to represent the king, with all the prerogatives attached to that capacity. The royal *audiencas*, or supreme courts, consisting of Spaniards nominated by the crown, enjoyed extensive judicial powers—as also did the municipalities and corporations:—but perhaps the clergy possessed more influence than any. Every body, however, possessed some privileges but the poor Indians, who were in no respect better than beasts of burden; for, although laws were made by the home government from time to time for their protection, they were never acted upon; and as the only object of the government was to raise a large revenue from the colonists (whom they taxed to the uttermost), no notice was ever taken of this disregard of the laws. The Creole or American-born Spaniards were excluded from all public offices, from the highest to the lowest, all of which were bestowed on the natives of Spain. These functionaries, whose sole object was to make money, acted the part of true despots towards the other classes; plundering, taxing, and exacting, without the slightest regard to mercy or justice. Men rose to affluence in offices without salaries, and the priests rivalled the laymen in the art of extracting money from the natives. In a word, the Creoles were little better to be envied than the miserable Indians. That this system should have continued for upwards of three hundred

* Their other possessions were Mexico or New Spain, Yucatan, and Guatemala (both now in the Mexican confederacy), and Cuba in the West Indies. With these, however, we have nothing at present to do.

years, can only be accounted for by the means adopted to keep the minds of the natives in darkness and ignorance. All books of general knowledge or information were prohibited from being imported; schools of every kind discouraged; while the priests filled the minds of the natives with the most childish superstitions and religious terrors. Nay, few could obtain leave to visit foreign countries.

Such was the state of things in Spanish America, when Ferdinand "the beloved" was dethroned and imprisoned by Bonaparte, and orders arrived in the colonies to ensure submission to the new dynasty of the conqueror's brother Joseph, who had succeeded to the crown. The functionaries and priests would have been very willing to purchase a continuance of their means of plunder on such terms, but the oppressed classes thought this would be a suitable time for procuring some remission of their miseries. Juntas were formed in almost all the states during 1809, and in 1810 the first insurrection broke out in Mexico. It would be impossible to give any consecutive outline of the various military operations. Besides, we will have to advert to them shortly in noticing the various states. Suffice it to say, that after a bloody struggle, protracted till the year 1826, the Spanish monarchy lost every foot of ground in the western world, if we except the islands of Cuba and Porto-Rico, which she still retains.

The atrocities perpetrated by the Spanish royalists during these wars are perhaps without a parallel in the annals of the human race, and point out that people as being infinitely inferior in all that characterises a Christian or civilised community among the nations of Europe. Men were massacred in cold blood, frequently by hundreds and thousands at a time; treachery, perfidy, and contempt for the most solemn oaths, were universally practised. Neither European nor Indian was spared in their thirst for blood and plunder; and it has been calculated that no less than a *million of human beings* were destroyed by them in the course of sixteen years!

COLOMBIA.

That division of South America known by the name of Colombia (after the celebrated discoverer), comprised, under the Spanish domination (as it now again does), three distinct States or governments, called by the names of the Vice-royalty of New Grenada, the Captain-generalship of Caraccas, and the Presidency of Quito. It is bounded on the east by the Atlantic Ocean; on the north it extends over part of the Isthmus of Darien, but it is scarcely yet known how far; on the west it is bounded by the Pacific Ocean; and on the south by the river Tumbez. The whole extent of territory is comprised between lat. 12° 30′ N. and 60° S., and extends over a surface of 1,100,000 square miles. The western part contains the loftiest ridges of the Andes, while the eastern stretches out into immense plains, intersected by gigantic rivers. In the vallies of the Andes, raised 10,000 feet above the level of the sea, the population is chiefly concentrated. The principal chain of the Andes is that of Caraccas, running along the north coast, with summits of from 12,000 to 14,000 feet high. The principal rivers of Colombia are the Magdalena, the Amazon (or Maranon), and the Orinoco. In Venezuela, the year is completely divided by the rainy and the dry seasons; the former commencing in November and ending in April. Gold, platina, silver, cinnabar, copper, mercury, iron, and coal, are among the mineral riches of Colombia. The principal articles of export are cocoa, indigo, tobacco, coffee, hides, and cattle. The imports comprehend manufactured goods of every description. The contraband trade is carried on to a great extent by the Dutch and English, owing to the facilities afforded by the Orinoco and its tributaries. The ports of La Guayra, Rio del Hacha, Santa Martha, Carthagena, Chagres, Porto Cabello, Panama, and Guyaquil, are those most frequented by foreigners. Besides these, the chief cities are Bogota, Caraccas, Quito, Cumana, Cucuta, New Valencia, St Thomas, Barcelona, Maracaibo, and Merida. The population, according to the report of 1827, amounted to the enormous quantity of 2,857,347, and consists of whites, Indians, mestizoes, negroes, and mulattoes. The creoles, or whites, have in general some mixed blood in their veins. All the Indians have been declared free since the revolution; and the government decided that the children of all slaves born after that period shall be free. A great many of the Indians in the interior still remain unsubdued, and in a savage state. The Romish is the declared religion of the state, but all others are tolerated, and the Inquisition has been abolished. There are four universities—at Quito, Bogota, Caraccas, and Merida. Provision has also been made for other seminaries and primary schools, but the unsettled state of the country allows but little to be effected in the way of education. Jury trial has been introduced into Colombia, for offences against the press, and in commercial matters.

Colombia will ever retain a prominent place in history, as having been the chief scene of the efforts of the immortal Simon Bolivar, who may well be styled the Washington of his country. He was born of noble parents, in the city of Caraccas, in July 1783. After receiving the elements of a liberal education at home, he was sent to Madrid to complete his studies. He then travelled through Germany and France, and returning to Madrid, married a rich and noble lady, with whom he embarked for Caraccas, intending to spend his future life in domestic peace and retirement upon his large estate. His lady having soon died, he again sailed for Europe; and on his return through the United States, became imbued with the principles of liberty, and immediately embarked in the schemes of the patriots at Venezuela. Previous to this, there had been two attempts at revolution in Colombia—once in 1797, and again in 1806; and although repressed, the doctrines of freedom had been disseminated far and wide. Upon the general movement in 1809, from the causes already explained, he was amongst its chief promoters, and received a colonel's commission from the Supreme Junta at Caraccas. From the period of the Venezuelan declaration of independence in 1811, accordingly, he took the most prominent lead in all their military operations; but we can only notice his future career in connection with the general current of events. A liberal constitution being established, affairs went on smoothly until the great earthquake in 1812 (to be noticed elsewhere), when a great change took place in public opinion, from the influence of the clergy on the superstitions of the people, who were made to believe that the dreadful casualty was in consequence of their adoption of the new order of things. Monteverde, a royalist general, taking advantage of the situation of affairs, marched against Caraccas, and soon effected its resubjugation, Bolivar himself escaping to Curacoa. In 1813, he returned; and being entrusted with an army by the confederation of Grenada, he again effected the liberation of Venezuela. Finding the necessity of entrusting their affairs to the guidance of some one energetic mind, the Venezuelans named him dictator; and by his exertions, a union between the republics of Grenada and Venezuela was for the first time effected in 1819, Quito being at this time under the dominion of the Spaniards. This was the first confederation styled the *Republic of Colombia*. At the congress which ensued, a republican constitution was established, Bolivar being elected president, and Santander vice-president. The former immediately afterwards returned to the seat of war; and after two years' campaign, the details of which it is impossible to give here, succeeded in completely overthrowing the Spanish power in Colombia. He then marched to effect the liberation of Peru—for the proceedings of which campaign see that head. Colombia remained tranquil and prosperous from 1823 to 1826, under the presidency of Santander in Bolivar's absence, when its misfortunes again commenced, and to which there has been hitherto no cessation. General Paez, who, next to Bolivar, had been the principal leader during the revolution, was a man of Indian extraction, and in his youth was a *llanero*, or cowherd. Possessing a daring and energetic disposition, he managed, at the period of the revolution, to raise a regiment of *llaneros*, and performed such essential services to the patriots, that Bolivar soon gave him a high command. Paez, however, was a man of a brutal, dissolute, and reckless disposition, and during Bolivar's absence in Peru, committed some excesses, which induced the senate to summon him to appear before them. Upon this, Paez placed himself at the head of his troops, and became the nucleus of a strong party disaffected to the central government. Things were in this state when Bolivar returned, in 1827, from Peru. In order to accomplish a reunion, he requested a personal interview with Paez at an inn near Caraccas; and the particulars of this meeting, as described by an eye-witness, Captain Chamier, R.N., in his excellent novel, the "Life of a Sailor," is worthy of a place here, as illustrating the character of one of the greatest men of modern times:—"Bolivar arrived in the vicinity of the inn at the appointed time, attended only by Colonel Wilson (son of Sir Robert Wilson) and one or two domestics. It was found, however, that Paez was not true to his engagement. It was an hour of intense anxiety to all but Bolivar, who alone could have been much injured by the perfidy of Paez, who had so often broken his faith, and had so frequently involved his country in civil discord. The Liberator, however, bore his usual equanimity of countenance, and, mounting his mule, descended into the valley. On turning a sudden angle, his surprise was great at beholding a plain covered with tents, and bearing the appearance of a hostile force encamped. As Bolivar neared his *friend*, he perceived the soldiers forming in two files, and flanking the road along which he was to pass; when his faithful aid-de-camp hinted that some perfidy might be intended; and as they advanced along the road, observed that the line of soldiers closed up in their rear. Bolivar, on being told this, had the presence of mind not even to turn round to watch the manœuvre, but steadily pursued his course. Bolivar soon saw Paez standing with some of his general officers, and directing his mule to the place, quietly dismounted, and folding the treacherous chief in his arms, exclaimed aloud, 'By this behaviour, and this submission to the government, you have saved your country!' The army immediately shouted, 'Viva Bolivar!' The mountains re-echoed the cheer; and Paez, overcome by his feelings, reclined on the breast of the president. It was immediately agreed that both should together make a kind of triumphal entry into Caraccas"—which took place accordingly.

Paez's example, however, was the occasion of disorders breaking out in other parts of the republic, entirely disunited in purpose or object, when Bolivar, at a general convention, promulgated his Bolivian code of government, the principles of which were in accordance with that of Britain—for he was confessedly anti-republican in his opinions—and which he had persuaded the Peruvians to adopt. The result, after great opposition, ended in his being chosen perpetual dictator, which office he accepted, although his character has suffered considerably by the measure. So violent was the indignation of the republican party, that an attempt was made to assassinate him, which, however, failed. In 1828, war broke out between Colombia and Peru, in consequence of Bolivar's alleged attempt to get himself also elected president or dictator of the latter state; but peace was concluded in the following year. Before the end of 1829, however, every town, province, and village of Venezuela had declared for a republican government, under the auspices of Paez. Bolivar, in short, became as nothing in Colombia, and he foolishly kept up civil discord by his presence, which was the occasion of repeated revolts and great bloodshed. Another commander and president was ultimately appointed in his place, when, worn out by grief and agitation, this great man expired at the village of San Pedro, near Santa Martha, on December 17, 1830.

After the death of Bolivar, the three component states of Colombia—Venezuela, Grenada, and Quito—peaceably agreed again to become independent of each other, severally recurring to the old republican form of government. Paez was elected president of Venezuela, which office, according to the latest accounts, he continues to hold with considerable popularity. Santander was chosen president of New Grenada; and General Flores of Quito (or, as sometimes now called, Equator or Equador). Whether these three states may ever again unite, remains to be seen.

BUENOS AYRES, OR THE UNITED PROVINCES OF LA PLATA.

The united provinces of La Plata are bounded on the west by Chili and Peru; on the east by Brazil and the Atlantic; on the south by Chili; and on the north by Bolivia, Paraguay, and Banda Oriental. The superficies of the united provinces comprised an area of 1,696,000 square miles, and was divided into fourteen provinces by the Spanish government in 1778, at the time Buenos Ayres was erected into a vice-royalty. The population of the entire vice-royalty, according to the report of special commissioners appointed for that purpose in 1818, amounted to 2,573,000. As the vice-royalty of Buenos Ayres at the time of its erection included the rich provinces of Upper Peru, the commerce of the La Plata rose into great importance, several Spanish ports being then allowed to trade with them; but it again sunk, never to revive, during the war between Spain and England, in 1797. In 1806, Buenos Ayres was taken by a small English expedition, under Admiral Popham and General Beresford; but the inhabitants, recovering from their surprise, soon afterwards drove their assailants from the town. In the following year, General Whitelocke arrived with reinforcements; the troops were quietly permitted to enter the town, when they were repulsed with tremendous slaughter, and ultimately compelled to evacuate the La Plata. There were no fortifications at the time the city was attacked by the British troops, and it was indebted for its strength solely to the peculiar structure of its buildings. In 1809, Buenos Ayres was the first to declare itself independent of the Spanish government, and the revolution was effected without bloodshed. The other provinces joined Buenos Ayres unanimously, and were completely triumphant. Up to 1819, various forms of government were successively tried and abandoned (the sittings of the legislators having been transferred to Buenos Ayres); when a constitution, founded on that of the United States, was established; and although the provinces were torn by dissensions, the general revenue increased. It was in 1825, upon a treaty of peace, commerce, and navigation, being concluded with Great Britain, that these provinces (then nine in number) assumed the name of the United Provinces of La Plata. The functions of the government were discharged by a constituent congress, the executive power being entrusted to the provincial government of Buenos Ayres. About this time the united provinces were involved in a long and devastating war with Brazil, concerning the possession of the intervening territory, Banda Oriental (of which see the separate head), which continued until 1828, when it was mutually agreed to erect it into an independent state. In the same year the able president of the congress, Rivadavia, whose talents alone had preserved the unity of the federation, resigned. This was the signal for general disorganisation, and each of the provinces again became independent. Each province now governs itself, having customhouses on their frontiers, with the anomalous exception that Buenos Ayres is still entrusted with the diplomatic function of arranging their relations with foreign powers.

The province of Buenos Ayres itself comprised in 1822 an area of not more than 1518 square leagues; but since then, an immense addition has been made out of the adjacent Indian territories, partly by force, and partly by conciliation. This recent acquisition comprises by far the finest land in the province. The whole territory is an almost uniformly level plain of great fertility, watered by a few rivers of moderate size, the largest being almost nowhere above four feet deep. There are almost no natural trees in the province, but there are numerous plantations or rather orchards of peach trees, which the natives cultivate for fire-wood—the fruit being applied to feeding the swine and poultry. Immense forests of thistles spring up at certain seasons of the year, of ten and twelve feet in height. Deer is plentiful in the wilder parts, but little prized where there is so much fine beef. The climate is extremely salubrious. The city of Buenos Ayres is situated on the southern margin of the river Plata, where the latter is formed by the confluence of the Parana, Uruguay, and Negro rivers. It is thus, as it were, the key to all the internal navigation. The length of the Plata from its formation to the ocean is upwards of seven hundred miles. The city occupies a large extent of ground, being about two miles long, and a mile and a half broad, all the streets crossing at right angles. There are a Jesuit university, an Episcopal church, and about fifteen other churches. The prosperity of Buenos Ayres and the other provinces is greatly impeded by the defective navigation of the river Plata, which is filled with shoals and sandbanks, and therefore dangerous to large vessels, otherwise the city of Buenos Ayres would become one of the largest emporiums of commerce in the world. The rivers Parana and Uruguay are each navigable for vessels of from two to three hundred tons, fifteen hundred miles into the interior; the former running through Paraguay into the centre of Bolivia.

Speaking generally, the so-termed united provinces of La Plata may be reckoned, from their natural riches and advantages, as one of the most important divisions of South America. In 1830, even in their disunited condition, the exports amounted to nearly two millions. One of the distinguishing characteristics of La Plata, are the vast plains called *pampas*, one portion of which extends from the banks of the Paraguay, westward to the frontiers of Los Charcas, and northward to the mountains of Chiquitos—another immense plain, three hundred miles in length from east to west, and fifteen hundred from north to south, as far as the interior of Patagonia, nine hundred miles of which appertained to the vice-royalty. These plains present one uniform expanse of waving grass, uninterrupted by either wood or eminence, although in some places parched and barren, and perfectly uninhabited, unless by innumerable herds of wild oxen, horses, ostriches, and other animals. Over these pampas lies the only route by land from Buenos Ayres to Chili, which journey was formerly performed by large companies, as the plains were infested by hordes of roving Indians, who went there to hunt, catch wild horses, and plunder. From the absence of all permanent landmarks, the travellers over these immense plains shaped their course by the compass, and their caravans were in reality moveable houses, solid and defensible. Of late years, regular post-houses have been established along the whole line of road betwixt Santiago (capital of Chili) and Buenos Ayres—a distance of nearly 1400 miles—and a regular communication is kept up betwixt the two provinces by means of couriers, who perform their journies with uncommon speed.

PARAGUAY.

The republic of Paraguay, formerly one of the united provinces of the vice-royalty of Buenos Ayres, is situated between the rivers Parana (on the east and south), and Paraguay (on the west). It is divided by a mountainous ridge from Brazil on the north. It comprises an area of about 50,000 square miles, with a population of about 250,000, seven-tenths of which are Creoles. At the revolution in 1810, the Buenos Ayreans sent a body of troops into Paraguay to subdue the Spanish authorities; but the people rose in arms, and after repelling them, quietly deposed the governor themselves, and proclaimed Paraguay a republic, under two consuls, Francia and Yegros. Soon after, the former caused himself to be elected dictator for three years, and at the end of that time procured his nomination for life. In 1827, he obtained an acknowledgment of the independence of Paraguay from Don Pedro, then emperor of Brazil. This extraordinary man is a native of Paraguay, and studied for the church, in which profession he actually took out his diploma as doctor of theology in the university of Cordova del Tucuman. He afterwards changed his views, and studied law, which he practised for some years, distinguished by his extraordinary learning, ability, and integrity. On the breaking out of the rebellion, a man of his talents could not be wanted; and being the only individual of learning and ability in the province, he may be said to have managed the whole affairs of that crisis himself. In fact, his practice was, whenever he was opposed by the rest of the junta, to retire into the country, when they were glad to recall him upon his own terms. The ascendancy he thus acquired he has since maintained in his dignity as perpetual dictator, and is certainly one of the most extraordinary despots on record. "He is sober, abstinent, and unostentatious, economical of the public money, and disinterested; but stern and capricious, employing the arm of absolute power to correct the vices and increase the industry of his subjects. He lives among the people with the simplicity and familiarity of a patriarch, and yet is a tyrant in spirit, and carries his tyranny into the most ordinary acts of private life. He directs one man how to build his house, another how to till his ground, a third how to fabricate the articles he manufactures; he fixes the price of commodities, and enforces all his orders with the most summary and rigorous penalties. Idleness is punished as a crime. He keeps a small army to support his authority and guard his frontiers, and will neither permit any stranger to enter the country, nor any of his subjects to leave it. Being dissatisfied with the meanness and irregularity of his capital—the small town of Assumption—he compelled the inhabitants to pull down their houses and rebuild them on a new plan. He prohibited nocturnal church processions as sources of profligacy, expelled the monks, abolished the Inquisition, and diminished the number of festivals."* Having completely "subdued, even to his very quality," the minds of his subjects, Dr Francia has latterly relaxed much in his austerity, and is as much respected as he was formerly feared. Several remarkable instances have occurred of his stern exclusion, or rather of his detention, of intruders. MM. Renger and Longchamp, two Swiss physicians, who fell into his power, were detained six years; and Bonpland, the companion of Humboldt, having incautiously ventured within the magic limits in 1822, was not liberated till 1831. It is not surprising, in these circumstances, that little or nothing should be known of the government or territories of this jealous despot.

The climate of Paraguay is mild and healthy, although moist, being low and level. All sorts of tropical fruits, corn, vines, sugar-cane, rice, maize, tobacco, indigo, and a number of valuable medicinal plants, abound in profusion. There is a particular plant peculiar to Paraguay, called *yerba*, and, when decocted, *mattee*, which greatly resembles the tea of China, and is by many preferred to the latter. It is universally used in South America. Of late years, it has been begun to be cultivated in Brazil with great success. Immense herds of cattle roam over the vast plains, whose hides and tallow form the principal article of their commerce.

BANDA ORIENTAL.

This comparatively small state, which occasioned such a long and bloody contention between the united provinces and the Brazilian government, is situated between the river Uruguay and the Atlantic from south to north, and between the rivers Plata and Parana from east to west. From its position, between the Spanish and Portuguese settlements, it soon became an object of contention; but it would be a waste of time to follow the course of the struggle. Suffice it to say, that after seas of blood and mines of treasure had been expended, in a war of more than half a century's duration, during which the disputed territory, by being the common battle-field, was devastated by both, the contending parties at last drew stakes, and it was erected into an independent state in 1829. Its extent is calculated at about 80,000 souls, almost all of whom are white. The capital, Monte Video, containing 10,000 inhabitants, holds a most important position, being situated at the very mouth of the river La Plata, on its northern bank.

CHILI.

Chili is bounded on the north by La Plata, on the east and south by Patagonia, from which it is separated by the Andes, and on the west by the Pacific Ocean, along the shores of which it stretches from 25° to 44° of south latitude. It is 1300 miles long, and from 30 to 120 broad. The ground slopes gradually up from the ocean to the Andes, but is intersected by their projecting branches, some of which run almost down to the sea-shore. Chili is at present one of the least valuable of all the South American possessions, the greater part of it being barren and uncultivated, owing to the want of streams. The two most northern of the thirteen provinces into which it is divided are almost deserts; but those in the south are equal in beauty and fertility to any other part of South America; and amid splendid woodlands, the finest crops of wheat, barley, rye, and other species of grain, are raised with scarcely any trouble to the cultivator beyond scattering the seed. Cotton, sugar-cane, vines, &c., are also extensively cultivated. The country is perfectly free of all noxious reptiles, the climate salubrious, and the weather serene. The want of navigable rivers is unfavourable to commerce; and although there are many rich mines of gold, silver, and copper, in the northern provinces, the sterility of the country around them prevents most of them from being wrought.

Chili, like the other Spanish possessions, assumed its independence in 1810, when the supreme authority was vested in an elective magistrate, called a "Supreme Director," with a senate of nine members, who held their offices for six years. But in 1827, the directorship was changed for a presidency, in imitation of the United States. The Roman Catholic religion is the established one in Chili. There are said to be nearly 10,000 monks and nuns in the country, and the religious institutions formerly possessed nearly one-third of the landed property of the state. Since the revolution, however, the influence of the monks has been gradually decaying, and their revenues and privileges abridged. Chiloe, an island in the Pacific, off the coast of Chili, was the last place of South America where the Spanish flag was displayed. It was captured in January 1826. It will be recollected that the success of the revolutionists was much indebted to the gallant exertions of Lord Cochrane, who commanded the Chilian squadron from 1818 to 1823. But it would go much beyond our limits to enter into any detail of the arduous and patriotic struggles of the Chilians. Of the warlike tribe of Araucanians, who have maintained the independence of every other nation or tribe so long, whether against force or persuasion, and whose indomitable resolution has led some geographers to divide the state into *Spanish Chili* and *Independent Chili*, we have already spoken at considerable length.

The total population of Chili is estimated at 1,200,000. The principal cities and towns are Santiago, or St Jago, the capital, containing 70,000 inhabitants, and distant about ninety miles from the principal sea-port, Valparaiso, which latter city contains 20,000. Besides these are Conception, or Penco, Coquimbo, Quillota, Peteron Guasco, Copiapo, and many others of inferior note. The revenue in 1824 was 1,636,000 dollars, while the expenditure was above 2,000,000. But this was during the hottest period of the war. The exports from Britain to Chili, in 1829, amounted to L.1,182,000, while the imports were only L.58,000 official value. Chili is entirely destitute of native manufactures.

The *Chilian Archipelago* is separated from the shores of Chili by a narrow and dangerous strait. There are here a cluster of islands about eighty in number, one-fourth of which are inhabited, and contain upwards of 20,000 inhabitants. They are a primitive race, of simple manners. These islands are all small, rocky, and sterile; some of them, however, are covered with unwholesome forests. There is also another cluster of thirty-five islands lying more to the south, and between 44° and 47° of south latitude, called the Archipelago of Chonos. These are still inhabited by savage Indians.

About 300 miles west of Chili, and in south latitude 33° 40', lie the two islands of *Juan Fernandes*. One of these, *Masafuero*, being only twelve miles long and six broad, is the scene immortalised by De Foe, who founded his incomparable tale of Robinson Crusoe on the singular fate of Alexander Selkirk, who, being *marooned*, or left desolate, on this island by his shipmates, was found four years afterwards by Captain Woods Rodgers. It is still uninhabited, although beautiful and inviting in appearance. The other, called *Shore Island*, is possessed by a few Spaniards.

PERU (LOWER).

History, poetry, and romance, have contributed to invest Peru with an interest which attaches to no other part of the southern world. Its inexhaustible mines of gold and jewels—the splendour of its ancient Incas—the stories of its wrongs from its first invaders—all have contributed to render it a land of "mystery and of beauty." But although the imagination may still delight to dwell on "the tales of the days of old," all of the romantic is now departed from Peru. It has been stripped of its richest provinces, and reduced to a very inferior scale in the list of the South American republics.

In our preliminary historical outline, we brought down our notice of Peru to the death of Pizarro. We have no room here to dwell on the succeeding annals, or detail the barbarities of the Spaniards, and the various efforts of the peaceful and unwarlike Peruvians to shake off their yoke. The extent of the ancient empire of Peru has been calculated at 500,000 square miles; at present it does not amount to the one-half. In 1718, the northern province of Quito was dismembered from it, and attached to the vice-royalty of New Grenada; and in 1778, the district of Potosi, and several others of the richest provinces, were annexed to the vice-royalty of Buenos Ayres. It is now called *Lower Peru*, in contradistinction to the latter disjoined provinces, which are termed *Upper Peru*, since formed into an independent state, and named *Bolivia*. Lower or modern Peru is a continuation, to the west, of Chili, bounded by Brazil on the north, and on the south by the Pacific Ocean, and stretching, like Chili, between the latter and the Andes. The western part is a mere desert of sands, 1700 miles long, and from 7 to 50 in breadth, intersected by innumerable streams, many of which, although some of them are 80 miles long, never reach the ocean, but are absorbed in the leafless and lifeless deserts, or drained off to irrigate the cultivated lands—for here rain never falls. This desert tract is also intersected by deep and dark ravines, where, as traditions tell, the descendants of the ancient Peruvians have lived concealed since the days of the Incas. The eastern parts of Peru, or highlands lying near the Andes, have a rich and deep soil, and raise all sorts of tropical crops, fruits, and vegetables in abundance, but, from their inland situation, are almost beyond the reach of commerce—for, like Chili, Peru has no navigable rivers. The greatest advantage possessed by Peru is in its abundance of the precious metals. Gold, silver, platina, tin, copper, lead, quicksilver, are in abundance, together with precious stones, salt, alum, saltpetre, coal, sulphur, &c. The wealth of Peru, in fact, has been entirely owing to its mines, as the general sterility of the soil has prevented much attention to agriculture. The revenue of Peru, in 1826, was set down in an official statement at L.1,400,000; but this is supposed to be exaggerated. The population is estimated at upwards of 1,500,000, of which the Indians outnumber the other castes three times over. Lima, the capital, which was formerly the grand *entrepôt* for the trade of all the west coast of South America, contains a population of between 60,000 and 70,000. All the trade is carried on at Callao, which, although six miles distant, is the port of Lima. The official value of the

* Encyclopædia Britannica—Art. *America*.

different articles of British produce and manufacture exported to Peru in 1829, amounted to L.376,552, besides L.13,076 of foreign and colonial merchandise. The imports from Peru into Britain during the same year was L.69,839.

The government of Peru is now a republic, but before obtaining which, it had to contend as much with friends as enemies. The Peruvians set up the standard of revolt, like the rest of their countrymen, in 1809; but the power of Spain kept all serious movements in check until the year 1821, when the Chilians sent a force under General San Martin, who succeeded in capturing Lima, and was soon afterwards declared protector of the new republic, with supreme power, civil and military. San Martin then drew up a constitution upon the most free principles; but the new views of the people ran into the extreme of democracy, and his plan being disapproved of, San Martin retired. Meanwhile, the Spanish generals, who had retreated to the highlands, again commenced operations, when, in 1823, Bolivar came to the assistance of the Peruvians. He was received at Lima as a sort of demigod, and received the title of *El Libertador*, with supreme military power. We have not room to follow the progress of the war here; suffice it to say, that in the year 1826 the war was ended by the reduction by famine of Callao, into which the Spanish general, Rodil, had thrown himself. Under the head Colombia we have noticed the dissatisfaction occasioned by Bolivar attempting to force upon that province a code constructed according to his own peculiar views of government. In Peru, where he had managed to impose it, it occasioned no less; and the general disaffection, and suspicion of the *libertador's* conduct, among the patriots of Peru, terminated in the revolution of January 1827, in which Bolivar's own troops, which he had left in Peru, cooperated. The Bolivian constitution was abolished, and that of 1823 adopted. In 1826, a new constitution was formed, which was to be in force till 1833. About the same time, Bolivia, then newly erected into an independent state by Bolivar, under his favourite constitution, becoming likewise disgusted with it, requested the aid of the Peruvians to shake off the yoke. A Peruvian army was immediately dispatched; Bolivar's favourite general, Sucre, who had been appointed president for life, was deposed, and Bolivia declared free. Bolivar forthwith published a declaration of war against Peru; but the Peruvians anticipated any hostile measures on his part by marching an army into Colombia, where, however, they were entirely routed by Sucre. The hostilities with Colombia were terminated in 1829, by treaty; and Bolivar and his plans of government having now fallen into disgrace with all parties, the Peruvians were at liberty to choose what constitution they thought proper. What the exact nature of the present one is, it is impossible to tell, from the repeated changes introduced; but it is decidedly republican in principle, having an elective president at the head of it. The Romish is the established religion of Peru; but the power of the priests is kept greatly in check, and all interference with the liberal education of the people prevented. The remembrance of the ancient heathen worship is still preserved by an honorary institution, called the "Order of the Sun." There was formerly only one temple dedicated to the great luminary, being in the city of Cusco, which is the inland capital of Peru. The riches of this temple are said to have been immense. The walls were encrusted with gold, as also the figure of the sun, of great magnitude. On each side were thrones of gold, on which were placed in a sitting posture the bodies of the deceased Incas. In another part of the temple was a large statue of the moon in silver, seated on a silver throne, and the bodies of the deceased queens seated on each side on similar thrones. But it would be endless, and not a little tantalising, to enumerate the boundless riches of this wonderful place, all of which were seized by the Spaniards.

Earthquakes are frequent in Peru. The city of Lima has been three times almost entirely destroyed by these visitations—in 1687, 1746, and 1828; but of these we will speak under a separate head. Besides Lima and Cusco, the next largest town is the maritime port of Arequipa, which has been six times destroyed by eruptions from a neighbouring mountain, and yet possessed a population of 40,000 previous to the revolution. There are also a great many other towns of minor importance.

Slavery was abolished for ever in Peru by San Martin, upon its declaration of independence, after the year 1815.

BOLIVIA, OR UPPER PERU.

This republic, as has already been repeatedly stated, was formerly a province of Peru, was detached from that state and annexed to the vice-royalty of Buenos Ayres in 1778, and finally erected into an independent state, by a declaration of the citizens, in 1825, receiving its modern name in honour of the *libertador*, Bolivar. As we have had occasion to speak so often of this part of the revolutionary struggle, we reckon it unnecessary again to enter upon it. It has been acknowledged by the ablest political writers, that the Bolivian constitution was founded upon the strictest principles of justice and liberty, providing for the liberty of the subject and the enjoyment of civil rights; and if Bolivar had, after promulgating it and seeing it put in operation, retired from public life, his reputation as a patriot and a statesman would have been handed down as one of the brightest in history. But, unhappily, circumstances occurred to throw suspicion on his motives, and, consequently, to bring unpopularity on his measures; and he expired after beholding all the schemes which he had dedicated his life to effect, prove abortive.

Upon the Bolivian code being adopted by a congress of the people's representatives, and sworn to unanimously by the people themselves, General Sucre, who, under Bolivar, had been the great means of achieving their independence against the desperate efforts made by Spain to retain this rich portion of their possessions, was chosen president for life, and for two years the state remained peaceable and contented, and the country increased in prosperity. Upon the movements taking place, however, against Bolivar's proceedings in Colombia and Peru, Bolivia caught the infection, and the people easily found a pretext for murmuring and discontent in the circumstance of Sucre retaining (but which had been originally sanctioned) a body of 5000 Colombian troops in Bolivia. In order to remove this cause of discontent, Sucre determined to send off the whole to Colombia, and requested the Peruvians to allow the soldiers to pass through their territories to the port of Arica, that they might be shipped off. Strange to say, this was refused by the Peruvian general, Gamerra, who thus would not permit the brave men, who had marched over the Andes to achieve the liberty of Peru, to return peaceably to their homes, unless they submitted to be disarmed. While occupied with this affair on the borders of the province, revolt broke out in the capital, Chuquisaca; and when Sucre returned with the view to quell it by persuasion, he was shot through the body and made prisoner. Upon this intelligence, Gamarra, under pretence of advancing to protect him, marched into Bolivia. Sucre was ultimately set at liberty, but it was only to resign formally the presidency, on the 16th August 1828, when General Santa Cruz was elected his successor. Since then, the republic has been in a complete state of turmoil and change. Colonel Blanco, in the absence of Santa Cruz, usurped the supreme authority, but, in a few months, was dispatched by assassination. Gamarra next seized on the president's chair, but has been ejected by Santa Cruz, who, according to the latest intelligence, continues to hold it, but amid great jealousy and suspicion of his ultimate ambitious views.

Bolivia is bounded on the north by Peru and Brazil, on the east by Brazil, on the south by the Buenos Ayrean provinces and Chili, and on the west by the Pacific Ocean and Peru. It comprehends a space of 480,000 square miles, and the population is estimated at 1,200,000, of whom probably two-thirds are Indians. This republic includes five of the provinces which were formerly under the Buenos Ayrean viceroyalty, but has been divided by the new government into six departments, viz. Potosi, Chuquisaca, La Paz, Santa Cruz, Cochabamba, and Oruro. The greater part of Bolivia is situated in a very high elevation, but towards the east it stretches down in extensive plains towards Brazil. The climate, therefore, is extremely various. On the high parts, snowstorms and hurricanes frequently prevail, and the plains, from the rigour of the weather, are destitute of vegetation. The climate of Potosi, at an average elevation of 13,400 feet, is so changeable, that it frequently exhibits in one day all the vicissitudes of the four seasons of the year. Thence descending through the regions of Oruro, at an elevation of 12,400 feet, La Paz at 12,100, Chuquisaca at 9300, Cochabamba at 8400, down to the plains of Majos and Chiquitos, all the known degrees of temperature, from extreme cold to extreme heat, are experienced. To compensate for the rigour of these elevated regions, nature has enriched it with the most valuable mines of gold and silver, which, with other precious metals, form the only articles of Bolivian commerce—(see *Mines*). The mountain of Illumini, in La Paz, which is supposed to contain rich veins of gold ore, is 24,000 feet above the level of the sea, and is only inferior to Sorata, in the same district, which has been determined by survey to be 25,400 feet. These are the giants of the Andes. From the great difficulty of working the mines, and the expense of extracting the ore, the greater part of the gold of Bolivia is obtained from the *lavadcros*, or gold washings in the beds of rivulets, where it is found in the shape of grains. The most productive of these *lavadcros* are those of Tipuani, in the province of Larecaja. Silver, however, is the great staple metallic production of Bolivia; and the famous mountain of Potosi is ranked next in importance to the mines of Guanaxuata in Mexico or New Spain. On account of the inconsiderable nature of the rivers flowing from Bolivia to the Pacific, and the badness of the roads, it is impossible this country can enjoy much commerce with the Pacific; but towards the east, several large streams communicate with the large navigable rivers that flow into the Atlantic Ocean. The river Paro, or Beni, which rises near Cochabamba, and the Guapey, which rises near Cochabamba, after a long sweep, unite with the Mamor., and, flowing to the north-east, mingle with the waters of the Maranon or Amazon. The Piecomayo, again, which rises near Potosi and Chuquisaca, and the Vermejo, which rises in the valley of Tareja, flow to the south-east, and mingle with the Paraguay, which empties itself into the Rio de La Plata. All these rivers are navigable almost to their source, and, with steam navigation, would open up a direct communication between these rich districts and the nations of Europe.

The table land of Titicaca is the most elevated table land in the globe, with the exception of Thibet; but while the latter only presents pastures and flocks of sheep, the latter exhibits towns and populous cities, and is covered with fine crops of wheat, barley, rye, &c. The lake of Titicaca is 12,700 feet above the level of the sea, and is twenty times the size of the lake of Geneva. It contains several islands, the largest of which, named Titicaca, is the place whence Manco Cupac, and his wife Manco Oello Huaco, came forth to found the empire of the Incas, and spread civilisation, industry, and good government through the nations. A magnificent and gorgeous temple of the sun was afterwards erected here, the whole ornaments and wealth of which were thrown into the lake, to prevent their falling into the hands of the Spaniards. During the revolutionary war, alas! it was used as a prison for those whose forefathers had worshipped in it.

PATAGONIA.

Little is known of this vast region, which has not been colonised by any European nation, and the greatest part of which has never been explored. It is the most southerly district of South America, and stretches from the Straits of Magellan to La Plata and Chili; a direct distance of 1100 miles, being bounded on the east by the Atlantic, and on the west by the Pacific Ocean. The country is thinly peopled, and inhabited by two nations of savages—the Moluches, or Warriors, and the Puelches, or Easterns. The former have a decided affinity to the Araucanians in Chili, and doubtless belonged originally to the same nation. The Puelches are the people known to voyagers under the name of Patagonians. Both are a wandering race, living by hunting, fishing, and the other means of subsistence among savage nations. They sometimes make incursions on the settlements of the colonists, to whom they are formidable from their courage and numbers. The accounts of the early voyagers respecting the huge stature of the Patagonians, are doubtless absurd; but it is certain, that, in general, they are above the average size of the human species. "They are a large bodied people," says Falconer the Jesuit, who resided forty years in South America; "but I never heard of that gigantic race which others have mentioned, though I have seen persons of all the tribes of southern Indians."

There is a remarkable circumstance connected with the climate of Patagonia, viz., that, even in its most sterile regions, all the most delicate of the tropical birds are to be found. Captain King observed parrots and humming-birds on the wing during a snow-shower, and saw the latter twittering about, and sipping the sweets of the fuchsia and other flowers, while the thermometer was at the freezing point. This would appear incredible, but for some other observations of the same gentleman on the nature of the climate. While employed in his observatory during the night, the thermometer frequently fell to the freezing point, without his feeling any sensation of chillness. Another peculiarity is the extraordinary warmth of the sea near the surface, compared with the state of the atmosphere; a difference of thirty degrees being frequently found.

To the east of Patagonia, lie the two Falkland Islands, the possession of which at one time, although perfectly worthless and uninhabitable, nearly occasioned a war between England and Spain. They are now held by the former. Still farther south, are the South Shetland Isles, containing not a vestige of vegetation, and covered with eternal snows. To the north-east of these is a large island, Georgia, which may be termed the throne of the southern winter, presenting nothing but rocks of ice and mountains of snow.

BRAZIL.

Brazil is by far the largest and most important state in the new world. The climate is more generally salubrious and agreeable than any other tropical country, and every part of the soil is rich, fertile, and exuberant of vegetation. It is in a manner encircled by Banda Oriental, Paraguay, Bolivia, Peru, Colombia, and Guiana; bounded on the east and north-east by the Atlantic, and possessing the immense range of coast from beyond the Rio Grande South (about half way between Rio Janeiro and La Plata) and the Amazon. The territory within these limits has been estimated at 2,000,000 of square miles. Of the amount of population it is hardly possible to speak, as no returns have been made from some of the provinces; but it is conjectured that it cannot be much under 5,000,000. The territory of Brazil, indeed, is nearly as large as Europe.

Brazil was governed in much the same way as the Spanish colonies, until the year 1800, when King Joam VI. fled from Portugal to escape the clutches of Bonaparte, who had taken a fancy to his dominions. He was warmly received by the Brazilians; nor was their joy misplaced, for he immediately set about freeing the territory from all the marks of colonial dependence. The press was made free, newspapers established, and the ports thrown open to the traders of every nation; and every thing done to promote education and industry. In 1815, also, Brazil was created an independent state, although annexed to the crown of Portugal. In 1817, some democratic insurrections broke out in Pernambuco; and although suppressed, discontent still continued, until in 1821 it was announced that the Portuguese constitution was to be conferred on Brazil. Before this, however, King Joam had sailed for Portugal, promising at his departure increased pay to all his officers and soldiers. But when he was gone, it was found he had carried off every farthing that was in the treasury, having also raised immense sums by means of treasury bills. The public indignation at this discovery, together with the suspicion that he intended again to reduce Brazil to the condition of a vice-royalty, occasioned a general call for his son Don Pedro, who had been left as regent, to assume the head of the government as an independent state. This he readily complied with: in 1822 he was proclaimed emperor; and in 1825, his title and the independence of Brazil were acknowledged by his father. Then followed the war with Buenos Ayres respecting the Banda Oriental, which, at its termination in 1828, left the country destitute of all currency but paper. This excited much discontent. About the same time, the abolition of the Portuguese constitution by Miguel excited the suspicions of the Brazilians that that event was only the prelude to a similar occurrence in Brazil; nor did the language and deportment of Pedro tend at all to allay their fears. In April 1830, the nation had become divided into constitutionalists (Brazilians) and absolutists (Portuguese); but an attempt having failed to induce the troops to declare the emperor absolute, he to all appearance joined the constitutionalists. His measures and conduct, however, continued so equivocal, that, in March 1831, manifestations of popular excitement broke out. The extreme rigour he exercised on this occasion, and his subsequent vacillation, increased and incensed his enemies more and more; and in the April following, disturbances broke out in which many persons were killed. Pedro immediately announced a change of ministry; the public remonstrated against this, but he remained resolute; an insurrection, in which the troops joined, was the consequence; and next morning Pedro abdicated in favour of his infant son, Pedro II., and embarked from Rio Janeiro, on board an English ship of war, carrying with him an immense treasure in diamonds and jewels. The infant emperor was at first much beloved by the Brazilians, but continued civil dissensions seem to render it doubtful if his reign will be a long one. His father's conduct has gone far to shake the public faith in the benefit of a monarchical government.

The comparative importance of Brazil among the South American states, as a commercial nation, as well as the deteriorating influence which civil discord has had upon her commerce, may be pretty accurately guessed by the variations in her trade with Great Britain. In 1829, all Spanish America, including Mexico, with its twenty millions of inhabitants, took goods from this country only to the amount of L.3,286,000, while Brazil alone, with five millions of people, one half of them negroes, imported British goods to the amount of L.6,100,000! This is *official* value, and affords a correct measure of quantity, though not of price. In the year 1831, the official value of the imports of British goods at Brazil was reduced to L.4,300,000, while several of the other states, by becoming settled, have been increasing. Brazil is rich in mineral treasures, especially in gold and diamonds. Gold is found in the beds of almost all the rivers that rise in the interior of Brazil, and almost all the towns were founded by adventurers for gold.

There is no silver found in Brazil, all the dollars in circulation coming from the Spanish mines; but there are several great mines of iron and nitre. Next to the gold, however, diamonds form the staple of Brazilian mineral riches. They were first accidentally discovered about 1730, having previously been supposed peculiar to the eastern countries.

Salt is extremely abundant in Brazil, and is an indispensable requisite not only in the food of man, but of cattle, sheep, poultry, and other animals. Even this article, however, has not escaped the rapacious gripe of the crown, which farms it out. From this cause, salt is so uncommonly dear, that the quantity necessary to salt an ox frequently costs more than the ox itself. The whole commerce of Portugal, indeed, loses from this cause, and is deprived of what it would gain from abundance of salt fish, meat, bacon, butter, and cheese, which would otherwise form articles of trade.

The chief cities in Brazil are Rio Janeiro (the capital), situated on the banks—not of the river, as is generally supposed, for river there is none, but—of the bay of that name. The population is estimated at nearly 200,000 inhabitants. The harbour is one of the finest in the world. The entrance to it is a narrow opening in a ledge of rocks, about half a mile wide, at the mouth of which is an island, upon which a strong fort is erected. After passing through this strait, the mariner finds himself in a magnificent bay 100 miles in compass, and encircled by lofty mountains. Vessels of all dimensions may enter and anchor in perfect security. The city is on the north-east side of the bay; the streets are narrow, and the whole appearance of the city somewhat mean. It is, however, gradually improving, by the erection of public and private buildings. The greatest portion of the mercantile inhabitants are Portuguese. The continual commotions have all along been distinguished by that criminal feature of the Portuguese character, assassination. An English gentleman, who resided there for some time after the abdication and departure of Don Pedro, mentioned that it was usual to find five or six dead bodies every morning in the streets; a circumstance which seemed to excite neither horror nor surprise among the citizens.

Bahia, or St Salvador, the ancient capital, is situated on the east side of the magnificent bay of All-Saints, which extends a whole degree from north to west, branching inland in every direction, and capable of holding all the shipping in the world. It is in fact a little archipelago, studded with islets. The population was formerly about 100,000, but has greatly decreased since the transference of the court to Rio Janeiro. From its centrical situation, the commerce is very extensive. Pernambuco is the next city in size and importance, and is increasing so rapidly, that new houses are built wherever space can be found; while the commerce is increasing in proportion. It is perhaps the handsomest city in Brazil, with broad paved streets, fine houses, an Episcopal palace, handsome churches, convents, hospitals, theatre, &c. The population is about 20,000. Besides these, are Villa Rica, Para, Rio Negro, and about two dozen others of lesser importance.

One peculiar trait of the Brazilian character is the sentiment of equality which pervades all ranks—a feature of disposition hardly to be expected under such a government. The white servant converses with his master on the most equal footing; and instead of promptly obeying his orders, discusses their propriety. This sentiment of equality operates with peculiar advantage to the slaves. The latter are well fed, well clad, and treated mildly. They are allowed two days in the week to themselves besides Sunday; and the general tendency of the laws is in favour of manumission. If the sum of L.5 is offered at the baptismal font, the master is forced to manumit the child.

GUIANA.

This territory is divided into British, Dutch, and French Guiana. It is situated north of Brazil, between Cape North and Essequibo, inclusive. Having, in our late Information on the West Indies, given a complete account of British Guiana, the most important of the three settlements, we feel it unnecessary to recapitulate the details here.

The settlement of Cayenne, or French Guiana, was first formed about 1630, by a colony from Caen, in Normandy, after which it is called. It did not succeed. From that period down to the peace of 1814, it passed alternately into the hands of the Dutch, British, Portuguese, and French, but was then finally restored to France. There are two settlements, one on the mainland, another on the island of the same name, separated from the former by the river Cayenne. The mainland is low and marshy, and the Indians in the surrounding territories are so troublesome, that the settlers attend to little else than the rearing of cattle. It is on the island that all the articles of merchandise are raised, consisting of coffee, sugar, cotton, cocoa, indigo, Cayenne pepper, &c. The island is 18 miles long and 10 broad. At the north point is the town of Cayenne, the capital of the colony, with a fine convenient harbour, and containing about 200 houses. The population of the whole colony does not exceed 17,000, of whom only 1000 are whites; and altogether it is a settlement of very little importance.

Dutch Guiana, until 1814, comprehended Surinam, Berbice, Demerara, and Essequibo; but the three latter being then transferred to Britain, the former is at present the only possession of the Dutch. It is about 210 miles long along the coast, and as much broad. The soil is low, rich, and fertile, and produces sugar, rum, cotton, and coffee, for exportation. In 1831, the imports of Surinam into the United Kingdom amounted only to L.899, while there were no exports in return. In 1815, the population was calculated at 49,000, of whom 2000 were whites, 3000 free coloured persons, 31,000 slaves, and 13,000 free Indians and Maroons. Paramaribo is the capital, situated on the river of that name, with a population of 5000.

GENERAL CHARACTERISTICS—POPULATION, CHARACTER, RELIGION, CUSTOMS, &c.

The question respecting the origin of the native population of both continents of America, seems to have been settled by the discovery of Bhering's Straits, and there is now scarcely a doubt entertained of their descent being Asiatic. We have seen that there are throughout most parts of the interior of South America innumerable hordes of these Indians still living in a savage and primitive state. Of the general features of these people it would be in vain to attempt an enumeration here, being divided into thousands of small tribes, or *nations*, as they call themselves, all distinguished by their own peculiar characteristics. Many of them, such as the Chilians and Peruvians—and of the former, the Araucanians more especially—were certainly marked, from the earliest period of their discovery by Europeans, by many of the finest and noblest traits of human nature while in an unenlightened state—hospitable, faithful, social, peaceful, and affectionate; while those in other parts of the immense continent were conspicuous, as many of them indeed still are, for all the cruel, deceitful, bloody, and barbarous features displayed by the most savage nations.

Whatever may be advanced against, and however condemnatory our own opinions may be of, the ritual of the Romish church, the experience of history would seem to show that it is of all others the best fitted, perhaps, to captivate a people involved in the errors, and addicted to the superstitious observances, of heathenism, from the strong power which it exercises over the imagination. We find, accordingly, it was through the influence of the Jesuits that a compromise or friendly understanding was first effected between the American Indians and their conquerors. This union has continued to grow gradually firmer from the sexual intercourse of their descendants, and by which the physical characteristics of the two races have been amalgamated in the present brown or rather olive-coloured population, who now constitute the great body of the Christianised inhabitants of South America. The events of the last half century, too, have contributed powerfully to annihilate that invidious distinction of *castes*, which in other European colonies has always been the constant source of mutual jealousy, envy, and heart-burning—displaying themselves in discontent and insurrection on the one hand, and oppression on the other. This gradual extinction of the observance of *caste* has naturally generated a more benevolent sympathy towards the unfortunate African negroes than is any where else exhibited; and, accordingly, it was one of the first objects of the patriots who threw off the Spanish yoke, to grant them their freedom. In some provinces—as those, for example, of Columbia—immediate emancipation was declared; in others, more gradually. In some parts, as in the Brazils and Guiana, slavery still exists; but the spirit of all the various governments is favourable to manumission, and universal freedom seems to be a matter neither improbable nor distant. The uniform establishment of the Roman Catholic religion throughout all the states, has also no doubt contributed much to produce a community of feeling and sentiment among all classes of the population, all being alike—negro as well as white—members of the church. The events of the revolution were naturally accompanied with marks of unpopularity towards all the original institutions introduced by the Spaniards, religious as well as civil; but in the matter of religion, the odium seems to have fallen not on the church, but on its professors. This was more especially the case in the commercial cities, where latitude of opinion generally first manifests itself in all nations, in almost all of which as complete an overturn and spoliation took place among the rich and indolent establishments of monks and friars, as during the period of the reformation in Scotland.

Generally speaking, the natives of South America are a much more active and industrious race of men than the creoles of other tropical countries. The Spanish custom of the *siesta*, or noon-sleep, is universally prevalent; but both before and after that period of repose, they are actively engaged either in transacting business, or in giving and receiving visits, attending public exhibitions, promenading, making short journies of pleasure, &c. As amongst the whites in the West Indies, universal hospitality prevails, every man's house being a home to the traveller; and this is the more necessary from the scarcity and bad provisions of the inns. The manners of the inn-keepers and their servants resemble those in the United States, where both sit down at table, and converse familiarly with their customers. The staple dish throughout South America, both at inns and in private houses, is the *olla*, consisting of boiled or stewed beef, covered with *friolas* and other vegetables. In these places of refreshment, too, travellers of all ranks and characters dine at the same board, and take their siesta in the same room, upon mats spread down for the purpose. Travellers of respectability generally endeavour, however, to stop at the houses of proprietors near the way-side, who live in a style of wealthy ease and luxury. Captain Hall gives the following description of the interior of a Chilian country house:—"We dismounted at the door, and were shown into a bleak comfortless room, with a mud floor, a rude unfinished roof, and lighted by a solitary black tallow candle, all of which made us feel instinctively sure of a cold reception. In this, however, we were much mistaken, for the master of the house no sooner saw who we were, than he begged us to walk into his sala or drawing-room, a very different apartment from the first, for, as we entered, we could scarcely stand the glare of light from a dozen wax candles. The floor was covered with a rich carpet, the roof and cornices were neatly finished, and the walls ornamented with mirrors and pictures. At the upper end of the room stood a grand piano-forte, by Broadwood, and, at the tea-table, near it, the lady of the house and her daughters received us most kindly. We soon became acquainted; and while one of the young ladies went out to gather some flowers for us, another opened the piano-forte, at our request, and played very good-naturedly, while we sat chatting with the old people, who entreated us to stay the night."

The Spanish amusement of bull-baiting is pursued with great avidity by the South Americans, although in a different manner from their ancestors of the Old World. Captain Hall describes the bull-baits at Valparaiso as extremely childish exhibitions, where the animals are merely teased by flags and blunt spears until irritated: at Lima, again, the animals are put to death with every circumstance of barbarous cruelty. But perhaps a more demoralising and pernicious amusement of the South Americans, even than these revolting exhibitions, is the besetting vice of gambling, in which all classes in the towns indulge to a fearful extent. In the streets, groups of natives are to be seen playing for their last farthing, and gambling away the whole substance and even clothes of themselves and families with the most complete indifference. The national game is one of cards, called *Monté*. The method of catching the wild cattle that rove in immense herds over the *pampas*, is a practice altogether peculiar to the South Americans, and for the following lively description of it we are again indebted to Captain Hall:—"The instrument used is called a lasso, from the Spanish *lazo*, signifying slip-knot or noose, and the operation of using it is called lassoing. It consists of a rope made of strips of untanned hide, varying in length from fifteen to twenty yards, and is about as thick as the little finger. It has a noose or running-knot at one end, the other extremity being fastened by an eye and button to a ring in a strong hide-belt or surcingle, bound tightly round the horse. The coil is grasped by the horseman's left hand, while the noose, which is held in the right, trails along the ground, except when in use, and then it is whirled round the head with considerable velocity, during which, by a peculiar turn of the wrist, it is made to assume a circular form; so that, when delivered from the hand, the noose preserves itself open till it falls over the object at which it has been aimed. The unerring precision with which the lasso is thrown is perfectly astonishing, and to one who sees it for the first time, has a very magical appearance. Even when standing still, it is by no means an easy thing to throw the lasso; but the difficulty is vastly increased when it comes to be used on horseback and at a gallop, and when, in addition, the rider has to pass over uneven ground, and to leap hedges and ditches in his course; yet such is the dexterity of the guasos, that they are not only sure of catching the animal they are in chase of, but can fix, or, as they term it, place their lasso on any particular part they please."

Captain Hall gives a similar account of the capturing of wild horses with the lasso; but we are assured by a gentleman lately returned from South America, where he was long resident, that a wild horse is rarely—almost never—taken with that instrument, but with what is called, in the language of the Gaucho, "las bolas," or balls—a most formidable weapon in the hands of him who knows how to use it. It consists of three thongs or cords of hide, each more than a yard long. The "boleador," or he who is going to fling the balls, takes one ball in his hand, and swinging the others rapidly round his head, throws "las bolas" with all his might, and unerring certainty, round the hind legs of his victim, which immediately comes to the ground. The horse, before being mounted, is tied several times for hours to a stake, and his spirit subdued by hunger, when he is mounted, and galloped, and gradually broken in. It is nonsense (says our informant) to talk of immediately riding a wild horse. He is not serviceable till he has been about a month in training.

Spanish is of course the language spoken in all the independent states of South America. At Panama, however, Captain Hall was surprised to hear the whole inhabitants, white, brown, and black, talking good English. This arises from the constant commercial intercourse kept up with Jamaica across the isthmus.

GENERAL ASPECT—CLIMATE, &C.

Every thing in South America is upon a grand scale. The mountains, the rivers, the forests, the plains—every feature of nature, in short, is characterised by magnificence and sublimity, and calculated to excite alternately admiration and terror. In one point are seen mountain-summits above the clouds, white with snows that never melt, while their bases rear the banana and pine-apple. In other places are to be seen ever-living volcanos, throwing out flames, smoke, ashes, and stones. Then again are vast and dark forests, which never yet rung to the woodman's axe, where vegetation prevails in its most gigantic forms. "In the interior of the new continent," says Humboldt, "we almost accustomed ourselves to regard men as not being essential to the order of nature. The earth is loaded with plants, and nothing impedes their developement. An immense layer of free mould manifests the uninterrupted action of organic powers. The crocodiles and the boas are masters of the river; the jaguar, the *pecoari*, the *dante*, and the monkeys, traverse the forest without fear and without danger; there they dwell as in an ancient inheritance. This aspect of animated nature, in which man is nothing, has something in it strange and sad. To this we reconcile ourselves with difficulty on the ocean, and amid the sands of Africa; though in these scenes, where nothing recalls to mind our fields, our woods, and our streams, we are less astonished at the vast solitude through which we pass. Here, in a fertile country, adorned with eternal verdure, we seek in vain the traces of the power of man; we seem to be transported into a world different from that which gave us birth."

The Andes derive their name from the Peruvian word *anti*, signifying copper. They stretch, as we have said, throughout the entire length of South America and the Isthmus of Darien, and are indeed supposed by some to belong to the same huge chain which runs through North America, even to the Polar Sea. The southern Andes vary very much in breadth. Near Potosi and lake Titicaca (in Bolivia) the chain is 180 miles broad. The loftiest are near Quito, under the equator, and which, until the Himalaya, in Thibet, was pronounced the highest by some late travellers, were always accounted the loftiest in the globe. The Sierra Nevada de Merida has a height of 14,000 feet; the Silla de Caraccas, 13,890; Chimborazo (in Quito) has generally been reckoned 24,000 feet in height; and there are several others of nearly 20,000. When Humboldt crossed over the Andes, he passed through a deep forest, which took him about twelve days to traverse, during all which time, not the slightest trace of man was to be seen. The pass over the ridge was not more than from one to two feet broad, and resembled a hollow gallery open to the sky. The Quebradas are immense rents, dividing the mass of the Andes, and breaking the continuity of the chain which they traverse. Mountains of great size might be swallowed up in those almost fathomless ravines, at the bottom of which only the terrified traveller can judge of the awful magnificence of the mountains.

A country embracing so many degrees of latitude and elevation, possesses of course equally diversified degrees of climate. "The three zones of temperature which originate in America," says Malte Brun, "and form the enormous difference of level between the various regions, cannot by any means be compared with the zones which result from a difference of latitude. The agreeable, the salutary vicissitudes of the seasons, are wanting in those regions that are here distinguished by the denominations of *frigid, temperate, hot* or *torrid*. In the frigid zone it is not the intensity but the continuance of the cold—the absence of all vivid heat—the constant humidity of a foggy atmosphere—that arrest the growth of the great vegetable productions, and, in man, perpetuate those diseases that arise from checked perspiration. The hot zone of these places does not experience excessive heat; but it is a continuance of the heat, together with exhalations from a marshy soil, and the miasmata of an immense mass of vegetable putrifaction, added to the effects of an extreme humidity, that produces fevers of a more or less destructive nature, and spreads through the whole animal and vegetable world the agitation of an exuberant but deranged vital principle. The temperate zone, by possessing only a moderate and constant warmth, like that of a hothouse, excludes from its limits both the animals and vegetables that delight in the extremes of heat and cold, and produces its own peculiar plants, which can neither grow above its limits, nor descend below them. Its temperature, which does not brace the constitution of its constant inhabitants, acts like spring on the diseases of the hot regions, and like summer on those of the frozen regions. Accordingly, a mere journey from the summit of the Andes to the level of the sea, or *vice versa*, proves an important medical agent, which is sufficient to produce the most astonishing changes in the human body. But living constantly in either one or the other of these zones, must enervate both the mind and the body by its monotonous tranquillity. The summer, the spring, and the winter, are here seated on three distinct thrones, which they never quit, and are constantly surrounded by the attributes of their power. Vegetation presents a greater number of gradations, of which it becomes necessary to point out the principal.

In the region of the palms, next the sea, the natives cultivate the banana, jatrophe, maize, and cocoa. Europeans have introduced the sugar-cane and indigo plant. After passing the level of 3100 feet, all these plants become rare, and only prosper in particular situations. It is thus that the sugar-cane grows even at the height of 7500 feet. Coffee and cotton extend across both of these regions. The cultivation of wheat commences at 3000 feet; but its growth is not completely established lower than 1500 feet above this line. Barley is the most vigorous, from a height of 4800 to 6000 feet. One year with another, it produces 25 or 30 grains for 1. Above 5400 feet the fruit of the banana does not easily ripen; but the plant is still met with, although in a feeble condition, 2400 feet higher. The region comprehended between 4920 and 5160 feet is also the one which principally abounds with the cocoa, or *Erythoxylum Peruvianum*, a few leaves of which, mixed with quicklime, support the Peruvian Indian in his longest journeys through the Cordillera. It is at the elevation of 6000 and 9000 feet that the *Chenopodium quinoa* and the various grains of Europe are principally cultivated—a circumstance which is greatly favoured by the extensive plateaus that exist in the Cordillera of the Andes, the soil of which being smooth, and requiring little labour, resembles the bottom of ancient lakes. At the height of 9600 or 10,200 feet, frost and hail often destroy the crops of wheat. Indian corn is scarcely any longer cultivated above the elevation of 7200 feet; 1000 feet higher and the potato is produced; but it ceases at 12,600 feet. At about 10,200 feet barley no longer grows, and rye only is sown, although even this grain suffers from a want of heat. Above 11,040 feet all culture and gardening cease; and man dwells in the midst of numerous flocks of lamas, sheep, and oxen, which, wandering from each other, are sometimes lost in the region of perpetual snow."

RIVERS.

In no one respect is South America more distinguished than in the number and magnitude of her rivers, some of which might with propriety be described as *running oceans*. Of these the Amazon, or Maranon, claims the first rank. For a space of 21°, in a direct meridional distance, not a single stream descends the eastern side of the Andes, but what contributes to swell the ocean-flood of this river, which, for length of course and volume of water, has no parallel in the world. The main trunk is composed of three principal streams, viz. the Apurimac, the Beni, and the Tunguragua. Having said this, we must refer the reader to the map for a description of its onward course to the ocean, as to give an account of it in words, and of the various huge tributaries which roll their waters into it in its progress, would occupy fully one of our present sheets. It is only very lately that the source and course of this river have been laid down with any thing like accuracy, owing to the mistakes into which previous voyagers fell respecting the actual main stream. The total navigable course of the Maranon is calculated at upwards of 3000 miles in a direct line; and if allowance be made for its sinuosities and windings, it cannot be less than 5000. Ships of 500 tons burden might ascend it for 4500 miles, while many of its tributaries are equally navigable almost to their source. More than one-half, indeed, of this vast continent might enjoy a maritime shore from these numberless streams, any of which would spread commerce and civilisation through a widely-extended empire. The territory watered by the chief stream and its branches is at least equal in extent to continental Europe, and the double of that watered by the Missouri and its tributaries, comprehending 2,500,000 square miles, upon the most moderate calculation. There are no sandbanks, nor shelving rocks, nor ice at any time of the year, to impede navigation; and so strong an easterly wind blows constantly from the Atlantic, as to carry up vessels against the tide. Yet, notwithstanding all these advantages, the mighty Maranon rolls on its course through regions unknown to industry or civilisation. Throughout its whole course it is studded with large and fertile islands, from five, ten, twenty, to a hundred leagues in circumference. From its leaving the Andes to the sea, the vast country washed by its waters contains neither veins of stone, minerals, nor metals of any sort. The streams, however, are stored with an infinite variety of fish of the most delicious kinds.

The La Plata, Plate, or Silver River, is next in magnitude to the Amazon. It is composed of three principal streams, the Parana, the Paraguay, and the Uruguay, and receives all the waters that flow from the eastern declivity of the Chilian Andes, and from the southern, south-western, and western faces of the Brazilian mountains. The three principal streams, with their tributaries, offer facilities for inland navigation little inferior to the Amazon itself. The estuary of the La Plata is broader than the British Channel.

The Orinoco is the third largest river in South America, and far inferior to the two above mentioned. Through a direct course of about 1200 British miles, it drains all the streams that water the Caraccas and New Grenada, with the exception of the coast rivers. It was only about fifty years ago that there was discovered a communication between this river and the Amazon, by means of the Rio Negro. Humboldt, who has since explored those rivers, has accurately laid down the previous courses and junction of the Rio Negro and the Orinoco. When united, they form what is called the Cassiquiare, down which Humboldt and his companion Bonpland passed. There are several cataracts and rapids on the Orinoco, described by Humboldt as splendid in the extreme.

MINES AND MINERALS.

Having under the various heads alluded to the mines and minerals peculiar to each district, we reckon it unnecessary to do more here than to show at one view the quantity of the precious metals which have been extracted from the mines of Spanish America and Brazil. The estimate is by Humboldt, from the registries of the various mints, and making allowance for the contraband traffic:—

Spanish America.	*Dollars.*	*Pounds Sterling.*
Produce of the Mexican mines, to 1803,	2,107,270,511	L.474,135,866 0 0
Produce of the mines of New Grenada, to 1803,	275,000,000	61,875,000 0 0
Produce of the mines of Chili, to 1803,	138,000,000	31,050,000 0 0
Produce of the Peruvian mines, to 1803,	891,350,593	200,555,684 0 0
Produce of the mines of Potosi (Bolivia) to 1803,	1,476,372,174	332,183,739 7 6
Total produce, registered and unregistered, of Spanish America,	4,888,001,200	L.1,099,800,269 7 6
Portuguese America.		
Produce of the Brazilian mines from 1756 to 1803, registered & unregistered,	855,000,000	L.192,375,000 0 0
Total produce of the American mines, to 1803 and 1800,	5,743,001,200	L.1,292,175,269 7 6

So much has the mineral produce of the Mexican mines diminished, consequent on the long-continued and destructive intestine warfare which so long afflicted that unfortunate country, that it does not now exceed 10,000,000 dollars, instead of L.27,000,000, as in 1805. From 1811 to 1826, the collective produce was only 166,297,400 dollars. The coinage of the Mexican mint, for 1827 and 1829, amounted to 5,700,053, and that of the four provincial mints, for these same years, 6,001,747 dollars. Total produce in eighteen years, from 1811 to 1828, 179,999,990 dollars, or 10,000,000 annually. The Chilian mines, which produced annually 2,060,000 dollars, registered and contraband prior to the revolution, and which even in 1817 produced a coinage of 1,101,283 dollars at the mint of St Jago, fell in 1824 to 193,000 dollars, or only one-sixth of the coinage of 1817. The mines of New Grenada, which produced, at an average, 3,000,000 dollars annually, fell to 1,270,000 dollars in 1822; so that the whole mineral produce of the American mines, whether Spanish or Portuguese, is not now one-fourth of what it was at the commencement of the present century, and before the late revolutions in Spanish America.

We have neither space nor inclination for comment on the extraordinary mining projects started in England about the year 1825-6. We may only state shortly, that, by the year 1827, there were no less than seven English companies employed in seeking for harvests of gold in different parts of Mexico, with nearly L.3,000,000 of British capital invested in different ways. Respecting the insane proceedings of some of these companies, it is simple charity to refrain from expatiating; of the whole, only one or two are now in existence; and of these we need only remark, that, when each dollar costs a doubloon, they can hardly be expected to be in a very thriving condition.

Gold is contained generally in a loose marl-like stratum of rounded quartzose pebbles, and adventitious matter called *cascalhao*, which rests upon granite, and is covered by earthy matter of variable thickness. The gold is sometimes found covered by the soil at the depth of twenty feet; while at others, on many of the hills, where water can be procured for washing, particles of gold appear in the soil, at little greater depth than the roots of the grass. After the process of washing (see *Mines*), the particles of gold are brought to the nearest mint, where a fifth part is taken for the crown; the remainder is afterwards formed into an ingot, which being sent to an assay-master, he ascertains its weight and measure, and stamps it, when it is delivered to the owner for circulation. The operation of smelting does not occupy ten minutes; and those who deliver into the mint any quantity of gold dust, will have it returned to them for circulation in less than an hour. The peculiar stamp on the various ingots marks the difference of their value.

Captain Hall gives the following account of the native mode of conducting their mining operations:—"There are two principal persons concerned in almost every mine, the proprietor and the habilitador. The first, who is also the actual miner, lives at his hacienda or farm, generally in the neighbourhood, and attends to the details of working and smelting the ore. The habilitador resides at some one of the three principal seaport towns, Coquimbo, Guasco, or Copiapo; he is the mining capitalist, and his character is that of a diligent, saving man of business, very different in habits from the miner, who is generally an extravagant and improvident person. The word habilitador may be translated enabler, as it is by means of his capital that the miner is enabled to proceed with his work. The proprietor of a mine usually farms his own ground on the banks of one of the rare streams which traverse this desolate country. His hacienda, or farm, supplies vegetables, and sometimes stock, for the subsistence of the miners. The smelting-house is also built on his hacienda, and the ore is brought to his door on mules. These farmers rarely undertake to work a mine with their own unassisted capital; they are seldom, indeed, sufficiently wealthy; and when they are so, it is not found, in the long-run, so advantageous a method as sharing the transaction with an habilitador, who takes charge of the commercial part of the business. Sometimes, however, the owner makes the attempt to work his mine single-handed, in which he usually fails."

We will likewise extract the following account of the process of washing by a mill:—"The mill consists of an upright shaft, or spindle, the lower end of which is fixed to a horizontal water-wheel, working in a sunk water-course, and giving a rotatory motion to the spindle, which passes through the centre of a large circular trough on the ground. In this trough a millstone is carried round upon its edge, on a horizontal axis projecting from the spindle. Small pieces of the ore are thrown into the trough, kept full of water by a constant small stream; and when the machine is put in motion, the stone goes rapidly round, crushing and grinding the ore under the water. As soon as the whole is reduced, by this process of trituration, to a fine mud, quicksilver is added, and an amalgam is soon formed, by its union with the detached particles of gold. This process is said to be quickened by the agitation of the water, and the friction of the millstone. The water is allowed to trickle off by a nick cut in the edge of the trough, and is received in long wooden channels, covered with coarse cloths, the folds and irregular parts of which catch any stray portions of gold, or of the amalgam, which the agitation of the water may have thrown out of the trough. When all the gold is supposed to be combined with the quicksilver, the water is drawn off, and the amalgam being exposed to heat in vessels adapted to the purpose, the quicksilver is distilled off, and the gold remains behind in a pure state."

The process of procuring diamonds may rather be termed washing than mining. They are found in the beds of rivers among the mud, which is placed in a range of troughs into which a stream of water is introduced. At equal distances are placed chairs for the overseers, and, after they are seated, the negroes enter the troughs, each with a rake of peculiar construction. The water being let in, the *cascalhao* or mud is spread abroad, and raked until the water runs quite clear. The stones are then carefully examined. When a negro finds one, he stands up and claps his hands, holding the diamond between his finger and thumb, whereupon an officer receives it from him, and deposits it in a bowl, suspended from the centre of the structure, half-full of water, whence, at the close of the day, the diamonds are taken out and weighed, and their weight registered. When a negro is so fortunate as to find a diamond 17½ carats weight, much ceremony takes place; he is crowned with a wreath of flowers, and carried in procession to the administrator, who gives him his freedom by paying the price to his owner. The finders of inferior stones are proportionally rewarded. These diamond-works are monopolised by the crown. Various precautions are used to prevent the negroes from embezzling the diamonds. To prevent them from setting aside some of them in the trough, and afterwards carrying them off, they are frequently changed into each other's troughs during the process of washing. If suspected of swallowing a diamond, they are put into a strong room, and powerful purgatives administered. The temptation to smuggle diamonds is much greater than that presented by gold, from the monopoly of the crown, and there are regulations of corresponding strictness and severity. For the security of the revenue, the country has been subjected to a most oppressive system of police; and the offender found guilty of illicit trade is subjected to imprisonment for life, or transported to the African colonies. The whole sum produced to government by the diamond monopoly (exclusive of expenses) averages about L.148,150 sterling. The diamonds are purchased by British and Dutch lapidaries, who cut and bring them into a state proper for sale. The diamonds of Brazil are not of so fine a water as those of Golconda. Little black garnets are often found in the diamond district.

Of late years the rage for gold and diamonds has been greatly abating, and the natives, luckily for themselves, have been directing more attention to agriculture. Indeed, it has all along been remarked, that the agricultural part of the population have been better fed, better clad, and more cheerful and contented, than these hunters after mineral wealth. This cause, doubtless, has co-operated with the interruptions arising from civil discord, in the great reduction which, since the beginning of the present century, has taken place in the quantity of gold produced in Brazil, which does not amount to one-twentieth of what it formerly did.

ANIMAL KINGDOM.

The multitude and diversity of its zoological riches is of a piece with the other magnificent characteristics of South America. Except at noon, when all living creatures in the torrid zone seek shade and repose, and when a solemn silence is diffused over the scene, illumined by the dazzling beams of the sun, every hour of the day calls into action another race of animals. The morning is ushered in by the howling of the monkeys, the high and deep notes of the tree-frogs and toads, the monotonous chirp of the grasshoppers and locusts. When the rising sun has dispelled the mists which preceded it, all creatures rejoice in the return of day. The gayest butterflies, rivalling in splendour the colours of the rainbow, especially numerous *Hesperiæ*, flutter from flower to flower, or seek their food on the roads, or collected in separate companies, on the sunny sandbanks of the cool streams. Agile lizards, remarkable for their form, size, and brilliant colours, dark-coloured poisonous or harmless serpents, which exceed in splendour the enamel of the flowers, glide out from between the leaves, the hollows of trees, and holes in the ground, and, creeping up the stems, bask in the sun, and lie in wait for insects or birds. Squirrels, troops of gregarious monkeys, issue inquisitively from the interior of the woods to the plantations, and leap, whistling and chattering, from tree to tree. Birds, of the most singular forms, and of the most superb plumage, flutter singly, or in companies, through the fragrant bushes. The green, blue, or red parrots, assemble on the tops of the trees, or flying towards the plantations and island, fill the air with their screams. The toucan, sitting on the extreme branches, rattles with his large hollow bill, and in loud plaintive notes calls for rain. The busy orioles creep out of their long, pendent, bag-shaped nests, to visit the orange trees, and their sentinels announce with a loud screaming cry, the approach of man. Above all these strange voices, the metallic tones of the *uraponga* sound from the highest trees, resembling the strokes of the hammer on the anvil, which, appearing nearer or more remote according to the position of the songster, fill the wanderer with astonishment. While thus every living creature, by its actions and voice, greets the splendour of the day, the delicate humming-birds, rivalling in beauty and lustre, diamonds, emeralds, and sapphires, hover round the brightest flowers. When the sun goes down, most of the animals retire to rest. Myriads of luminous beetles now begin to fly about like *ignes fatui*, and the blood-sucking bats hover like phantoms in the profound darkness of the night. These bats, or vampires as they are generally called, are enormous animals, measuring sometimes six feet from tip to tip of each wing. The body is small, resembling very nearly the British bat. They generally fix upon horses, and keep the animal in a comfortable sleep by fanning him with their wings during the time they suck his blood. It is reckoned that the pain of the bite must be very trifling, as the victim sleeps on regardless of the puncture; in the morning the animal is found streaming with blood, and weak from its loss. Human beings have repeatedly fallen victims to these revolting animals; and Captain Chamier tells an anecdote of a beautiful young lady of Carthagena, who, having an intrigue, left the casement of her apartment open for the admission of her lover during the night. Before dawn, her duenna, alarmed by some cause or other, entered the room; the rays of the moon fell on the bed, and there, fixed on the bosom of the cold and inanimate form, was a large and savage vampire, the dusky darkness of its wings, as they cooled the air, contrasting strongly with the marble whiteness of the form below, while the blood, which the greedy mouth was unable to contain, ran in a rapid stream along the corpse. She was dead, the vampire-bite having opened an artery.

Among the quadruped beasts of prey, the jaguar, or tiger, is the most formidable, being of enormous size. They generally frequent the impenetrable jungles that skirt the banks of the larger streams; and Humboldt, who explored the Orinoco and many of its tributaries, had many narrow escapes from them. The natives, however, attack them fearlessly, receiving them, when they spring, upon the point of a pike; a manœuvre in which they seldom fail. A small species of lion is also common; but the jaguar is decidedly the king of the forest in South America.

EARTHQUAKES.

These fearful visitations are, beyond all example, frequent in South America; and there is not a town, city, or village, in the immense continent, but has suffered more or less at various times. One of the most destructive in modern times was that which occurred at Caraccas in 1812, when about 20,000 people in the city and surrounding district (10,000 of whom belonged to the city alone) were destroyed. The principal part of the people who were swallowed up by the rending of the earth, or buried beneath the ruins occasioned by the shock, were at prayers when the fearful destruction occurred. Every church, protected either by St Francis or St Nicholas, fell to the ground; the belfry of the cathedral alone withstood the concussion; but, as if sensible of the calamity, and alarmed at the work of desolation which threatened the general extinction of the inhabitants, and aware that some record should remain to inform the historian of the hour and minute when the shock occurred, the clock stopped at seven minutes past four, at the very instant when the first rumbling noise was heard, and still remains with its hands pointed to the hour, as a fearful memorial of the past, and an awful warning of the future. The superstitious reverence paid to this clock grants it an eternal repose; and this and the ruins of the former palace are the only sights that strangers are shown as worthy of observation.

COMMERCE OF SOUTH AMERICA.

It is impossible for us to give any probable estimate of the present state of South American commerce. The capabilities of this vast continent for a trading intercourse with foreign nations are perfectly incalculable as to value and extent. Having, therefore, briefly stated, in our notice of the various provinces, the principal articles of import and export from each, we will here give the published official report of the entire commerce between South America and Great Britain, for the year ending January 1831, and from it a guess must be made at the entire traffic of the former with foreign nations:—

OFFICIAL REPORT of the ENTIRE COMMERCE between SOUTH AMERICA and GREAT BRITAIN, for the year ending January 1831.

	Official value of Imports into the United Kingdom.			Official value of Exports from the United Kingdom. British & Irish produce & manufactures.			Official value of Exports from the United Kingdom. Foreign and Colonial merchandise.			Declared value of British and Irish produce & manufactures exported from the United Kingdom.

CHAMBERS'S INFORMATION FOR THE PEOPLE.

CONDUCTED BY WILLIAM AND ROBERT CHAMBERS, EDITORS OF "CHAMBERS'S JOURNAL" AND "HISTORICAL NEWSPAPER."

No. 38. PRICE 1½d.

DUTIES OF LIFE—SECOND SERIES.

OUR previous article upon this subject embraced the Duties which one owes to himself as a rational Being. The present is not less important in its character, being intended to point out those moral duties which we are required to perform with respect to our various public and domestic relations.* We begin with our

DUTIES AS SUBJECTS.

EVERY civilised nation is governed by some species of authority, for the purpose of preserving order in society. Some governments are good, others are bad; but it does not fall within our province to point out where the ruling authority is injurious, or where it is most advantageous to the people. According to a law of universal application, every independent nation is understood to have the undoubted right to model its government according to its own fancy, genius, or necessities, provided that, in the execution of its plans, it does not wantonly injure its neighbours. Directing our attention to our own country, with which we have here alone to do, we find, as soon as reason dawns upon us in youth, that we are members of a great and enlightened community. We find ourselves subject to laws which were framed long before we were born, and that we must act in a manner not to please our own caprice, but according to the arrangements which have been instituted for the benefit of society at large. But if we thus discover that we are trammelled by certain legal restrictions, not very agreeable perhaps to the wildness of our untamed nature, we likewise find that we possess a great many compensating privileges. While yet opening our eyes to the light, we enter into the enjoyment of all the transcendant privileges of British subjects, and come within the powerful protection of the laws as fully as the oldest and most honoured in the land. It will be perceived that this is a boon of incalculable value. For us, armies have fought and bled; for us, in past times, hosts of martyrs and patriots have contended; for us, the wisest statesmen and legislators have transacted negociations securing civil liberty; for us, the people who have gone before us have established a variety of the most excellent, the most beneficent, institutions. All these things we enjoy without having been put to the smallest trouble. All that we are called on to give in return, as soon as emancipated from the ignorance of childhood, is *obedience to the laws*.

A cheerful obedience to the laws is, therefore, our chief public duty. Possibly some of our laws, from having been framed for a former state of society, or in order to meet particular exigencies, may not now be very judicious in their provisions; yet that forms no solid reason why we should break through them. It is always safer to obey a bad law than to oppose it by violence. Unhappily for some nations, they seem to have no accurate idea of the value of obedience to the laws. When they find themselves aggrieved by oppressive state measures, they are exceedingly apt to break into tumults, and take up arms against the officers of their governments. This is a very short-sighted policy, as the history of all nations proves; for the people are always sure to suffer far more by the coercive measures adopted to restrain them than they would have done by submitting to the evil they originally complained of. It is the boast and glory of Britain—and long may it be so—that its people know how to respect the laws, even while they consider them to be injurious, and how to correct them by quiet and orderly procedure. In this lies the important secret of their national greatness, their wealth, their public liberty. The advantages arising out of a scrupulous obedience to the laws, consist, in the first place, of social order and quietude, by which the rights of property are respected, commerce and trade permitted to flourish, and the sacred inviolability of the person preserved. The results of turbulence and civil commotion are, poverty, ruin to property, insecurity of the person, destruction of commerce and trade, and at length, military oppression and barbarism. Every intelligent man, therefore, in this country, yields not only a bare submission, but a becoming respect to the laws, as well as to the various institutions established by their authority.

Perfect obedience both to the letter and the spirit of the laws, does not, however, imply that we should not examine whether they are in every respect answerable to the present condition of society, nor keep us from resorting to legal means to have them corrected, or altogether rescinded. The constitution points out how this is to be done. It is illegal to conspire secretly to overthrow the law. All measures calculated to improve our social condition must be conducted openly and honourably. The means put into our hands by the constitution for improving the law are very powerful, if wielded with discretion. The people have the appointment of the men who constitute the most influential branch of the legislature; if they do not appoint individuals who will meet their views with regard to correcting or abolishing laws, they have themselves to blame: the constitution confers upon them a liberty of choice. It besides gives them the right to present petitions to the legislature, either individually or in bodies, praying in respectful terms for the amendment or abolition of any law which is deemed oppressive or antiquated. This right gives a vast addition to the power of the people. It is of much greater value than one would at first be inclined to suppose, and is infinitely preferable to the use of violence. The right of petition implies the right of meeting publicly to discuss the propriety of petitioning. This practice of meeting together excites the public mind to renewed efforts in the cause it undertakes. The speeches of the orators are circulated and commented upon by the newspapers all over the country. One meeting gives rise to others, men's minds are enlightened and warmed, and the public opinion acquires a degree of moral force, any resistance to which would be useless. It is not without reason, therefore, that the people of this country set so high a value on the right to assemble for the discussion of public affairs, and place it in the first rank of their constitutional prerogatives.

Besides yielding obedience to the existing laws, we are under a collateral obligation to be loyal to the sovereign who rules over us. Loyalty is hence another of our chief public duties. There is some difference of opinion with regard to what extent loyalty ought to be carried. It appears to us that this is a simple matter. A power to protect the nation from foreign insult, and to preserve the internal peace of the country, *must be lodged somewhere*. It is found to be most convenient to lodge it in the hands of one person, under proper restrictions. In Great Britain, as has been seen in our history of that country, it has been placed in the possession of a hereditary prince or king. This person is entitled our ruler or sovereign; we are termed his subjects. Loyalty signifies a fidelity and willingness in serving the king, so that he may be enabled both to protect the nation from outward harm, and to preserve order in society, through the agency of the laws, or, failing them, through the application of force. Seeing that the sovereign is prevented by the constitution from infringing upon the rights of the subject, through the exercise of his power, it is discovered that loyalty is rewarded in the comfort we enjoy; or, to use another expression, self-interest alone, if no nobler sentiment interfere, would lead us to afford assistance to the king in the execution of his high and important trust. This assistance is demonstrated, not only by personal service, if necessary, but by respect. Loyalty may be greatly enhanced by esteem for the private virtues and conduct of the sovereign. When so influenced, it is certainly both an amiable and commendable feeling, and can never, but in ill-regulated minds, degenerate into servile prostration.

In the United States of America, in which the executive is lodged in an elective president, the people call themselves citizens, not subjects; and what we mean by loyalty to the sovereign, they term duty to the commonwealth. It is obvious that there is extremely little essential difference, *practically*, between these phrases, whatever there may be in *feeling*. The subjects of Great Britain are as free as any people in the civilised world; much freer, indeed, than the inhabitants of France, who disclaim the appellation of *subjects*. These explanations are perhaps useful in admonishing us to beware how we vex ourselves about mere words and sounds. Our duty clearly consists in appreciating the numerous blessings we enjoy in our public and private relations, by whatever name these relations may be called. We are each individually fractional parts of a great nation, whose honour we are called on to sustain through good and bad report. Let us remember that individual virtue can alone promote social happiness, and that social happiness and peace form the basis of political independence. No man can be a good and respectable subject or citizen who is a bad son, a bad husband, a bad father, or a bad master. The nation is but a composition of a great many families, knit together by kindred sentiments and mutual wants; and how can it be great, or worthy of esteem, if its component parts exhibit in their constitution the worst of vices?

Loyalty to the sovereign leads to a subordinate but important duty. It induces us to respect inferior constituted authorities. All judges, magistrates, or other civil functionaries, stand in the light of representatives of the sovereign. The king cannot be every where at once, and he deputes these individuals to attend to the wants of his subjects, and to keep good order in society. To show contempt for any court of justice, or for any magistrate, is, therefore, equivalent to showing contempt for the king himself, as well as for the laws, and is justly punishable. To show our respect both for the laws and the sovereign, we must respect the decisions of judges and magistrates, and support their due execution by our personal influence. Nevertheless, it is in every one's power, when they feel themselves aggrieved by these decisions, to appeal to higher authorities for redress; such being the only means allowable by the constitution, in opposing the legal power of the established courts of civil and criminal jurisprudence.

A becoming obedience to the laws, and a generous respect for the supreme and inferior constituted authorities, produces the agreeable result of good order and peace in society. Every one is not acquainted with the different ramifications of the common and statute law; indeed it would be impossible for us to acquire a correct knowledge of these things unless we devoted a lifetime to the study. This difficulty in acquiring a knowledge of the laws, has sometimes given rise to a low sort of jeering at our excellent constitution, and it has been represented as cruel to compel an obedience to laws which few can have an opportunity of learning. But this is a fallacy into which we hope our young readers will not fall. The administration of the common law, such as that which applies to inheritance, debtor and creditor, and civil rights generally, rests with a body of educated men, or lawyers, whose services may at all times be commanded. Besides, we may, if we please, purchase digests of these laws for our private amusement and instruction. The

* The former article was an entire abstract from the Moral Class-Book of Mr William Sullivan, a work published at Boston, in the United States. The present is partly original, and partly selected from the same production. Excellent as Mr Sullivan's book is, it is singularly deficient in the inculcation of some of the principal public duties of life, and is in many parts adapted only for the perusal of American readers. The heads in the present article, Duties as Subjects, as Electors, as Jurors, as Masters and Servants, Conduct at Public Meetings, Making a Will, Misfortunes and Evils, Inequality of Rank, Duties which the People of one Country owe to those of another, Duty of Trusting to ourselves, Religious Obligations, and Conclusion, are the composition of one of the Editors, as also a number of passages in other places. It is humbly trusted that both numbers will be found to form the most complete as well as the most applicable body of admonition on the moral duties ever given to the public; and that parents and teachers of youth will find it available in their purposes of intellectual cultivation.

other description of law which is made applicable to the preservation of the peace of society, any one can understand, if he have the ability to know right from wrong. We surely all know that it is illegal and criminal to steal, to rob, to murder, to break into our neighbours' houses, or to attack their persons by violence. It can require no reading of acts of Parliament to understand this. Common sense here serves us instead of legal knowledge.* Our duty in this matter is very easily defined. We must ever bear in mind that one of the principal acts of duty which the constitution enforces, is the abstaining from meddling violently with the persons and property of our fellow-subjects. In this well-regulated realm, the person of every man, woman, and child, is inviolable from private attack. It is a crime almost punishable with the highest penalty of the law to strike any one, either from an idea that they have injured us, or through the influence of passion and prejudice. If we consider that we have been injured, we must apply to the law or the magisterial authorities for redress. We are only permitted to use physical force when in absolute danger of losing our lives or property by violence, there being then no time to apply to the law for protection. It would be gratifying if these regulations were more generally attended to than they seem to be. There are many young men, who, from what they are pleased to term a love of fun, but which can be no other sentiment than a love of mischief, or gross ignorance, assail the persons of individuals of both sexes, to their great discomfort, and sometimes serious injury. Now, it is clearly illegal to do so, and is generally punished by the infliction of severe penalties by the civil magistrate, though seldom marked with that ignominy which it deserves. Inasmuch as it is held that ignorance of the law does not excuse its infraction, so is it reckoned an invalid apology for the commission of crime to say that you were under the influence of intoxication at the time. Drunkenness is very properly esteemed an aggravation, not a palliation, of the offence.

CONDUCT AT PUBLIC MEETINGS.

The right of meeting together publicly to discuss matters connected with our social condition, being so invaluable a prerogative, it is right and fitting that all young men entering into the busy scenes of life should make themselves well acquainted with the rules which have been established by general consent for the proper conducting of such assemblages.

According to usage, a public meeting is not constituted until a person be appointed to preside, or to "take the chair." Without this ceremony, the meeting is a tumultuary assembly, or a mob. The first movement is, therefore, the appointment of a chairman. This functionary, on taking his seat, is for the time supreme in the meeting. His chief duty is the preservation of order. He allows only one to speak at a time, giving the preference to him who has first caught his eye in the act of rising, and giving every speaker a fair hearing. Another of his chief duties is the preventing of speakers from wandering from the subject under discussion; and if they do, he must remind them to keep to the point. In the execution of these and other duties, he claims the support of the meeting, and all are bound to yield to his reasonable dictates, and help to maintain his authority. In proportion to the firmness, yet mildness of manner, of the chairman, so is the meeting well or ill conducted.

At some public meetings there is no set plan of operations, and a general discussion on the subjects which are brought forward takes place; but at all meetings for specific important objects, there is a previous arrangement among a certain number of individuals to bring forward particular points to be spoken upon. In this case speakers are prepared, and the business assumes the form of the proposal and carrying of a set of resolutions, or motions. The following is the routine of procedure: The chairman having stated the object for which the meeting has been called, an individual steps forward and proposes a resolution for the adoption of the meeting. Whether he enforces the propriety of carrying such a resolution by a speech on its merits, or simply propounds the matter, he must be *seconded* by another individual (with or without a speech), otherwise the meeting cannot entertain his resolution for a moment. If duly seconded, then the motion is fairly tabled. It is before the meeting. After a resolution is proposed and seconded, it is the duty of the chairman to ask the meeting if it be carried or not; if agreed to by a general acclamation, or by an obvious majority, he pronounces the word "carried," which settles the point, and the business proceeds by the bringing forward of the other resolutions in the same manner. It is unusual for any member of a meeting to oppose the passing of a resolution, unless he have a better to offer in its stead. If he have, and if he wishes "to take the sense of the meeting" on the subject, he has a right to be heard. Yet this can only be permitted, provided the meeting has been called in general terms. For instance, if the inhabitants of a town or district generally be called, in order to *consider* of the propriety of such and such measures, in that case every one is entitled to give his opinion, and to oppose the formal resolutions brought forward. But if the meeting be described by advertisement to consist of those inhabitants or others only who agree in the propriety of such and such measures, then no one is entitled to intrude himself on the deliberations who professes opinions contrary to the spirit and end of the meeting. An inattention to this exceedingly delicate point often creates serious heartburnings and disturbances; and, on that account, committees who call public meetings ought to be very particular in the terms of their announcements.

As much regularity is necessary in respect of opposition to motions as in their proposal and carrying. The counter motion of an opponent is called an amendment, which, to be available, must also be seconded. If not seconded, it drops, but the opposer may place his protest on record; that is to say, if the discussion be in a corporation or other meeting, where books of the minutes or transactions are kept. On being seconded and discussed by those who wish to speak upon the subject, the matter is brought to the vote by the chairman, but not until both the mover and amender have replied, if they please to do so. After they have spoken, not another word can be uttered, and the vote is taken, a majority carrying. If the votes be equal in number, the casting vote of the chairman carries. There is another way of suppressing a resolution, which is by "moving the previous question." This signifies, to return to the point at which the business of the meeting stood previous to the tabling of the motion; or means, in other words, to do nothing on the subject. But this must also be seconded, and put to the vote in opposition either to the motion or amendment, or to both. The routine is generally to place it in opposition to both; if carried, the matter is settled; if not carried, the order is next to place the motion and amendment against each other, and vote.

Such is an outline of the mode of procedure at public meetings, and it is particularly desirable that attention should be shown to the preservation of regularity. At all public meetings there is a strong tendency "to go out of order." By this expression it is meant that speakers are under a constant liability to wander from the point under discussion. They are apt to digress into other subjects, and confuse their auditors; and these getting impatient, are equally apt to interrupt them, so that a single irrelevant observation may lead to hours of idle debate or colloquy, or "speaking to order," as it is termed, and thus the harmony of the assembly be destroyed. Those who attend such meetings should therefore have a regard for the following regulations:—If they speak, they should keep closely to the subject in hand. If they be listeners, they should preserve a strict silence. It is ungentlemanly, not to say disorderly, to utter any sound or make any observation on what a speaker is saying. The speaker must on no account be interrupted, so long as he keeps to order; and if not in order, it is the chairman's duty to check him. It is likewise disorderly to speak more than once, except in replying before the vote is put, or except it be the rule of the assembly to permit it. Sometimes persons who have spoken rise again to speak as to "a matter of form." This is allowable, but in speaking as to form, the merits of the case should not be introduced. On this, however, as on every other point, there is a perpetual tendency to go out of order, and hence the absolute necessity for appointing a chairman well acquainted with the forms of public deliberation, and who has the strength of mind to insist on order being preserved.

At all our public assemblages, a certain degree of courtesy is used both among speakers and listeners. On an individual rising to speak, he addresses himself politely to the chairman, and the chairman in return politely mentions the name of the speaker; by which means the audience is made acquainted with the gentleman who is about to address them. When the discussions of the meeting are over, the chairman closes the business with a few observations, and then dissolves the assembly by leaving the chair.—When any dispute arises in the course of the business of the meeting upon points of form, it is customary to appeal to the usages of the House of Commons for an example to be followed.

DUTIES AS ELECTORS.

There are duties of another nature which we may be called on to perform in our character of citizens. We are invested with the high and solemn trust of electing our representatives in Parliament, as well as representatives in our municipal institutions. In the execution of our duty as electors, we are bound to divest ourselves of all factious or personal considerations. We have certainly to consult our own good in making a choice of a representative, but it is only as flowing from the good of the whole community. We must hence act entirely without passion or prejudice. Let us examine the previous habits of life, public conduct, and avowed sentiments, of candidates, and calmly consider whether they are such as we can approve of, or as being consistent with the general welfare of the people. We should also recollect that we exercise the trust of electors for many who do not possess that privilege. A large proportion of the community consists of women and children, persons in a humble condition, the sick, and the helpless. These look to us for protection from wrong, and it is our duty to afford it to them. If we, therefore, act with levity and imprudence in appointing men, who, from their conduct and character, are unfitted to exercise the important function of public representatives, we in more ways than one commit a crime against society, and are unworthy of possessing the valuable prerogatives with which the constitution has invested us.

In our capacity as citizens, we are frequently called upon to elect representatives in different municipal bodies; such as civic managers of the city in which we reside, managers of local trusts—general, political, and religious. There is often much heat at such elections: a petty factious spirit frequently governs the choice which is made: sometimes the meanest passions of our nature are exhibited during the contest. The observations we have made on our duties as electors generally apply here with peculiar force. As those who present themselves as candidates live amongst us, we can never find any difficulty in estimating their character and qualifications. But we must take care not to be borne away by private feelings; we must not give our vote simply because the candidate is an acquaintance. A consideration for *what is best for the public interest* should in every case govern us; and we should not be afraid to let these our sentiments be known, for they can give no honourable man offence. In all cases of elections of members of civic corporations, and such like bodies, the chief merit in electors, after that of good and respectable character, is soundness of judgment, and after that, activity of habits. The power of fine speaking, or eloquence, is not required in such a functionary, and should be esteemed very lightly. That which is required is a power of thinking coolly, an integrity of purpose, and a willingness and ability in taking a share of the burdensome duties to be performed. Our qualifications as electors, perhaps, render us liable to be ourselves elected. In the event, therefore, of being called forward by our fellow-citizens to fill the honourable situation of their representative, it is our duty to sacrifice perhaps our own feelings and a portion of our time in the public service, provided we conscientiously consider ourselves qualified for the task, and that our health and private circumstances permit it. The principal question we have to put to ourselves, when we are so brought forward, is, "Have we sufficient time to spare to attend the various meetings—to sit and deliberate in the numerous committees—to have our minds frequently occupied with public affairs?" If we deceive ourselves in answering this important question, we wrong society, and give ourselves cause for much after-disquietude. Is it, or not, the proper way for every one who is worthy of this trust, calmly, deliberately, and, to the best of his knowledge and belief, to do those acts which will best preserve for his own use the beautiful fabric of his political institutions? If he perceives and rejoices in the good which he and others derive from it, will he not best perform his duties to those who come after him, to use it, and not abuse it, that they may have the like good? Little suggestions of selfishness, rivalry, and petty local interests, and, most of all, perverted and mischievous ambition, are the blocks over which citizens stumble and fall, in the otherwise luminous and clear path in which they are permitted to move.

DUTIES AS JURORS.

The laws under which we live give us the invaluable privilege of trial by jury; in other words, we are tried for the commission of offences by a body of men chosen indiscriminately, as nearly as convenient, from the class of society in which we have moved. By such a considerate regulation there can be little risk of individual oppression, provided those who compose juries do their duty. It is therefore incumbent on citizens who are liable to serve in juries, to make themselves acquainted with what is understood to be their duty when so called upon. It requires no learning to fulfil the character of a juror. It requires no more than a coolness of thinking, and a mind above being carried away by prejudices or feelings. The juror is to remember that it is the jury which is the judge in the case, not the judges who sit on the bench. Keeping this in view, it is one of the chief qualities requisite in a jury to maintain its proper dignity and honour inviolate, nevertheless with all courtesy, and to act with firmness in the execution of its important function. Besides deliberating dispassionately on the evidence presented, it is the duty of the juror to be totally regardless of every consideration but that of strict justice. He is neither to regard the rank of life of the culprit, nor of the injured party. In a court of jurisprudence all men sink to an equality. It is also the duty of the juror, after forming his conscientious opinion, not to be coerced, or flattered, or spoken into a different opinion. He is invested with a solemn trust, and that trust he must preserve with scrupulous care, as consonant with the dearest interests of society.

DUTIES AS NEIGHBOURS.

Besides the duties which we have to perform as members of a great nation, we have duties of a similar nature to perform as inhabitants of a town, district, or neighbourhood, and in relation to which we sometimes receive the appellation of citizens. Every person belongs to a neighbourhood, which is both local and social. Even those who have removed into new countries, and who dwell in solitary abodes, do not lose the sentiment of neighbourhood. The nearest person to them is a neighbour, though separated by long distance. And when this sentiment

* At the same time, we willingly allow that there is room for great improvement in the dissemination of a knowledge of the statute law, particularly that of a recent date. It is likely that some plan will soon be carried into execution to remedy this defect.

cannot be preserved in fact, it may be in thought, and by that means it usually is so. Perhaps the last impressions that leave the heart of one who has wandered into far distant regions, are those made in his early days, in his native home. In general, as every one lives in a neighbourhood more or less dense, he can promote his own happiness, and that of those around him, by observing a becoming moral conduct. He has a right to enjoy life, and to use all things which he has, to that end; but he has not a right to any enjoyment which necessarily disturbs that of others. Peace, tranquillity, and security within one's own walls, is the main purpose of life. No one has a right to interfere in these things but by order of the public law. A neighbour, therefore, who so conducts himself, and those means of pleasure which he commands, as to vex, harass, and disturb those who are necessarily within sight, hearing, &c., commits an offence against morality. It often happens to be the pleasure of one who dwells in a dense neighbourhood, to keep one or more animals, whose habitual noises disturb those who necessarily dwell within hearing, in the hours allotted to repose, and frequently when persons are visited by sickness, and when any noise is distressing. Now, whatever the rigid law of the land may say in such cases, the law of morality says that the suffering party has an unquestionable right to remove his trouble, if the proprietor of the cause of such nuisance will not, on request, remove it himself. A more peaceable way would be, to have it removed by order of the public magistrate. Many of such petty nuisances ought to be removable on summary verbal application, and not in the slow, written, and printed process, in which the movements of ordinary law are commonly made.

The moral duties of neighbourhood extend to all things which minister to the common comfort, convenience, and security. Each one of a neighbourhood is bound to make his own dwelling-place as agreeable and pleasant to those around him as he reasonably can. Each one is morally held to uphold and sustain a good name for his own little community. He is, therefore, to join, with a liberal and manly feeling, in all the improvements which tend to please and adorn. Such things, even if they occasion some expenditure, are sources of self-satisfaction; and one comes at last to take an honourable pride in hearing his street, his village, his town, or city, commended by observers.

There is another sort of neighbourhood which is founded in social intercourse, and in the interchange of visiting and hospitality. As the world now is, this is commonly regulated by artificial and somewhat unnatural rules. It is often ostentatious, luxurious, and destitute of all feelings and thought in which well-trained moral minds can take pleasure. A profuse and voluptuous entertainment, comprising food little adapted to promote health and vigour, and in quantity sufficient for ten times the number, that rather look at than consume it, is an unsatisfying way of being happy in social intercourse. There are modes of maintaining such intercourse, which are innocent, pleasing, and dutiful. Mankind are fitted for such. The interchange of friendly visits, for conversation, music, and rational amusement, with such things as may be used without suffering or impairing health, is that kind of neighbourhood (in such relations) which is permitted and enjoined. We have, however, little reason to think that intimacies of this sort are likely to meet with such consideration as would induce the further extension of them.

Every person, in general, is a member of some kind of society or association. Some persons belong to many. These are intended for some useful purpose. Every one who is such member has some duties to perform. He owes some proper part of his time, some proper contributions, to the common object, and has an interest in the prosperity of the design. All these institutions do some good, and some of them eminent good, in helping on the great purpose of social life, which is general improvement. Of this nature are public charities, educational institutions, libraries, agricultural societies, and those for suppressing intemperance and immorality. No well-disposed citizen can conscientiously abstain from giving his aid and support to such objects. It is each one's duty to try to leave the world a little better than he found it. No one can say these are matters which do not concern him. Suppose every one should say so, and had said so from the beginning, society would still be made up of barbarians. Every good that is done in any community affects directly or indirectly every member of it. The law of example, of imitation, of doing as others do, has a most pervading and astonishing influence. Every community is like a full vessel of water; no one drop in it can be moved without affecting every other drop.

DUTIES IN OUR DOMESTIC RELATIONS.

Marriage.—This institution is agreeable to a law of nature, and is an ordinance of the Creator. There are profligates who have doubted this; but they have exhibited no reason on their side. It is obvious that man is not only a gregarious, but a pairing animal. Marriage is consistent with the finest of his feelings—the most noble of his faculties. It began when man began. It is ordered to perpetuate the succession of the human family. It is ordered for the whole duration of adult age. It is man's peculiar privilege in this: it connects him with generations which are gone, with that which is passing away, and with those which are to come. The memory and the ashes of the dead are precious to him, and no other animal has that sentiment. He alone contemplates that his own memory will be held in honour, and that the place of his earthly quiet will be sacred. He only is enabled to conceive that moral and physical wrong will bear his own stamp in the character and in the frame of those that follow him; he only knows that a good name may be an honourable inheritance. These are the sentiments which spring from the beneficent gift of marriage. However much one may misunderstand or abuse this gift, nature, ever faithful to her trust, forces these sentiments on the heart.

Marriage is recognised as a contract of a binding nature in all civilised nations. By some it is considered, from its solemnity, to be of a sacred character; by others it is deemed only a civil bond of connexion. All, however, agree in holding it to be an irrevocable contract. The laws of the land, those of nature, and the divine law, disclose the sentiments, the feelings, and the awful sense of duty with which this undertaking should be regarded. Yet it is frequently entered into from motives highly reprehensible, and sometimes with shocking thoughtlessness. It is from such causes that we see that this sacred union, which should be the true source of the highest human happiness, becomes that inexhaustible fountain from which both parties are daily and hourly compelled to drink, and from the same cup, the bitterest waters.

In a great number of instances, marriage is contracted with exceedingly little regard to the qualities of the mind on either side, particularly on the side of the man. If one could penetrate the ear of enamoured youth, some good might come from such suggestions as these:—Do you know what will come of that engagement which you are about to make? Are you about to tie yourself by hands, absolutely indissoluble while you live, to a mortal who has feelings, wishes, wants, hopes, and fears, which must become your's, and a part of your very self; or which you must resist, control, or contend with? Do you know that pain, suffering, and sorrow, originating in either, must be borne by both? Are you aware that whatsoever of error, folly, or crime, may be chargeable to either of you, or to any who may spring from your contract, will be your common burthen and shame; and that from these you can relieve yourself nowhere but in the grave? Or, do you know that this attractive being will be your kind friend; your counsellor; the welcome soother of your cares and anxieties; the generous and charitable judge of your infirmities; the inspirer of honourable ambition; your fellow-labourer in joint interests; the ornament of your life; the gracious, considerate, faithful, gentle companion, who will make your own virtuous home the place to which you refer all earthly happiness? Who that is "in love" has leisure or inclination to think of such *trifles* as these?

There is no reason why the passion of love should be wrapped up in mystery, nor any, why the mind should be stained in considering its nature. It would prevent much and complicated misery in the world, if all young persons understood it truly. There are in every human being seeds, each one of which may be made to germinate, and may be so cultivated as to produce the most odious vices, or the most serene and heavenly virtues. There is in every human heart a fund of kindness, tenderness, and affection, which makes itself known to be there in due time. It demands to be applied. This is the trying and perilous moment in youthful life. There is some one, somewhere, who will take that fund, and give its full equivalent. The external senses and the heart are in search of that one. Happy will it be for the searcher, if he will take reason as a monitor to keep the senses and heart in order. But reason is commonly regarded, not as a kind and faithful friend whose duty it is to whisper, "begin nothing of which you have not well considered the end," but as a withered scowling matron, who, being utterly dead to the impulse of youth, denies that there ought to be any. If there has been no preparation for this eventful period; if the mind has not been enriched with the teachings of rational prudence; if the eye has not been taught to distinguish between the real and the fictitious; if the ear has not learned to discriminate the meaning of sounds; if life as a whole, if the consequences of irrevocable deeds be not thought of, there is peril; and the pure drop from the fountain may flow into any sea but that of happiness. In seeking for that being who is to be a companion during life, one grievous failing must be avoided. Young men frequently amuse themselves by playing with the feelings of young women. They visit them often, they walk with them, they pay them divers attentions, and, after giving them an idea that they are attached to them, they either leave them, or, what is worse, never come to an explanation of their sentiments. This is to act the character of a *dangler*, a character truly infamous. Young men cannot be too cautious in the attentions which they bestow on unmarried females, who on their part should be equally guarded in not encouraging the addresses of any individuals whom they would not choose to marry.

According to the present state of society, one of the influential counteracting elements to marriage is, or ought to be, a high degree of prudence. No one ought to marry who cannot foresee that he will be able to support the additional expenses of a wife and family, and at the same time fulfil his other necessary obligations. By good management, those additional charges are not great, but they amount to something, and he is worse than an infidel who does not provide against them. We are of belief that every industrious, active, and sober man, will find no serious obstacle in this respect. It is from idleness, love of company, and intemperance, not from simple expenditure on family necessaries and comforts, that ruin and poverty in the married life are produced. The dread of encountering the expenses of a family, though acting as a salutary check on imprudent marriages, is frequently productive of many gross vices, tending to the injury both of individuals and of society. Celibacy, especially when circumstances would permit marriage, is not respectable; it is considered akin to vagrancy. He who marries and settles down as a householder, meets with the approbation of the world. Why is this? it may be asked. Because in marrying we give a guarantee to society for our good behaviour. It is not to be doubted that a young, well-educated, industrious couple, who are sincerely and affectionately attached, on a sober examination and conviction of each other's worth and suitability to each other, may be happy with means far short of the fashionable standard. Presuming that such a couple are wise enough to take life for the real and substantial good that it can produce—and as a whole, it would do them great injustice to suppose that they could not find that good in a small, simple, cheerful, tranquil mansion—it would be doing the friends of such a couple the like injustice to suppose that they could not visit them, and be satisfied to see them happy through such means. We may add, that such a state of things conforms to the laws of nature. If such a couple desire a more enlarged state of things, they will *earn* it by frugality and industry. What one has earned is sweet to him; and he who sees something before him which he may strive for and attain to, is impelled by the same laws to honourable exertion.

In whatsoever circumstances, and with whatever motives marriages occur, the parties *are married*; and the question which they have to propose and solve, is, in what way they can secure to themselves the greatest good during their union? In general, the duties of married life are very well understood and observed in this country. We do not assume to teach on this subject. We venture no more than to mention some causes of unhappiness, taking the risk whether they are worth notice or not. They will be arranged under such heads as may arise, without any solicitude as to particular order.

Gentleness.—It is believed that the absence of this excellent virtue is a common cause of unhappiness in families. The members of a family who think civility or politeness due to every one out of it, sometimes think neither of them necessary in their own intercourse with each other. It would be much better for them to reverse this opinion. If family connections are bound together by the strongest ties of common interest; if they are, as they may be, dear to each other; if politeness and civility are good things for any body, they must be good things among such persons.

Gentleness is manifested in many ways—by making no unnecessary and troublesome noises; by kind looks; by being mindful of each other's accommodation and convenience; by avoiding the expression of harsh contradictory opinions; by forbearing to wound self-love even in trifles; by avoiding loud and irritating tones of voice. The tongue is a great mischief-maker in families; and when it makes itself known by a harassing voice, it is a constant disturber of domestic peace. A strong-toned, harsh, disrespectful remark or reply, will produce its fellow from its auditor. Certainly there is nothing which sweetens domestic intercourse more than a kind, gentle, and affectionate tone of voice. Let any one test the worth of this virtue (for it deserves to be called such), by examining who among his friends and acquaintance have it or have it not. Let him inquire into the pleasure or displeasure which he has from their presence, and satisfy himself how much depends on mere tone of voice. This is a sort of index which shows to an habitual observer in what manner a stranger, who is seen for the first time, has been educated. It frequently discloses to what purpose he has been educated; and is, like the eye, a window in the heart.

Trifles.—There are a great many trifles in this life, when considered as a whole. It is a common failing to magnify them into serious matters. It would be, perhaps, descending rather too much to particularise them. They may relate to dress, food, visitings, insignificant purchases, management of children, treatment of, and remarks upon, domestics; and a multitude of little matters on which difference of opinion arises. Now, it is not of the least possible consequence, in the long-run, whether the matter be disposed of in one way or another, if no moral duty be broken. To-morrow, or soon, it will be so thought of. Yet a sudden observation, in an ungentle voice, will produce an irritating reply, and this a severe rejoinder. This ungentleness has a mournful effect on the character of children when exhibited in parents. It deprives brothers and sisters of a happiness which kind nature intended for them. It is wholly useless, and worse than useless, in asserting authority. It can only be classed among those sad mistakes which tend to make this a miserable world. How can any two rational beings, who must live in familiar intercourse while they do live, so misapprehend the purposes of life as habitually to torment each other on insignificant trifles? If any one of the household should be unhappily betrayed into an unbecoming expression, silence best becomes those who hear it.

HUSBAND.

It must be assumed that the parties to a marriage act according to their own will and pleasure in entering into it; and that they expect to promote their own welfare by such measures. They were, or might have been informed, of each other's suitability. Both knew, or might have known, that new circumstances and unexpected events might change or destroy qualities, and bring dormant or newly acquired ones into operation. Both agree, each with the other, to bear and forbear, and to make the best of the matter, however it might prove to be. Each one solemnly promised that the contract should be kept, if it reasonably could be, although the other might fail to perform. Let us suppose, then, that there were no mistakes in the beginning as to the qualities and conduct of the wife; and that she is, in all respects, and under all circumstances, such an one as has been before suggested. Can it be reconciled to the law which commands one to promote his own good, to perform the duties voluntarily assumed, to exercise a power over this dependent female, which not only deprives her of the expected benefits of connubial life, but which makes her a daily and hourly sufferer? How can any one who calls himself a man, and who claims to be considered and treated as such by other men, habitually prove himself not to be a man, but a brute, towards a defenceless, unoffending woman? If one could look into every family, how many voluntary scenes of misery would be disclosed? We assume now that the woman is in no fault, and that she strives continually to accommodate herself to her condition, and to bear in silence, and to do her best to console and soothe, and make of home what it should be. Might not one, in such case, say to the husband, are not you your own cruel enemy? Do you not make to yourself the misery which you complain of, as being incident to this state of being? If you have troubles and vindictive feelings towards any who have wronged or oppressed you abroad, have you any sense of right and justice, or any conformity to the law which commands you to do as you would be done by, in making your innocent wife the victim of your morose and angry feelings? Did you not solemnly promise her, that if she would devote her life to you, that you would support, cherish, and faithfully reward her affection? Do you avail yourself of the secrecy of domestic life, and of the certainty that prudence, and regard for you, and for your offspring, will keep all causes of complaint within your own walls, to play the tyrant towards one whose tongue must be silent, until she charges you as a criminal in a court of justice? Has she done you any wrong? Has she upbraided you that your social hours are spent away from her, and that your earnings are not brought home to be used for the common comfort, but dissipated in follies? When you have come into her presence, from she knows not what company, with an unsteady step, a giddy and throbbing head, and a bewildered brain, has she not sought to hide your and her own shame? Has she reproached you for these breaches of your solemn promises in any way but with tears—tears, not shed for herself, but for you and for your children?

WIFE.

It must depend in this case, as in that of a husband, whether a contract shall be made. As it is the proper course for the other sex to propose, and for this to accept or reject, a female should have opportunity to know the character and temper of a suitor, before she consents to make him master of her welfare for life. If this serious negociation were treated with the sincerity and frankness which it so much better deserves than any other that can be named, the proper knowledge would be had. The true state of the case is this: A man proposes to a woman to surrender herself and her expectations of happiness to him as long as she lives. The decorum enjoined upon her sex has shut her out from the inquiries and knowledge on which, if she have any pretension to prudence and good sense, her answer must depend. It may be very unfortunate for both parties, whether her answer be yes, or no, under such circumstances. It would better conform to reason for the female to reply that she cannot answer, and that it will be wiser for both of them to consider the matter, and to take time to form a candid and just opinion. Any sensible man would feel a respect for such a woman; and if the final answer did not accord with his wishes, still the female has done him no wrong.

Those who are wives and mothers have taken on themselves a very serious responsibility. That kind Providence which never sleeps and never errs, has enabled unperverted woman to feel her connubial and maternal duties; and if she have good sense enough to know how that feeling should be directed and used, she will not err. Her condition is often a trying one; but happily, in general, in this country, though painstaking and busy, it is not an unhappy one, and frequently far otherwise. When it is a trying one, her task is to find out how she can do herself and those connected with her the greatest good. It may depend on many circumstances how she is to effect that object of which she must judge. It is easy to show how she will not effect it. No husband who errs is ever corrected by the sharp and upbraiding tongue of a wife. She may make him hate her, without making him any better. She is the last person in the world from whom he will endure, unretorted, the language of reproach. She bound herself by her original contract to hold and bind him by gentleness, kindness, and forbearance. These are her armour. They are the only one which she can ever use with any hope of victory. This may be proved by a short illustration. A couple had lived long in happy alliance. The husband, misled by evil associates, yet fully sensible of domestic duties, spent his afternoons at a gaming table. It was his custom to return to his family at a certain hour in the evening, and to find his wife at the table awaiting his coming. Divided between the duty which he owed to her, and the habit of gaming, the time of his return grew later and later; he always found her at the tea-table clad in smiles, and welcoming his return. The hour was more and more prolonged into night, till it became midnight; but she was still at the table ready to receive him. No word of complaint escaped her. Subdued at length, he burst into tears, declared his follies, and renounced them. The next day, and always after, he joined his family circle at the accustomed hour. Let us suppose that this wife had addressed to her husband that language which came at last, through her kindness and good sense, from his own heart, what would have been her condition, his own, and that of their children?

There is one in the world who feels for him who is sad a keener pang than he feels for himself; there is one to whom reflected joy is better than that which comes direct; there is one who rejoices in another's honour more than in any which is her own; there is one on whom another's transcendant excellence sheds no beam but that of delight; there is one who hides another's infirmities more faithfully than her own; there is one who loses all sense of *self* in the sentiment of kindness, tenderness, and devotion to another. That one is HER—the WIFE—the tender companion of man.

CHILDREN.

The place which children may hold in society depends essentially on the character and conduct of the mother. In this busy nation, a husband is commonly too much occupied in his own concerns to devote his thoughts and time to any systematic course of discipline. The sum of duty, comprising manners, cleanliness, associates, time out of school, amusements, morals, religious impressions, example, precept, temper, gentleness, depends mainly on the mother. She commonly feels the weight of her responsibility, and is willing faithfully to acquit herself of it. But she deserves every possible encouragement from her husband. The husband, too, often thwarts her purposes by interposing his own contradictory views. If he think he can do any good by his better knowledge, the medium of influence is through the mother. If he can kindly convince her of some better mode, he will best promote the common welfare by that course. The bringing up of children is a fearful responsibility. So great is it, that many parents feel, that, if they were not involved in it, and could have foreknown what it is, they never would have assumed it. But this distrust and dissatisfaction is, in part, from their own errors. Have they ever seriously thought how this duty should be performed? What books have they read? With whom have they conversed? What have they learned as to the best means of promoting the true interests of their offspring? If they have done nothing to inform themselves, how can they be instructors to others? Not only are parents bound to know what is right, but they are bound to know how to use knowledge in a right manner. One rule to-day, and a discordant one to-morrow; harshness and severity at one time, and the most weak and injurious indulgence at another, are poor qualities for instructors. There must be in these matters, as in every thing else, a best way. It may be found somewhere in or extracted from these principles. Children have as good a right to be happy as their seniors. Their happiness consists in having and doing what will make them intellectually capable, morally correct and amiable, and physically pure and strong. These ends will be obtained by a systematic regularity, mildly and kindly, but certainly, enforced. Love, respect, and obedience, are its consequences. A child will soon learn what it can have and do, and what it cannot; and it will soon know that it cannot ask again for what has been, on due consideration, refused. The excellence of society has its root in infancy, and that excellence is confided to the care of mothers.

The duties of parents do not cease till their children are removed from under their charge on arriving at man and womanhood. They have a serious trust in the education of their children. Besides setting them a good example, they must instruct them privately to the best of their abilities, and likewise send them to proper schools. The scholastic education they give them ought to be suitable to their means, and their powers of introducing their children into the world. For a poor man to toil, and deprive his family of comforts, in order to highly educate one son, perhaps, is utter folly. His duty is clearly to give his sons such an education as he can afford, and to the extent which will enable them to fill respectably the station in life in which they are to move. It would be well if fathers of families would endeavour to give their sons a taste for reading. If they do so, and put them in a right bias, they may depend on them acquiring a great deal more useful knowledge after they leave school than they could possibly have learned there. Nearly all the men who have distinguished themselves in the world are found to have acquired their knowledge through private desultory study after leaving their classes, and many, in their autobiographies, trace their good fortune to the taste for reading given them by their parents.

DISAPPOINTMENTS AND SORROWS OF PARENTS.

It is not to be wondered at that parents, who have, as they think, done all that parents should do to make their children worthy, are afflicted, when their labour and exertion do not produce the intended effect. Their reasonable hopes are disappointed, their best feelings are tortured. An idle, ungrateful, dissolute son, is such a complicated cause of suffering, as may, if any thing may, lead one to murmur at the order of things. It may be admitted that such a parent is very likely to break out with complaints against the world. This suffering, however keen and biting it may be, is not a natural, but a moral evil. There is a moral wrong somewhere. Is it in the parent himself? Has he watched the beginning of error, and drawn his child off from the descending plane? But, perhaps, the downward course has been long begun upon, and that art and deceit have made such progress that the child has been able to elude parental inquiry. This can hardly happen with a watchful parent while his child is under his own roof. Perhaps the downward course has been begun upon when a child is at a distant school, college, or in a place of business, preparing for manhood. If a parent has placed a child where he cannot superintend him, or with those who do not undertake to do this, or who will not if they do, the parent is not excused because others are in fault. A child who is sent away from home, is, as the world now is, always sent into some hazard. The hazard is, when least, that the preceptor, guardian, and master, may be deceived. The seductions may be such as to plunge a boy into ruin, even before those who see him daily, and who mean to do their duty, have the least intimation of it. There must be error, then, somewhere. Probably it is in society itself.

In all large cities, towns, and even in villages, there are some persons who live and thrive, in whole or in part, by aiding young persons to ruin themselves, and to make life itself a burthen to parents. These persons are well skilled in the arts of seduction. They cannot go and put their hands into a father's or a master's pocket, and take thence what they covet. But they know how to put other hands there. They know what appetites to awaken, what desires to create, and how to cultivate them, and make them deep-rooted and firm, so that no wind of conscience can blow them over. They know what the fruits will be to them. Those who have been by such means withdrawn from the paths of innocence and virtue, and who have succeeded in stifling the cries of conscience, strive to add to their degraded number. They place temptations before the unsuspecting, and lead them on; and thus one plausible young villain is enough to seduce and to poison a whole generation.

This mournful course of seduction, profligacy, and crime, is called by some persons the natural evils of society. Such persons are poorly instructed. They are as clearly mere moral evils as murder is a crime; but they can only be eradicated by strict municipal regulations, and by the moral surveillance of the well-informed.

BROTHERS AND SISTERS.

These relations make a very great mistake as to the real good of life, in not cultivating a cordial and affectionate friendship with each other. In early life they are apt to be in each other's way, and to have irreconcilable wants; thus they very soon fall into alienations. They cannot, however, shake off the laws of nature. They must have an interest in each other whether they will or not, and it will essentially promote their mutual welfare to have a kind and gracious one. The common causes of their differences are exceedingly insignificant, and often are contemptible. They will see the day when they will so think of them. The time presses hard upon them when they will need counsel, support, and some one to care for them in a manner which none but brothers and sisters can do. When all has gone on well from the cradle upwards, among such relatives, they become to each other not only the most useful friends, but the most agreeable companions. They are the natural confidants when it would be folly to trust any one whose sympathy and solicitude may change. Brothers and sisters who are thus bound together by affection, sometimes hazard the connection by volunteering friendly, but very unwelcome, commentaries and advice. This is a very delicate matter. Giving unasked advice on any occasion requires very great discretion. If one sees that his brother is blundering, there are many modes of so approaching him, as to lead him to find that he needs advice, and of putting him in search of it. If there be a right understanding, he will go where he is sure of having the best and the sincerest. To assume a dictatorial authority over a brother and sister, is to inflict a wound on self-love which cannot be forgiven. We have already noticed the value of civility and politeness between such near connections; and we add, that sincerity and truth are nowhere more profitable and necessary. "Familiarity breeds contempt" is a true saying, and is very apt to find an application of its truth not only in the intercourse of brothers and sisters, but in that among more distant relations. We beg to warn all classes of relations who frequently meet together, against using too much familiarity, against using too little ceremony, against taking liberties with each other. Let them preserve towards one another the most respectful yet friendly terms, if they wish to avoid falling into differences. Let them remember that the quarrels of relations are almost irreconcilable, and that, even when forgiven and in a great measure forgotten, they leave very disagreeable feelings among all parties.

DUTIES OF MASTERS AND SERVANTS.

From the earliest ages down to the present time, there have been different classes of society. As elsewhere explained, this necessarily arises from the very order of society. The well-established and very proper right of inheritance, and the ability which some members of society have to acquire, and which others have not, the difference of education and other obvious causes necessarily produce these distinctions. Who among the various classes is the most contented and happy, is quite another matter. There must be some to serve, and some to be served. They are mutually dependent. We hear great complaints, sometimes from masters with regard to their servants, and sometimes from servants with regard to their masters or employers. This connection is regarded as one of the miseries of life; yet it is not necessarily so. If the connection produce vexation, there must be error somewhere. We shall first speak of the duties of masters, in which we always include those of mistresses.

It is the duty of masters to cultivate the esteem and affection of those whom circumstances have placed under them. Servants have the same sort of bones, muscles, heads, and hearts, the same self-love, and the same sensibilities, as their employers. They may not be so refined, still they have rights to be maintained, and must not be tyrannised over, merely because they are in an inferior condition. They have as good a right to be happy as those above them. If they behave with propriety, and do their duty, they should be spared when sick, advised and relieved when in trouble, and be made as comfortable as circumstances will permit. The commands given to them should be plain, clear, uniform, and not contradictory or capricious. They are not to be sneered at, or commanded with virulence and reproach, but mildly and rather by request. They are also to be treated with uniform civility; but every approach to familiarity with them should be avoided, if respect on both sides is to be preserved. It is always best to let servants know what is their duty, what is expected of them; this being beneficial to both parties. Much mischief is sometimes created by not attending to this rule.

The duties of servants to masters are equally clear. Their entering into servitude is a contract which they engage to fulfil. They are bound to execute all reasonable and proper orders in the line of service in which they are engaged. But besides this, they would consult their interests in being generally obliging and willing to assist in any kind of exigency. A seeming wish to please an employer goes a great way to compensate for deficiencies in ability. A civil obliging turn is indeed one of the chief virtues in a servant, and is certain to secure the affection of masters and mistresses. A strict attention to an employer's interest, regularity of habits, and perfect integrity both in speech and action, form the principal qualifications of a servant. There is usually much less actual dishonesty among servants than a regardlessness of their masters' interests and time. This is more the case with domestic than other servants. This class of persons, who are chiefly females, are very apt to encroach on the time of their employers for their own pleasure and convenience. If sent an errand, they will spend a great deal of more time in executing it than is necessary. It is an idle love of gossiping which generally produces this great failing among servants, and it is our duty here to admonish them of its impropriety. Their time belongs to their master, and it is dishonest to use it for their own purposes, unless by permission. Speaking with regard to persons in service generally, we are sorry to notice that there is a tendency to reduce the terms of contract betwixt employers and employed to one of a purely mercenary nature—so much work for so much money. There appears to be a growing inclination to drop all kindliness of intercourse betwixt the two classes. The consequence is, that many masters feel perfectly indifferent with respect to giving employment to those who have long served them. The injury is, however, mutual; for, when servants know that they are only valued in proportion to the amount of their actual labour, and that they will be paid off without regret, they care little for a master's interest. There can be no question as to who began this improper system. It originated in servants and workmen endeavouring to establish by violence and intimidation a certain amount of wages for their labour, and which the state of society could not warrant. We earnestly trust that it is not yet too late to restore the ancient bond of sympathy betwixt every description of employers and employed. Individual and social benefit would be the result.

DUTY OF TRUSTING TO OURSELVES.

There is a duty of an important nature which we have to perform towards society; and that is, we must *trust to ourselves*. We have each been endowed with reason to guide us, and hands to work; why, then, unless prostrated with bodily disease, or some other infirmity, should we think of leaning upon others for support or assistance? It would not be desirable to see men shut up their hearts against each other, and each stand in the panoply of his own resolutions, determined against every friendly appeal whatsoever. It is possible, however, to be not altogether a churl, and yet to take care lest we be tempted into an exertion of benevolence dangerous to ourselves, while it is of little advantage to our friends. Notwithstanding the many ties which connect a man with society, he nevertheless bears largely imprinted on his forehead the original doom, that he must chiefly be dependent on his own labour for subsistence. It is found by all men of experience, that, in so far as one trusts to his own exertions solely, he will be apt to flourish; and in so far as he leans and depends upon others, he will be the reverse. But there are many who do not recognise this principle. They trust only partially to themselves, and are always poking about after large favours from friends. We find them asking loans of money, asking others to be surety for them, asking acquaintances to interfere to get places for them. If they ask for nothing else, they intrude upon their friends to seek advice. Neither physically nor morally do they seem able to exert themselves for their own behoof. This is so contemptible a mode of living, that it cannot be too severely reprehended. Those who depend on others can never succeed in life. In whatever manner they may be assisted, they can never become front rank men in society. We would earnestly impress upon the young the propriety of depending as little as possible upon prospects of advantages from others, all of whom have enough to do with themselves. It is obviously the duty of every one to think and act for himself, as soon as he attains manhood, and neither be burdensome on relatives, nor troublesome to acquaintances. The acceptance of a trifling favour from an acquaintance always lays us under an obligation, which is sometimes difficult to remove. If the acquaintance ever need similar favours, we feel bound to grant them, and perhaps he estimates the original favour so highly, that he thinks we cannot do enough to serve him. In this way hundreds of men are ruined. We would say, accept no favours, unless upon a principle of common courtesy. If you employ any one to execute a piece of work, take care to pay them faithfully and promptly, and lie under no obligation to them, otherwise you may be called upon when you least expect it, to make payment an hundred fold. Be liberal, affable, and kind; but, knowing that you cannot do more injury to society than by greatly injuring yourself, exercise a just caution in giving way to the solicitations of your friends. Never be too ready to convince yourself that it is right to involve yourself largely, in order to help any person into a particular station in society; rather let him begin at the bottom, and he will be all the better fitted for his place, when he reaches it, by having fought his way up through the lower stages.

MAKING A WILL.

Much distress among families is often produced by individuals who have property to bequeath, not making a will or testament. Why such individuals do not make their wills, it is difficult to explain. Perhaps it arises from carelessness and a spirit of procrastination, or a want of resolution in men to make up their minds with respect to how they would distribute their property at their decease. Some may indeed be so foolish as imagine that the making of their will would hasten the approach of death. From whatever cause it proceeds, it is a highly blameable failing. It is the duty of every person possessing property, whether engaged in business or otherwise, to make a will, and describe in some species of document how he would wish his affairs to be arranged in the event of his dying. There certainly are cases in which men of property would not wish their possessions to be distributed in any other way than as the law would dictate; yet it is a mark of a well-regulated mind to leave a will descriptive of the means to be pursued in the accession to, and management of, their property and concerns. To do so, at least, would often save a great deal of trouble and some expense, and be a preventive of litigation among relations. We therefore must insist that the making of a will is a sacred duty which ought to be performed, and performed without procrastination. In the midst of life we are in death; no one knows but in an hour hence he may be no more. We beseech fathers of families, and others similarly placed—those even who may have property but to the value of a few pounds—to lose no time in executing their will. By leaving so much as a letter subscribed by their name, to be opened after their decease, they may spare much vexation to those whom they hold dear, they may quench much petty jealousy, much unseemly disputation. In a country such as Scotland, where a wife dying without having had any live children, the one half of the moveable property of the husband goes legally to her relations, it is incumbent on wives so circumstanced, if they have any love and esteem for their husbands, to make their wills: that is, put in writing a simple expression of their desire that their husbands may inherit the property which belongs to the wife in virtue of their marriage. By an inattention to this easily performed duty, there are many litigations—many widowers ruined.

MISFORTUNES—EVILS.

Evil is a part of the system of things in which we live, and, as such, must be patiently submitted to. Man was intended to be an active creature. One of the grand aims of the Creator, in his formation, evidently was, that he should never settle down into a sluggish or stagnant state. It would have been easy for the divine power which breathed into him so wonderful a thing as life, to have surrounded him with nothing but blessings, as they are called, so that he would have nothing to do but enjoy himself. But this would not have produced what the Almighty wished, a world in which a rational being was to exercise his faculties, and use his endowments, with a proper regard to a certain end—an account, namely, to be rendered at the close, of what and how he had done. We are here placed between evils which we are to avoid or subdue, and good which we are to aim at and enjoy; and hence, instead of being a set of torpid machines, as we would have been in any thing like a world of perfect happiness, we are in a perpetual state of vigilance and activity, making the fullest use of those mental and bodily properties with which we have been gifted.

If we narrowly inspect the evils or misfortunes with which we are visited, we will find them invariably to be, either of two kinds. Some are the simple result of an occasional or habitual violation of the laws of nature, or an occasional or habitual failure in that vigilance and activity which we are bound to employ for the avoiding of such distresses. These may be called moral evils. The second class are the result of circumstances over which we had no control, and may therefore be called natural evils. Such a division, however, is only necessary in the present state of our attainments as a race; for there can be no doubt that means were intended to be discovered by the ingenuity of man, for the avoidance and neutralisation of all evils whatever; and, therefore, in the case of what we call natural evils, we should only consider ourselves as the victims of imperfect knowledge, and be the more induced to strain after the improvement of ourselves and of our fellow-creatures, so as to obviate these as well as the rest.

Great care should be taken, when an evil befalls us, to ascertain whether it be moral or natural—in other words, whether it be the consequence of our own error, or of circumstances at present beyond our control. Our self-love makes us extremely apt to attribute all our mishaps to the latter cause; but if we are wise, we will not do so. We will rather search back unscrupulously into our own nature, or our own history, for the causes of the evil; and if we find them there, resolve for the future to be more circumspect or more active, so as to make a recurrence of the mischief less likely. The most of the accidents that occur, though they appear at first sight to be natural evils, would be found, on close inspection, to be moral. The most of the diseases that befall us could be traced to a failure in our duty to ourselves, and are therefore moral evils: the rest, such as cancers, wens, organic transformations, &c. which appear natural and unavoidable, are, we have no doubt, moral evils also. If *we knew better*, we might probably avoid them, as easily as we can avoid colds. They may be called natural in the meantime, but not so unless we strive to discover their causes, so as in the long-run to obviate them. They are certainly destined to be obviated at last, as many disorders, now understood, formerly were; and we must at present consider them only in the light of an inducement to the exertion of the spirit of inquiry.

There are some evils which we incur through hereditary channels, and are quite beyond our own control. We are charged, for instance, with the seeds of a harassing ailment, or of an early death, by the long forgone and perhaps long repented vices of our parents. But all this may be accounted for on the same principle. It has been intended that our moral natures should be so much improved, that even the possible distresses of a descendent may operate as a check to our wickedness; and what is a contemporary instance of innocent consumption but a warning to prevent us from doing that which may bring future lives into the same hazard? It is hard, in the meantime, for the sufferer; but what can we say against the course of nature? Perhaps the spectacle (and few can be more painful) of a youth dying in his very bloom, in consequence of natural debility derived from weakly parents, may be the means of preventing two persons from putting themselves into the situation for bringing on similar evils. A very high kind of conscientiousness, but one not unattainable even by ordinary minds, is called into force by the contemplation of such a case of unbought distress. A man who has any reason to fear for the validity of his own constitution, will, if fully impressed with a sense of such results, as likely to arise from his quitting a condition of celibacy, condemn himself to perpetual solitude rather than purchase an improvement of his own happiness, at the expense of unreckonable evil to others. Fortunately, society is beginning to look more narrowly into such matters than it used to do; and we do not despair of seeing a time when it will be nearly as infamous to communicate life under certain circumstances, as, under others, to take it away.

There are other evils which affect society, and which do their full part in making this a world of woe. There is squalid, miserable poverty; there is disgusting, lamentable vice; there is horrible crime, public execution, and national war. All these things, it is said, are inevitable; they spring from the nature of man, and from the laws which compel him to dwell in social connection. Those who say so are shallow thinkers. The world is naturally a beautiful world. But what God has made a Paradise for our dwelling-place, mankind have often rendered a desert by their crimes. Nature and revelation alike proclaim that the Creator intended we should be happy; but how has brutal ignorance, vile intemperance, gross crime, and every species of evil desires, blighted our comforts and degraded our immortal being? It has never yet been proved that there must *necessarily* be poverty, which is the source of many evils. A striking instance of the absence of poverty in a large class of society is found in the case of the Quakers, or community of Friends. With some peculiarities in speech and dress, not worth while to heed, this numerous body of individuals act upon a fixed uniform principle of suppressing the passions. They curb the appetites and headlong impulses of human nature. In this may be said to lie the substance of sound morals. The Quakers, therefore, habitually practise what other classes only theorise upon, at least are seldom performing. The consequence of this guardedness in thought and action is, that although there are many thousands of Quakers in Great Britain, and many thousands in the United States of America, neither in the one country nor the other do we ever find a Quaker begging in the streets, or an intoxicated Quaker, or any one of this class of subjects and citizens at the bar of a criminal court! The Quakers are, like other people, engaged in the common affairs of the world; they are merchants, mechanics, artificers, mariners, and otherwise employed in the ordinary business of life. They are subject to the same temptations and perversions that we are; yet, by the exercise of a singular degree of prudence, they avoid them. Here, then, is a clear demonstration, that even without the aid of civil power, but by the mere force of moral influence, there is a class of men, in the midst of society, who do escape disgraceful poverty, and who are free from vice and crime.

With regard to death, which is so generally looked upon as an evil, and the last and worst of all, it is in reality no such thing, unless it occur prematurely, which it never would do if men were perfect in the observation of the laws of nature. As the conclusion of an existence which never could have been given if others had not died, it must be regarded as only a part of our earthly destiny, and submitted to accordingly.

INEQUALITY OF RANK AND CONDITION.

When the young grow up, they find society to consist of classes of various degrees of rank and condition; some with titles of distinction, others without any title whatever; some rich, some poor, and many in a middle state between great wealth and poverty. The youthful reasoner perhaps thinks that all this is wrong, and that by *natural right* all men ought to be upon a level. It is proper that not only the young, but others who take up notions of this kind, should be told why these differences originate, and why they exist. Mankind, we may suppose, were originally equal in rank and condition; and they might have remained so, or nearly so, had they continued to remain in primeval barbarity, and lived apart from each other. But it was not in their nature to remain in this condition. According to naturalists, man is a gregarious animal; that is, he desires to live in society. As soon as men began to consort together, they began to separate into ranks and conditions. He who was the bravest was made king; he who was the most clever or the most prudent became the most wealthy; he who was the most idle became the most poor. From this kind of beginning all ranks and conditions sprung; and subsequent events have modified society into what we now see it. It may be said that this explanation would do very well if we now found that those who enjoy distinctions in rank were the cleverest of the people; if we found that the richest were always the most deserving of riches. Here, again, we must apply to human nature.

In one sense, titles are contemptible; they are fantastic trappings which a wise man would not covet. But, on the whole, there are few men possessing that degree of wisdom and self-denial which would lead them to despise titles, or the dignities connected with them, *when applied to themselves*. As far as we can discover, the Quakers are the only people who do not regard these things. The citizens of the United States of America affect to despise titles; yet, it is curious, they give a title of distinction to their chief magistrate, whom they style "*His Excellency*;" they also write *Master*, or its contraction *Mr*, before their names. In this we see a degree of the same vanity and weakness which affects the subjects of ancient monarchies. It would appear that there is a yearning after these follies among mankind. Be it so or not, it is an idiosyncrasy which, from time immemorial, has been seized hold of by rulers for the purpose of stimulating men to deeds beneficial to their country. The prospect of being entitled to write *Sir* before their names, or of being called a *Lord*, induces numbers of individuals to do great and good actions, which they would not do for money. As these titles generally descend to their children, they have a double stimulant to action. Genius not being hereditary, these titles may and do fall into the possession of men of no ability; nevertheless, the stimulant to acquire titles such as they have, continues to act beneficially, as it is thought, through the nation; and they themselves feel bound to maintain a certain honourable character consistent with their rank.

The principles of human nature apply in a similar manner in solving the mystery, why there are men enjoying riches which they never wrought for, and may be undeserving of. Riches consist of that part of the surface of the earth which can be used for human habitations and their appendages; of that part which can be used to produce vegetation; of that part over which, and near which, there are flowing waters capable of imparting motion; they consist of all personal estate; and of money, the agreed representative of all property, which is, at the same time, property in itself. Possessions of these various kinds are acquired by inheritance or by industry. Right by inheritance is not wrong. Would any rational mind maintain, that, when the father of a family, or any one who has no family, has acquired property, and dies, that it shall belong of right to any and to all who can get possession, by fraud, force, or whatsoever other means they may? Society could not be held together if such were the rule of right. It is at once apparent, that if such were the rule, there would be nothing to contend for; because all inducement to acquire for the benefit of one's family and connexions would be annihilated. Society would be forthwith reduced to barbarism. The right to acquire, and the right of inheritance, are wisely ordained to be a necessary consequence of society, and one of its strongest motives to act to useful ends.

If it be irreconcilable to justice, to convenience, and to the common good, to take by fraud or violence that which the dead must have left behind them, much more so is it, to take from the living, by like means, that which they can honestly acquire by the exercise of their own industry. If a member of a community were always liable to be despoiled of the fruits of his labour, the great principle of the system of being to which man belongs, would have been misplaced; there would have been no sufficient motive to action. If one would know what society would be, if such were the law and the practice as to property inherited or acquired, he must visit countries steeped in barbarism, and on which the light of Christianity does not shine.

It is contended by some persons that there should be a periodical division of land and property, and that every member of the community shall have an equal share. How often should this division be made? Shall it be made once a-year, once in ten years, once in fifty years? Why should it be made at one time rather than at another? Suppose it could be made, and were made, it must be but a very short time before it ought to be made again, if the reason for making it be, that some have more and some less, and that some are rich and some poor. One must be wilfully blind not to see that either the whole action of society must stop, or that inequality of condition would arise in a single year, perhaps in a single month; and even such inequality as would call for a new division. In a country where the spirit of enterprise and speculation has an unrestrained agency, the causes of regret are, that sad reverses occur, and that property changes hands too often, rather than that it is unreasonably held in the hands of a few of their successors. A small number of generations is sure to bring equality, considering our community as a continuing one. Thus, property comes and goes, in this country, as fast as any one can reasonably desire to have it. The changes which are seen, as to the ownership of it, are regulated by authority far wiser than any of man's institution.

ON FORMING OPINIONS.

Opinion signifies belief. There are good and bad opinions. It is our duty as rational beings to cultivate good or correct opinions upon every subject, and to eschew those which are of a contrary description. There is nothing more easy than to form hasty inaccurate opinions, but it is very difficult to form a correct belief on many topics. Opinion is found to be more or less dependent on times, circumstances, and bodily temperaments. It frequently arises out of prejudice, and is often influenced by impulse. When we form an opinion upon any subject, we are inclined to believe that all opinions of an opposite character have been, and are, erroneous. We are apt to laugh at every body's opinion but our own. All this betrays a deficiency of sober reflection, an ignorance of the history and faculties of mankind, and a want of knowledge of the world. The people of every country possess opinions favourable to their own fashions, customs, laws, and religion, and unfavourable to those of other nations. A love of one's own country is certainly a commendable feeling, but it should be a love arising from examination and conviction, not from prejudice. The Hindoo worships the river Ganges. *We*, by our education, know that this is nonsense. The bigoted but conscientious Turk will go to death upon it, that Mahomet was a true prophet. *We*, by our superior intelligence and reading, know that Mahomet was a vile impostor. The people who lived in our own country a hundred years ago were of belief that certain old women, whom they termed witches, could, by supernatural powers, raise tempests at sea and land, and malevolently interrupt the course of human affairs. The people who possessed this belief were perfectly conscientious in their opinion; yet, *we* know that this opinion was a gross absurdity. *We* know that our ancestors believed in an impossibility. Opinion is therefore, as we see, a thing of time and place. The opinion that is supposed to be right in one century, is wrong in the next. What is considered to be a right opinion in Asia, is thought wrong in Europe. What is deemed a correct and praiseworthy belief in Britain, is reckoned an absurdity in France. Indeed, it is often seen that the opinion which is held good in one district of a country, is looked upon with contempt in other districts—so that the whole world is found to be covered, as it were, with a variety of opinions and shades of opinions, like the diversified colours by which countries are depicted in a map. Opinion, we have said, is also dependent on temperament of the body. This is a melancholy truth. A fat and choleric man does not think in exactly the same way as a lean man. A man who enjoys all the comforts which opulence can purchase, has a tendency to think differently in some things from a man who is suffering under misfortunes or poverty. So strangely constituted is the principle which governs opinion, that most men have reason to alter their opinions on many points in their progress through life. They form an opinion in youth, from which, in manhood, they depart, and form another; and this other they modify into something else as old age comes upon them.

What does all this wonderful contrariety of opinion teach us? Since we see that opinion is dependent on the locality of our birth, on the age in which we live, on the condition in which we may chance to be placed, and on the physical qualities of our bodies, have we therefore no power over opinion? Must we be its slave? These are questions of a solemn character, and we must answer them soberly. The contrariety of opinion existing in times and places teaches us, in the first place, *humility*, which is the foundation of many heavenly virtues. It shows us that the opinions which we may form, particularly on abstract subjects, may possibly neither be the most correct nor the most enduring. Perhaps what we have taken up and cherished as our opinion may after all be a delusion. In learning a lesson of humility and distrust of our own style of thinking, we are impressed with a tender regard for the opinions of others—opinions which, most likely, have been taken up on grounds equally conscientious with our own.

Although opinion is commonly dependent on those contingent circumstances which we have noticed, it cannot be allowed that we have no power over it. We have a power over the formation of opinion to a certain extent, and it is our present object to show how this power can be exerted in order to enable us the better to fulfil the duties of life. The reason why opinion is so illusory in its nature, is, that mankind have ever been excessively careless in the adoption of their opinions. They are in the habit of picking up random ideas, which they mould into an opinion; and after having made up their minds, as they call it, on what *they think* is their opinion, they will listen to no explanation of the opinions of others. Their obstinacy, their self-conceit, their self-interest, their wish to please the party to which they have attached themselves, induce them to hold fast to their original opinion, until time or experience, in all likelihood, wear it down, and its absurdity is secretly pressed upon their notice. But even after its absurdity is disclosed, they are sometimes ashamed to say they have altered it; and so, perhaps, they have one opinion which they keep locked up in their bosom, and another which they bring into daily use, and flourish before company. In the apposite language of Scripture, these men war against the TRUTH.

It is our duty as good members of society, and with a view to self-respect, to be very cautious in the formation, and, most of all, in the display of our opinions. Many excellent men, on arriving at middle life, have deeply regretted that they should have heedlessly published their early and hastily-formed opinions in youth. They had reasoned, as they thought, soundly, but it was without a knowledge of the world, or its history. Speaking to the young, we would say—while yet under the training of parents, guardians, and teachers, it is your duty to receive with confidence the instructions by which it is attempted to enlighten your minds, and to put you in the way of well-doing. But these friends of your youth will probably tell you that when you pass from under their guardianship into the active scenes of life, you become a responsible being, responsible alike to human and divine laws; and that you must now think for yourself. At this critical period of your existence, you have every chance of coming in contact with the idle, the dissipated, the frivolous, who will try to make you embrace erroneous opinions, and who will possibly put the most mischievous books into your hands for perusal. Do not be led away by such machinations; neither be dismayed by the number of wits or profane jesters who may assail you. Do your duty manfully. In order that you may attain a correct opinion on the great debateable subjects that you will hear rung in your ears through life, begin a course of reading those good and authoritative works which intelligent friends will recommend to your notice. Take every opportunity of cultivating your understanding, of enlarging your ideas, of banishing prejudices. Look always at the different sides of a question; for you must remember that there are always many ways of telling a story. In proportion as you advance in your private studies, and acquire a knowledge of the passions and conduct of mankind, you will more and more be able to form a correct opinion. There is one thing which you will learn with surprise from this kind of experience, and that is, that many, though holding different opinions, are driving towards the same end in the main. They have only differed upon trifles, and perhaps fought about mere words. This is one of the strange weaknesses of the human race, into which you will find it difficult to avoid falling. The more that you learn, the more will you see cause to entertain a liberal view of the opinions of others. It is the exercise of this liberality of mind which forms a distinguishing trait in the manners of our country. By the British constitution, every one is allowed perfect freedom of opinion, a gift above all price, which it is our duty not to prostitute or abuse. Let us form our opinions on solid grounds of conviction—let us cherish these opinions to the adornment of our lives—and let us so maintain a due regard for the opinions of others, that we show forth, in our feelings and actions, that most excellent of all virtues—CHARITY.

These observations apply indifferently to various subjects upon which opinions may be formed; and we would, in conclusion, beg to say a few words, in particular, on opinions of a political nature, which are the most difficult of all to be correctly formed. Political opinions are applied to the theory and practice of national government. The policy of national government is not an exact science to be learned, as some would imagine. It is more a fashion than a science. It is a thing dependent on time, place, and other circumstances. The form of government which suits one age or country would not suit another age and country. Some nations are best governed by a despotism, others by a mixture of monarchy and democracy, others by a pure republicanism; but, as we say, what is best at one time is not best at another. The genius and necessities of every people are subject to change, and consequently their governments change with them. If we feel the force of these facts, we will be cautious how we assume an unalterable opinion upon any mode of administering government. The young are particularly liable to take up notions on this subject which they afterwards feel inclined to fall from. We would admonish them to read and digest the history of their country, and reflect well upon the genius of the nation, before they come to a determinate opinion in politics. They will learn, as they advance to maturity, that in nothing is there such a mass of duplicity and affectation as in political matters. They are therefore called upon, by duty, to examine extensively, and probe deeply, the grounds upon which they form their opinion. They will find it much the safest course, as already expressed, to think lightly in the matter till they have had some experience of the world, and been convinced by the evidence of their senses. National exigencies sometimes call upon us to engage more deeply in politics at one time than another. Discretion must here be our guide; yet there is generally greater danger in our wasting much precious time on political disquisition, than in falling into an apathy upon public affairs. He is a wise man who knows how so to guide his steps as to preserve himself from falling into either extreme. Every one who has been for a long series of years politically busy, will acknowledge, that though he thinks he was right in the main (in which opinion he may be right or wrong), yet, that he has spent many busy hours, and anxious thoughts, on subjects, which, looked back upon, are seen to have been profitless and insignificant.

DUTIES WHICH THE PEOPLE OF ONE COUNTRY OWE TO THOSE OF ANOTHER.

It is seen that all the people of the earth belong to some one of the many nations with which it is covered. It is also seen that nations are generally separated from each other, not only by language, manners, customs, religion, and forms of civil government, but also by geographical boundaries. The division of mankind into nations is natural, and possesses obvious advantages. There is a limit beyond which the government of a nation cannot well be administered. By being confined within certain limited bounds, the national institutions may be improved, security and prosperity promoted, and the interests of the people advanced. We frequently find that the people of one nation live at enmity with those of another nation. We find many at open war with their neighbours—that is, they are resorting to brutal physical force to settle a dispute. These are evils deeply to be deplored. Nations have mutual wants which a mutual intercourse and trade will obviate. They have similar interests at stake. Their inhabitants all alike belong to the great human family, and should live at peace with each other. But ambition, and many evil passions—strife, malice, and uncharitableness—are continually in operation to retard their advancement towards a universal philanthropy. National war is the heaviest curse which affects humanity. It leads to enormous debts and taxations, and in reality is the beginning of all kinds of distresses among the people. Yet the people have been frequently very clamorous for war. We say *have been*, for we hope that this sentiment will in future be otherwise regulated. We ought to impress upon our minds a surpassing horror of war. Let us think of it as the scourge of the human race, and as one more destructive, physically and morally, than the most virulent epidemic. Were the inhabitants of countries duly impressed with these feelings—did they reflect upon the blessings which are showered upon nations during a lasting peace, they would henceforth resolve to oppose, by every constitutional means, the commencement of wars by their governments. Besides the actual loss of lives and of property to a nation during war, it is incalculable the injury sustained by society by such an infliction. A war of a few years' duration may retard intellectual improvement for a century. We hold, therefore, that it is the duty of every man to discountenance such a system of folly. He cannot be a lover of his country, he cannot be the friend of moral cultivation, who would countenance such an idiotic process of settling quarrels between intelligent nations. According to a rational view of man's condition in separate nations, war can in no case be reconcilable with social happiness, unless on the obvious principle of self-defence. So long as there remain such masses of ignorance on the earth, so long, we are afraid, force must be employed to preserve the little spots of civilisation from the flood of barbarism which might overrun them. May it be anticipated, however, that this urgent necessity will not exist much longer! How glorious would be the prospect if universal peace were permanently established! We should find one nation instructing another in all the arts and sciences of which it was itself master: we should find an honourable spirit of emulation running through the whole, and all shaping their policy so as to promote the most beneficial intercourse in commerce, literature, and refinements. In the present state of things, as far as it can be accomplished, a kind and friendly international communion is a high moral duty. It is our duty to look with an eye of charity on national peculiarities. We have no right to insult the feelings of the people of any nation, however strange their language, their fashions, or their [illegible] appear to us. We have likewise no right [illegible] with any apparently improper characteristics in their forms of government. It is our duty to consider them as entitled to live and act according to their own fancy, as [illegible] dependent responsible beings. To write, print, and disseminate any scurrilous jests tending to lower them in general estimation, is not only immoral, but inconsistent with the principles of honour, which do not permit any one to be struck who cannot defend himself. When we therefore insult a foreign nation by our obloquy, we commit the mean and cowardly action of injuring a party which has no means of redressing the grievance.

RECREATIONS AND AMUSEMENTS.

We have often had occasion to show that this state of being is one of alternate action and repose. There must be serious action, and there must be amusements. It was intended that mortals should be pleased and happy, if they deserve to be so. Those who maintain that life is to be an uninterrupted scene of labour and gravity, are, we hope and believe, entirely mistaken. We discern nothing in the natural world, nor in man's peculiar constitution nor relations, which gives the least countenance to such an opinion. Amusement, like every thing else in which free agency is concerned, may be innocent and grateful, or improper, pernicious, and introductory of the worst of evils. Young persons must have the former, or they will seek out the latter. It is the duty and the interest of parents to lead children to take pleasure in such things as can be approved of, and to divert children from such as must be injurious to them, and afflictive to those who are deeply interested in them. We apprehend that there may be persons, and classes of persons, who will disagree with us on this subject, as they may have done on some which have been already touched upon. We should deeply regret to displease any one; but on a matter so important as the making good citizens and good moral agents out of children, one should not hesitate to speak frankly and sincerely. If wrong, persons better able to judge will take care that no evil visits them in consequence of such error.

Amusements are physical or mental. It may be more proper to say, that there may be, first, amusements which are intellectual, and, second, such as consist of some bodily motion, in which the mind is more or less interested. If there be such distinctions, athletic sports may be of the second sort. The simple use of the eye, of the ear, and of the imagination, may be of the first sort. It is believed that all amusements must have some contemplated end or result, whether that be defined and certain, or contingent. We believe so, because every thing in this world seems to be moving on to some purpose. One who is acting without knowing for what, is neither labouring, nor amusing himself, but is trying to get rid of himself, and of time. The most captivating sports are those which are contingent; that is, sports or occupations wherein the result may be highly favourable or otherwise. No one engages in them without expecting to come out on the successful side. Hence, hunting, fishing, horse-racing, and gaming, are of this order. The hope of success is a very high excitement, but the mortification and distress of failure ever far exceed the pleasures of success. There is a tendency to discourage out-of-door sports. This is certainly wrong. If not carried to excess, they are among the most salutary and pleasing amusements in fine weather.

Every one admits that the mind and moral faculties are to be developed, and strengthened, and made to do the best, by exercise. This is equally true of physical power. Every action which it can be proper to do at all, ought to be done in the best way, otherwise we do not answer the end of our being. In the vegetable and animal departments, all proper care and cultivation tend to use and beauty. Is there any reason why the physical powers of man should not have care and cultivation to the same ends? Those who prefer a stooping, lounging, awkward, graceless figure and motion, may be on one side of the question; those who think that it was intended that man should be an upright, easy, frank, comely, and convenient being to himself, and pleasant to all within whose observation he may come, will be on the other.

Although the frame of man is so made as to permit him to assume an endless variety of positions, and to apply his strength in all of them, he does, or should, return always to an upright position. No essential deviation from this position can possibly be a natural one, but for a temporary purpose. This is proved by the framing of the human bones. This framing shows, that, when one walks, it was intended that he should be perpendicular; if he walk in an inclined position, he has not only to move himself, but to resist the power of gravitation at the same time. The muscles, in such case, have a strained and unnatural duty to perform. It seems to have been intended, by the same sort of proof, that human beings should walk with the lower limbs, that is, from the hips downward, and not with an unmeaning and ungraceful action of the whole person, as is often seen to be done.

Dancing.

As to the best modes of acquiring strength, ease, and grace, there may be very different opinions. There are many persons who think the discipline of *dancing* a proper mode, and others who think this highly improper. We would not run against any opinions whether they be well or ill founded. But as to dancing, just like every thing else, it may be misused and perverted, or be made to be an innocent, healthy, and commendable accomplishment. There is no mode so much within the reach of the community, in general, as this. Properly taught, it brings out the power of the muscles, and gives them their natural action; all natural motion is graceful. Why should not man conform to this general law of nature? Dancing well is one mode of conforming. Possibly it is considered frivolous and corrupting. Nothing is frivolous in this system of being, which is innocent, pleasing, and adapted to promote healthy action. Persons who are capable of being corrupted by dancing, will certainly find some much more effective mode to become so, if this be denied to them. Dancing among the very young is usually conducted under the eye of discreet seniors, and well-educated adults need no supervision in dancing, but that of good sense and their own self-respect. But suppose dancing could in any case be perverted, so may every thing else be. If we are not to do any thing till it is impossible to err in doing it, what will there be for any one to do?

Music.

It is one of the most convincing proofs of the benevolence of the Deity, that he has so formed the human ear, as to make it capable of finding a rational and elevated pleasure from the action of sound. There might have been organs of speech, and ears to hear, without imparting to the ear the power of knowing and delighting in music. It must have been intended that this gracious gift should be used, and (most probably) as one mode of praise and thanksgiving as well as for innocent pleasure. Music is action; it is action to some end; the end is innocent and delightful. The enjoyment has the double advantage of being solitary and social. Music may be made to produce a sense of high moral feeling, and it may be made to produce a feeling of very opposite character. The same rules must be applied to this subject as to all others, that every thing was created, and for some good and wise purpose; and that every thing must act, and will act, to some useful end, if human ignorance or error do not interfere. We therefore contend that the power to make music is to be cultivated, and its benefits to be thankfully enjoyed.

It is consistent that man, as he is so superior to all other animals, should be alike superior in the making and enjoying of musical sounds. He undoubtedly is so. His voice (it would be more proper to say woman's voice) includes all the sweet sounds which can be made by all other animals. He has, by cultivating this power, by applying the atmosphere through the human lungs, and by delicacy of touch, and by bringing substances in contact with each other, and by sending the wind through that wonderful work of his own hands, the organ, found the means of rendering tribute to the Most High, and of softening and purifying his own heart. No doubt music was given to mortals for their amusement, and that it is their duty to take it in that light, and be thankful for it.

Games.

Games at cards are a very common amusement. They may be innocent, but there is nothing to recommend them. They give no action to the body; they are a very humble occupation for an intelligent mind. Whether the chances in distributing fifty-two pieces of spotted pasteboard fifty successive times in three or four hours, shall possess some of the engaged with fortunate pieces, and others with unfortunate ones, can hardly be said to be doing any thing to any useful end. When the sport is over, the thing proved or arrived at is, that in this use of four hours of a short life, A counted so much, and B so much. This, however, is not the end usually proposed in playing cards. The cards are only the machinery which, with more or less skill, submits, to the laws of chance, the result of emptying one man's pocket and filling another's. A passion for this kind of gaming extinguishes, or converts into a withering curse, every fine feeling of the human heart. Time, health, property, the proper use of the tongue, character, self-respect, and peace of mind, are the sacrifices made at the gaming-table. Unnoticed by the miserable victim, the shackles of habit are put on, which no earthly power can unrivet. When the gambler's last shilling is gone, he starts, as from a dream, into a full sense of the complicated misery and ruin in which he has involved himself. He must then devote himself to infamy, and submit himself to the power of a gravitation, which will bring him inevitably to the bottom of its abyss. The evils of gaming may be judged of by the number of suicidal deaths which it occasions, especially in the great cities of Europe.

All gaming for property leads, in proportion to its character, to such results. The means of gaming, and especially with cards (as they are the easy and most common implements in use), are regarded with the abhorrence which is associated with them by all persons who feel an interest in the young. The young and the middle-aged have no need of cards for amusement. They may have many amusing occupations which are innocent and improving. There may be persons in an advanced time of life, who are beyond the seduction of gaming, to whom the interest of a game of cards may be an innocent and welcome amusement. Undoubtedly, friends who are met for social purposes, and who have nothing better to do with their time, hands, and minds, may play cards in a manner to give no offence to themselves or others. But it is pleasing to know that the state of improvement is such, that in most social meetings there are higher entertainments than that which cards afford, and which are justly in higher esteem.

There might be games, one would think, adapted to amuse children, and to be at the same time innocent and useful ones. Whatever they are, they must be consistent with the principle which requires a beginning, an interesting succession of circumstances, and a result worth attaining. Children must be busy. To require of them to be still, is to require what nature has forbidden. To place a child on a hard bench, and tell him to sit still there two or three hours without any employment for his hands or mind, is as great a violation of natural law as to require of him to stand on his head for the same length of time. There is an obvious want in the means of amusing children; and we apprehend that it arises from disregarding the principles on which the construction of physical and intellectual being rests. If there were an extensive workshop, provided with every variety of tools, with a proper superintendant, to which boys might resort on some proper arrangement, and where they could make articles for themselves, there can be little doubt that it would be diligently frequented. The reason is, that their little efforts would be to some end, and by natural means. On the other hand, the gymnastic machinery is fallen into disrepute. These exercises are uninteresting repetitions to no end, except with those who know that bodily motion must be had to secure health. In such case they endure the labour for the end in view. But the amusements of the young must be of a nature to secure action to an innocent and useful end, and health will take care of itself. Perhaps there may be some persons who can follow out this matter, and invent rational amusements. They would deserve to be regarded as benefactors, and would probably find a substantial reward. We cannot but remark that there is one game, which is one of the most interesting and healthful that can be played—that of tennis, or hand-ball. There are many things to recommend it; and among others, it is one sufficiently interesting to be played for itself, without adding to it the zest of winning or losing any thing but the game. We incline to think that it is the game, of all others, which deserves the patronage of colleges and seminaries, and is well adapted to develope the physical force.

Conversation.

The principal amusement of rational people is the interchange of thoughts by speech, or conversation, which word is made out of the Latin words *con* and *versor*, and means literally *to be turned to* or *with*. The principle of this amusement is found in the law of association of thought. Intelligent persons can always make a conversation. The only difficult step is the first; that ought not to be so considered. Persons who are skilled in the art of talking can always give it a direction. The purposes of conversation are, to put one's self in the way of learning something; to impart something that others want to hear; to form opinions on interesting subjects; to settle the merits or demerits of public action; to recount amusing or extraordinary facts, &c. &c. Every human being knows something which he is willing to tell, and which any other that he is in company with wishes to know; or which, if known to him, would be amusing or useful. To be a skilful conversationist, one's eyes and ears should be busy; nothing should escape his observation. His memory should be a good one, and he should have a good-natured willingness to please, and to be pleased. It follows that all matter of offence in conversation should be avoided. The self-love of others is to be respected. Therefore, no one is tolerated who makes himself the subject of his own commendation, nor who disregards the feelings of those whom he addresses. There is as much demand for politeness and civility in conversation as in any other department of social intercourse. One who rudely interrupts another, does much the same thing as though he should, when walking with another, impertinently thrust himself before his companion, and stop his progress. Under favourable circumstances, and among persons who know how to train a conversation, there are few if any amusements more grateful to the human mind. We need not say any thing of the amusement derived from reading. It is very properly one of the standard amusements of persons of all ages. The influence of the press on the character of a country is not to be measured or calculated. It is strikingly true of this admirable invention, as it is of so many other things in natural and moral agency, that, *well used*, it is an inestimable blessing; ill used, the corrupting demon of social life. Happily, attention to the proper wants of the young has required of the press its action for their benefit; not as to books of study only, but sheets of amusement.

RELIGIOUS OBLIGATIONS.

Religion signifies a system of faith and worship. Religion arises from man's perception of his relation to the system of being of which he is a necessary part. The presence and influence of religion is to be felt and manifested throughout the duration of human life, in all that is thought and done, with a view to a happier and more perfect state of existence after death. Just conceptions of the character and attributes of the Deity, are of the utmost importance, especially to the young, whose minds require to be led aright in all that pertains to the great truths of religion. The religion professed in this country is Christianity—the most cheering, the most noble of all faiths. The books to which we point for instruction in the religion of Christ are those of the Old and New Testament. To them the instructors of the young will direct the religious studies of those under their charge, as may best seem fit. Besides inculcating religious obligations, these works furnish us with the most perfect system of moral duty ever promulgated. The sum of the earliest delivered moral law is comprehended in the Ten Commandments, which are as follow:—1. Thou shalt have no other gods before me.—2. Thou shalt not make unto thee any graven image, or any likeness of any thing that is in heaven above, or that is in the earth beneath, or that is in the water under the earth: Thou shalt not bow down thyself to them, nor serve them: for I the LORD thy God am a jealous God, visiting the iniquity of the fathers upon the children unto the third and fourth generation of them that hate me, and showing mercy unto thousands of them that love me, and keep my commandments.—3. Thou shalt not take the name of the LORD thy God in vain: for the LORD will not hold him guiltless that taketh his name in vain.—4. Remember the Sabbath-day, to keep it holy. Six days shalt thou labour, and do all thy work: But the seventh day is the Sabbath of the LORD thy God: in it thou shalt not do any work, thou, nor thy son, nor thy daughter, thy man-servant, nor thy maid-servant, nor thy cattle, nor thy stranger that is within thy gates: For in six days the LORD made heaven and earth, the sea, and all that in them is, and rested the seventh day: wherefore the LORD blessed the Sabbath-day, and hallowed it.—[By the practice of Christians, the Sabbath has been transferred to the first day of the week.]—5. Honour thy father and thy mother, that thy days may be long upon the land which the LORD thy God giveth thee.—6. Thou shalt not kill.—7. Thou shalt not commit adultery.—8. Thou shalt not steal.—9. Thou shalt not bear false witness against thy neighbour.—10. Thou shalt not covet thy neighbour's house, thou shalt not covet thy neighbour's wife, nor his man-servant, nor his maid-servant, nor his ox, nor his ass, nor any thing that is thy neighbour's.

Such was the sum of the moral law, until Christ added to it a number of the most transcendantly excellent admonitions, and which are found scattered throughout the history of his ministrations in the four gospels in the New Testament. The chief moral which he inculcated was, "Whatsoever ye would that men should do unto you, even so do unto them, for this is the law and the prophets." But the whole of his sayings breathe a similar spirit of benevolence and gentleness. He preached, for the first time that it had been done on earth, the doctrine of "peace and good-will towards men;" that is, universal love and peace among all mankind. "Ye have heard," said he, "that thou shalt love thy neighbour as thyself; but I say unto you, Love thine enemies: bless them that curse you: do good unto them that hate you: pray for them which hurt you and persecute you." Again, he said, "Blessed are the poor in spirit, for theirs is the kingdom of heaven: blessed are they that mourn, for they shall be comforted: blessed are the meek, for they shall inherit the earth: blessed are they which hunger and thirst after righteousness, for they shall be filled: blessed are the merciful, for they shall obtain mercy: blessed are the pure in heart, for they shall see God: blessed are the peacemakers, for they shall be called the children of God: blessed are they which suffer persecution for righteousness' sake, for theirs is the kingdom of heaven: blessed are ye when men revile you, and persecute you, and say all manner of evil against you for my sake falsely." In this manner he taught the great necessity for being humble and lowly in spirit as the basis of all virtue and social happiness. He likewise inculcated, at different times, the necessity of putting away every thing like ostentation in doing good actions. He tells us not to give our alms before men, but to bestow them in secret; not to pray ostentatiously in public, but in a private place. No one, until he appeared, ever pointed out that there was no difference betwixt actual transgression and the wish to transgress. He tells us that sins of the heart are equally punishable with the commission of an offence. He likewise taught that men "cannot serve two masters," that is, do evil actions, however apparently trivial, and at the same time be good men. To break "the least of the commandments" is to be reckoned equivalent to breaking the whole; and it is further said, it is impossible that our oblations to God can be accepted of so long as we live at enmity with a brother, that is, having a quarrel with any one—"Leave thine offering before the altar, and go thy way; first be reconciled to thy brother, and then come and offer thy gift. Agree with thine adversary quickly whilst you are in the way with him." Who among us, may we ask, keeps this saying in remembrance? Do all who attend the public worship of God, hold it in mind?

Again, he says that we are equally to avoid hypocrisy, or a pretence of self-righteousness and ability to show our neighbours their faults, before we have put away the same or other faults from ourselves. "Hypocrite, first cast out the beam out of thine own eye, and then thou shalt see clearly to cast out the mote out of thy brother's eye. Judge not, that ye be not judged." How valuable are these reproofs! Continuing to admonish us of the danger of hypocrisy, he says that we shall know men by their fruits, that is, we shall know them by their actions, not their words. "A good tree cannot bring forth evil fruit, neither can a corrupt tree bring forth good fruit: therefore by their fruits ye shall know them. Not every one that sayeth unto me, Lord, Lord, shall enter into the kingdom of heaven, but he that doeth my father's will that is in heaven." We are likewise told that there must be no stop to the extent of our forgiving of injuries. Being asked if we should forgive an injury for seven times, he said to those about him, "I say not unto thee, until seven times, but until seventy times seven;" by which we are to understand that there is to be no limit to our forgiveness. Three things, we are told by St Paul, are essential—Faith, Hope, and Charity, but that the greatest of these is Charity, or a disposition to think well of our neighbours whatever may be their actions. It is also variously inculcated that charity is the first of the Christian virtues. Personifying it, it is said, "Charity suffereth long and is kind; charity envieth not; charity vaunteth not itself, is not puffed up, doth not behave itself unseemly, seeketh not her own, is not easily provoked, thinketh no evil, rejoiceth not in iniquity, but rejoiceth in the truth; beareth all things, believeth all things, endureth all things."

Such are some of the invaluable moral admonitions conveyed to us for our temporal guidance by the Christian dispensation. It would be needless to quote farther from a book which we earnestly hope is in every one's possession. The summary we have presented will point out that the Old and New Testament form the basis upon which all our morality is founded, and are the only correct guides under the solemn obligations of religion.

CONCLUSION.

We have now given an elucidation of what we consider to be the principal duties we are called on to perform during life, both to ourselves and to others. The subject is by no means exhausted, yet enough has been said to afford human beings a view of what line they ought to follow in the pursuit of individual and social happiness. The object we held in view has been accomplished. We have, to the best of our ability, put young and old, high and low, rich and poor, *in the way* of executing their temporal duties. We hope we have shown that if man be not a happy, a grateful, a satisfied being, he must accuse himself, and not complain that the system of being to which he belongs is wrong and malevolent. We have attempted to prove that man, individually and socially, is capable of improvement; that he has removed himself from his original condition, and has advanced far in disclosing his own powers, and in applying them in the promotion of his own happiness. But it has to be added, that he has still much farther to go in the same course, that the way is known to him, and that there are no obstacles in it which he may not remove. We do not believe in the perfectibility of mankind. The crimes and follies, which affect even the most cultivated of our race, tell us too plainly that there is a natural bias towards evil, which it requires the utmost skill on the part of religion and reason to counteract. The passions ever seem to stand as a barrier against human perfection, and it is only by their due regulation that we can gain so much as comparative worldly happiness. Yet it is incalculable to what extent the exaltation of the mental faculties may be carried by systems of education, and to what extent the community may be purified of its vices. Let us hope that nothing may occur to interrupt the physical, the intellectual, and moral improvement of society, which is now so happily in the way of advancement.

No. 39. PRICE 1½d.

HYDROSTATICS AND HYDRAULICS.

THE term Hydrostatics is compounded of two Greek words which signify the *stopping or balancing of water*, and hence designates the science which treats of the pressure of water. The term Hydraulics is also formed from two words of the same language, which signify *water* and a *pipe*, in reference to the movement of water in certain musical instruments used by the Greeks, and accordingly denotes that branch of science which treats of the *motion of water*.

Although water has given a name to these branches of mechanical philosophy, and although the phenomena which it exhibits, and the laws which it is said to obey, are those in general spoken of, yet these phenomena and laws are alike referable to all bodies which exist in a similar state—that is, in one of liquidity. It is difficult to define in a few words what a liquid is, notwithstanding that the term when employed is perfectly understood even by a child, and a correct idea of the substance meant conveyed to the mind of every one. The distinction between a liquid and a fluid is, that the term liquid implies only one class of fluids. There is another class distinguished by the name of aëriform fluids, such as the atmosphere; to these the name of liquid is never correctly applied, but is only referable to bodies such as water.

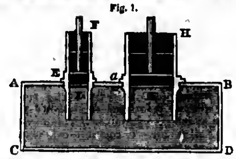
A liquid may be called a body in which the attraction of cohesion is so far overcome as to admit of its yielding to the slightest pressure, and the particles composing its mass easily changing their relative position with reference to each other, without separating from the mass, or repulsing one another as those of aëriform substances do. This explanation does not apply to a mass of matter which is pulverised into fine grains, such as sand; for in this case the cohesion between each grain and the rest, even those which lie contiguous to it, is entirely destroyed, whilst amongst the particles composing every individual grain it still exists in full force. But in a watery fluid, the cohesion of all the particles composing the mass is overcome in exactly the same degree, to a greater extent than exists between the atoms of each grain of sand, and to a less extent than is seen to exist between grain and grain of the same material. In other words, the mass of any liquid possesses a certain quantity of cohesion which is distributed equally amongst all the particles composing the mass. Hence, it may be assumed, that in such bodies the particles are all placed at exactly equal distances from one another. This, however, is the case with all aëriform bodies, and also with many solids. But the former do not answer the condition which it has been observed is characteristic of a liquid, that the particles which compose it should not repulse one another; and the latter are deficient in another characteristic, namely, that the particles which compose a liquid should move easily amongst themselves.

Between the solid and the aëriform state there are a great number of conditions in which a body may exist, corresponding to the extent to which the attraction of cohesion has been overcome, and repulsion established amongst the particles. Honey and spirit of wine or alcohol, for instance, exhibit very different degrees of liquidity. Scientifically speaking, however, there is but one state—namely, that in which a body is perfectly liquid, as water is; hence it has been fixed upon as a type of all other bodies of the same kind, and has given a name to the divisions of science, Hydrostatics and Hydraulics.

PRINCIPLE OF EQUAL PRESSURE.

In treatises which are strictly mathematical, there is one property which is considered as the leading characteristic of liquidity, indeed as forming the basis of all reasoning upon the science. This remarkable quality of fluids is their power to transmit pressure equally in every direction. Each particle of the mass presses equally on all the particles that surround it, and is equally pressed upon by these. It equally presses upon the solid bodies which it touches, and in return is pressed upon by them to a similar extent. This singular property may be illustrated in the following manner:—Let A B C D, fig. 1, be a vessel

Fig. 1.



having an aperture E, in which a tube or cylinder E F is inserted, and another aperture *a*, in which the tube or cylinder *a* H is inserted, and let I and K be severally a piston which works in these cylinders. Let us now suppose this cylinder to be filled with water up to the mouths E *a*, and the level A B. The pistons are conceived to be pressed down to a level with the surface of the water. Now, if upon the piston I we place a pound weight (for the present the piston K is supposed to be immoveable), then to every part of the surface of the vessel, equal in magnitude to the base of the piston I, the same degree of pressure will be transmitted. Thus, supposing the base of the piston to be a square inch, and the number of square inches in the vessel to be 20,000, then there is urged upon the inner surface of the vessel a pressure tending to burst it, equal to 19,999 square inches. This is very easily proved in the following manner:—If the base of the piston K be equal to ten square inches, and if, after having loaded the other piston, which is only one square inch, with one pound, and placed upon the large one any weight less than *ten* pounds, it will rise in the cylinder quite in accordance with the principle above explained. For, since the large piston is *ten* times the size of the small one, it must necessarily take *ten* times the weight with which the latter presses upon the water to balance it and maintain an equilibrium. Accordingly, if ten pounds be placed upon it, it will be found to do so. It is to be observed in this case that the piston I does not resist the whole of the ten pounds which are laid upon the piston K; nine of them press upon the bottom of the vessel, and the remaining one alone is resisted by I. It is evident, that, in ordinary cases, the friction of both pistons will prevent the experiment from being performed with perfect nicety and exactness. But this inconvenience has been obviated by employing a liquid lighter than water, such as oil, as an equivalent for the piston and weight. Suppose that a pound of oil were poured into the cylinder at F upon the top of the piston, and that the piston was provided with a valve at *l*, which, when opened, allowed the oil to reach the water, upon the surface of which it would float, being lighter than that fluid. The same may be done with reference to the other cylinder, which could also be provided with a valve at *m*; and if *ten* pounds were here poured in, the oil in the two cylinders would be found to stand at the same level; thus clearly proving the truth of the theory.

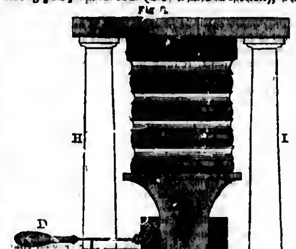
This very remarkable property of water and other such fluids has been termed the *hydrostatic paradox*. But in reality there is nothing paradoxical in it, any more than in many of the effects produced by the mechanic powers. The above case is explained on the principle of action of a lever. Ten pounds on the shorter arm is balanced by one pound on the longer arm. The liquid is the bar which transmits the effect of the lesser weight to the greater, and the surfaces of the vessel perform the office of the fulcrum, by sustaining both the power and the weight.

This principle is strikingly illustrated in the instrument which is called the *hydrostatic bellows*. It consists of two wooden boards, connected together with leather, as in a pair of common bellows. There is of course no valve, but in place of it a long narrow tube A B is inserted into it, through which water is poured, so as to fill the space between the boards. If these be a foot and a half long, and sixteen inches broad, and the upper one be loaded with three hundred-weight, a quarter of a pound of water poured into the tube, and rising to the height of three feet in it, will raise the weight as high as the leather allows. If, instead of using water, the pipe is blown into by the mouth, the same effect will be produced. The smaller that the bore of the pipe is, the easier will any weight be raised. This evidently results from the principles already explained; for if the section of the tube at E have the magnitude of one square inch, and the surface of the upper board C contain 10,000 square inches, then a column of water in the tube weighing one pound will sustain a weight upon the board of 10,000 pounds. But suppose the magnitude of the tube were only the hundredth part of a square inch, still, however, by being sufficiently lengthened to contain a pound of water, then upon every hundredth part of a square inch there will be the pressure of a pound; on every inch 100 pounds; and on the 10,000 square inches, 1,000,000 of pounds, or 446 tons, 8 cwt., and 64 lbs.

Fig. 2.

Striking as this property of fluids is, it remained until recently only a barren fact in science. It has, however, been applied by Mr Bramah in the construction of a singularly powerful machine, called the *hydraulic* or *hydrostatic press*. Compared with the bellows, there is merely substituted a forcing pump for the lofty tube, and a barrel and piston for the leather and boards. It consists of a short and very strong pump barrel A B (shown here in section), with

Fig. 3.



a solid piston C of proportionate strength, which piston is pushed upwards against the thing to be compressed, G, by water driven into the barrel beneath it at F, from the small pump E. The whole machine is bound together by a very strong metallic framing, of which H I are two pillars. If the small pump have only one-thousandth of the area of the large barrel, and if a man, by means of its lever-handle D, press its piston down with a force of five hundred pounds, the piston of the great barrel will rise with a force of one thousand times five hundred pounds, or more that two hundred tons. The power of such a press becomes, therefore, prodigious, and the advantages which it possesses over those worked by a screw are obvious. Between solids and fluids there is comparatively little friction; and, accordingly, in the hydrostatic press none of the force which has been generated is lost by friction, except what is necessary to overcome the friction of the pistons in the cylinders. It is much used for condensing and pressing substances, particularly by printers and bookbinders, who employ it now in general instead of what is called the dry-press (which was wrought by a screw), for squeezing the printed sheets of books in order to smooth the surface of the paper.

Dr Lardner observes, that the property of fluids, which we have been describing, might be easily applied to transmit force to any distance, and under circumstances in which other mechanical contrivances might be inapplicable. It would only be necessary to have a tube filled with water, which stretched from the point where the force originated to that to which it was to be transmitted. A pressure excited on the liquid at one end of the tube would thus be communicated to any surface in contact with the water at the other end, and this instantaneously, although the tube extended from Edinburgh to London, and were curved and angular instead of straight. On account of this rapidity of transmitting impressions which water possesses, its application in telegraphic communications has been suggested, and even practically illustrated, by an ingenious individual in England, who laid several miles of pipe for the purpose, and, we believe, succeeded in verifying the truth of the hypothesis.

Dr Arnott has suggested the application of the same principle to surgical cases. He considers that a liquid might be conveyed through a flexible tube, so shaped, that, when filled by the liquid, the proper degree of pressure will be exerted on those parts of the body which require it. It is occasionally necessary to produce a certain degree of pressure on some internal parts of the human frame which cannot well be reached except by a tube or channel, through which a surgical instrument could not be very safely or easily conveyed, but in which the effect might be conveniently produced by means of fluid pressure. An account of the instruments necessary in these cases will be found in Dr Arnott's able work on Physics.

The fluids of the animal frame exhibit many apt illustrations of the principles of hydrostatics, as the solids do those of mechanics. The heart being an instrument possessing great power of expansion and contraction, and the reservoir from which the blood is supplied to all other parts of the system, by its expansion, excites a pressure upon the sanguine fluid, and impels it into the arteries; from thence it is urged forward into the [illegible], and so is made to complete the circulation, passing through various pipes and conduits, which are composed of a material so elastic as to continue the pressure commenced at the heart.

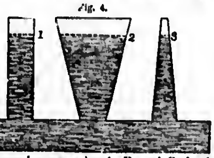
PRESSURE OF FLUIDS IN PROPORTION TO THE DEPTH.

In every fluid the particles that are below sustain the pressure of those that are above them, which pressure is in proportion to the perpendicular depth, and is not influenced by the size or shape of the containing vessel. The first part of this proposition has already been proved in the case of the *hydrostatic bellows* and *press*, but many remarkable illustrations of it may be adduced. One general truth we may mention, which the reader would do well to keep in recollection: it is, that the pressure of water at any depth, whether on the bottom or sides of the vessel, or on any body immersed in the fluid, is nearly one pound on the square inch for every two feet of depth. It is at sea that the effects of fluid pressure at great depths are most strikingly exhibited. A strong square glass bottle, empty and firmly stopped, if sunk to the depth of about ten fathoms, will be crushed together, the shape of the vessel being unfavourable to strength. But if a common empty cylindrical bottle be firmly corked in the same manner, and plunged to a considerable depth in the ocean, the cork is generally pressed inwards at a certain depth, and this does not depend upon the direction in which the mouth of the bottle may point. The cork thus carried far under water, beautifully illustrates the doctrine of equal pressure in all directions. It is not flattened as if it had been pressed from above only, but is reduced in every direction, so as to appear like a small phial-cork of the usual shape. It frequently happens that vessels entirely disappear in the ocean, leaving not a fragment of wreck to reveal their fate. This occurs when they founder in great depths of water; the vast pressure of the sea far down compresses the wood, and renders it specifically heavier than the surrounding fluid, so that it can never reascend through the immense column of water which fixes it for ever to the bottom of the deep.

As pressure, then, increases in proportion to the depth, many valuable suggestions are afforded as to the construction of sluices, dams, and bulwarks or walls for keeping out the ocean, as is the case in Holland in particular. It is evident that, as pressure is in proportion to depth, in a vessel whose bottom and each of whose sides are severally two square feet, the water which it contains presses upon the centre of any of the sides with half the force with which it presses upon the bottom. At the surface the pressure is inconsiderable, and hence the wall or other erection may be made of corresponding lightness; but as the depth increases, the pressure increases in the same ratio; and hence the building must become gradually thicker and stronger, so that, when completed, it will resemble the perpendicular half of a pyramid, whose base is of great breadth, but whose top is comparatively a point. It matters not what the breadth of the water may be. A flood-gate which shuts out only a small lake or sheet of water, that is, provided the depth be the same, sustains as much pressure as if the broad expanse of twenty Atlantics were resting against it.

The second part of the proposition at the beginning of this head was, that pressure is entirely uninfluenced by the shape, size, or position of the containing vessel.

Fig. 4.



Here we have three vessels, A, B, and C, having all different shapes, but provided with flat bottoms of exactly the same dimensions. If water be poured into them to the height represented by 1, 2, and 3, although the quantity in each vessel be very different, the pressure upon the bottom of all will be the same. This truth is proved experimentally by making the bottoms moveable, fixing them in their several positions by springs or weights calculated to measure the degree of pressure which each sustains. Or, it may be proved by allowing all of them to communicate with a vessel of water below them, and then observing that the fluid in all has still the same level. For, as a column of the water resting on the middle of each bottom just presses with its whole weight, and, therefore, according to its altitude, this column could not remain at rest if there were any greater or less pressure than its own near it. Then, as the fluid is actually at rest in all the cases, and in all a central column is of the same height, the pressure must be equal on all the bottoms.

The scientific fact of water rising in no case able to rise beyond the height of its fountain head, whatever may be the volume of water in the fountain, suggests a plan by which cities might in some instances be saved from inundations by rivers. When the inundation takes place, not from the surface of the river, but from the water projected through the common sewers running into it—as, for instance, in the case of Glasgow—and rising through the gratings in the streets, wooden funnels might be inserted in a tight manner into the openings, whereby the water, instead of spreading along the streets, would rise in the funnels to the level of the surface of the river, and then stop. Of course there is no necessity for the vessel so applied being funnel-shaped; it is sufficient that its base be suitable to the orifice of the sewer.

AMOUNT OF PRESSURE.

In the above cases, we have seen that the pressure on the bottom of a vessel depends upon the magnitude of the bottom and the depth of the liquid, and does not in the slightest degree depend upon the shape of the sides, or upon the quantity of liquid in the vessel. It may be generally inferred that the pressure upon a flat horizontal bottom is ascertained by multiplying the number of square inches in the bottom by the number of feet in the depth of the fluid; the product will express the number of solid feet of the liquid whose weight is equal to the pressure on the bottom. In a vessel similar to that represented in fig. 2, the pressure on the bottom is less than the whole weight of the liquid. In one like that shown in fig. 3, it is greater than the weight of the liquid; and in such a vessel as is represented by fig. 1, it is equal to the weight of the fluid.

In these examples the surfaces are supposed to be flat; but as surfaces are subject to every variety of shape, it is necessary to have rules which are applicable to all surfaces containing liquids. The point first to be ascertained is the medium pressure, for there is in every case a certain mean, which is the result of the various pressures. This is the centre of gravity, and to find it, the finding of the total pressure is reduced. When the mean is found, and the magnitude of the surface in contact with the liquid is ascertained, the whole amount of pressure is readily found. For instance, if the average pressure be 15 lbs. upon the square inch, and the magnitude of the surface be 200 square inches, then the whole amount of pressure will be 3000 lbs. The average pressure is produced at the average depth, which is of course an average of the depths of all the surfaces in contact with the liquid, and where the surfaces are irregular this is very difficult to discover. Indeed, to determine the centre of gravity in such cases is a mathematical problem of considerable difficulty, and can merely be alluded to in this place. With respect to a sphere or a cube, however, it is comparatively an easy matter. In a sphere, the total pressure is ascertained by multiplying the number of feet in half its diameter (for its centre is obviously the centre of gravity) by the number of square feet in its surface. It is proved by geometry that the solid contents of a globe are ascertained by multiplying the number of feet in half its diameter by a third part of the number of square feet in the surface. Hence the pressure on the surface of a globe is three times the weight of its contents. In a cubical vessel, which is one having four square sides, each of which is equal in size to the bottom, the centre of gravity is that point which is equally distant from the four sides, the top, and the bottom of the vessel. The pressure on each of the sides is equal to half the weight of the fluid in the vessel; the pressure of the four sides will therefore be equal to twice the weight of the contents of the vessel; and as we have already seen that the pressure upon the bottom is equal to the whole fluid, the total pressure upon the vessel will be equal to three times the weight of liquid which it contains. The pressure which a body sustains when immersed in a fluid is determined by the same rules. We have already noticed some of the phenomena which admit of explanation by the hydrostatical theorems which we have endeavoured to explain; namely, that liquids transmit pressure equally in all directions; and that the amount of pressure is in proportion to the depth of the liquid; but a few more remarkable instances might be adduced. If a fissure in a rock happen to communicate with an internal cavity of a considerable size, and if by means of rain this cavity becomes filled, and the fluid finds no means of escape, then it is possible that the rock or mountain may be rent asunder by the pressure of the small strip of water percolating through it.* In large and extensive walls of masonry, which are intended to confine banks of sand or earth, we generally see openings left at the bottom, for the purpose of allowing the water which collects during rain to pass through them. Where provision for this has not been made, the wall will be inevitably rent, and many extraordinary catastrophes have occurred in this way. The increase of pressure in proportion to the depth of the fluid, proves the necessity of making the sides of pipes or masonry, in which fluids are to be contained, stronger the deeper they go, and shows that it is a superfluous expense to make them equally thick and strong from the top downwards. The same remark applies to flood-gates, dams, and banks, as we have already observed. The lower hoops and other securities of brewers' vats, some of which contain many thousand barrels of liquid, are made of far greater strength than those higher up. The increased pressure nea the bottom of such vessels is seen in the force with which the fluid rushes out when a plug w[illegible] it is removed. For some feet it flows in nearly a horizontal line; a few yards farther up, the current is bent downwards considerably, immediately after it issues from the vat, and this curve continues to increase the higher up that we ascend.

FLUID LEVEL.

Besides the two properties of fluids explained in the foregoing observations, there is a third of no less importance than either of them, and which indeed may be said to result from them; that is, the tendency which fluids have to find and to maintain their level. The level or equilibrium of fluids is a natural result of their gravitation, or of all the particles of the mass being attracted towards the centre of the earth independently of each other, and being perfectly moveable amongst themselves. Hence it follows, that, when any part of the water in a vessel is raised by agitation higher than the rest, it is drawn downwards again by the force of attraction; for it has an equal tendency towards the earth's centre with the other portions of the fluid surrounding it. And this force is never failing, but continues to operate, lessening the height to which it is elevated at each successive ascent of the wave, until it is brought finally to a level with the rest of the liquid. Thus, then, a fluid left to itself will settle at the same level, no one part of its surface being more elevated than another. Hence, if water be poured into a vessel shaped like the letter U, although one limb be twice the diameter of the other, the liquid will attain the same level in both. In further illustration of this, we may increase the number of vessels to an indefinite extent, and vary their shapes as fantastically as fancy can devise; yet if they all have a common communication with each other, and if water be poured into one of them, it matters not which, still each will appropriate to itself a quantity of the fluid proportionate to its containing capacity; and when this is completed, the water will be found to stand at exactly the same level in all the

* May not the remarkable property of water, above described, be applied in explanation of at least some of those phenomena which are usually ascribed to the agency of a central fire? The power of water to produce convulsions of the most tremendous nature, is evident from the facts which we have stated; and that the liquid exists in a considerable depth in the interior of the earth, we have abundant evidence. Suppose that at certain depths downwards there are cavities (such as will be afterwards shown to be the reservoirs of springs) which are supplied with water by means of fissures communicating with the surface of the earth. When these cavities are filled, the columns of water will press upon their surfaces with an extraordinary degree of force; the water communicates this pressure to the minerals, metals, and other matter with which it is surrounded. These will yield, and, splitting into fissures, which, of course, widen as they proceed upwards, create those openings and chasms upon the surface of the globe, such as frequently occur, and where the agency of fire is not apparent. Indeed, occasionally there are seen in them bodies of water of considerable size. It is to be observed, however, that convulsions of the earth are generally sudden, and that those which are likely to arise from liquid pressure would not commonly be gradual; but it is easy to suppose circumstances in which they would also be instantaneous. The pressure of water may also, in some cases, be the cause of that heat, which, it is now generally admitted, increases as we descend into the bowels of the earth. It may even condense some species of matter so much as to ignite them, and thus originate combustion. It is not here, however, that we should speculate upon conjectural theories; perhaps the idea is not worthy of more space than has been devoted to it.

vessels, so that any body resting upon the surfaces of the water in the whole of them would lie perfectly horizontal. Although, from the law of gravitation, the surface of water in every vessel is a portion of a sphere, yet the sphere of the earth which it represents, as far as it goes, is so exceedingly large, that any deviation from the horizontal cannot be discernible in a space so small as that to which such experiments are confined; and thus a body resting upon surfaces confined within three feet or so of each other, will seem to press equally upon the whole surface of each, and appear to lie in a perfectly horizontal position, even when a spirit-level, which we shall immediately describe, is laid upon it. Any small portion of water, therefore, for all common purposes, may be looked upon as a perfect plane. So completely does water assume the level, and so glassy smooth does its surface become, that in some instances a polished mirror cannot reflect the rays of light which fall upon it more exactly in the order which they had on leaving the object than it does. Perhaps one of the loveliest sights in nature is to contemplate over the sides of a vessel the gorgeous array of clouds mingled together in beautiful confusion around the setting sun, as they appear mirrored in the bosom of the deep.

It is in the magnificent operations of nature that we meet with the grandest displays of this property of water to find its level. The ocean is to the earth what the heart is to the human body: it is the great reservoir whence is derived that fluid, which, circulating through it and over it, nourishes the vegetation upon its surface; thus perpetuating the present state of things. All the rivers and streams which we see flowing into the mighty basin of the deep, had their origin there. By the action of the sun's rays upon it, water is converted into vapour, which, ascending into the higher regions of the atmosphere, is formed into clouds. These, again, descend to the earth in the shape of rain, snow, hail, &c.; and part of it falls upon lakes, rivers, and other sheets of water which communicate with the sea, whilst a very great proportion descends directly into the ocean itself. But not a little of it sinks into the porous earth, where it forms springs and fountains, these again giving rise to rivers. To the subject of springs we shall return immediately.

RIVERS.

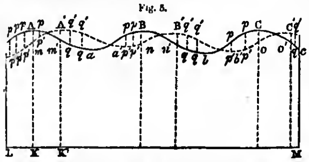
It is the tendency of water, then, to find its level, which gives rise to those far-stretching and perpetually-moving bodies of water called rivers. If in the interior of the land, water be confined on all sides, and prevented from flowing to the sea, it forms a sheet of water called a lake. If any of the earth or rocks which surround the fluid be removed, it immediately flows downward, and a very slight declivity is necessary to give the running motion of water. A descent of only three inches per mile in a straight and smooth channel, gives it a velocity of three miles per hour. The Himalaya mountains, in Asia, the highest in the world, give rise to the great river Ganges, which has a course of 1800 miles, and yet at its commencement is only 800 feet above the level of the sea; that is, about the height of Arthur Seat, near Edinburgh, or twice the height of St Paul's Church, at London; and to fall these 800 feet in its long course, the water requires more than a month. Some of the great rivers of South America travel above a thousand miles, and yet in all that extended course fall only four or five hundred feet. Rivers as they advance towards the ocean sometimes suddenly disappear in the bowels of the earth, where they run for a considerable way through subterranean beds, and then re-appear, and flow in a channel upon the surface of the deep. They take the passage underground because it is more precipitate than that which the surface of the earth afforded; but sometimes this becomes choked, and they are again compelled to seek a channel on the surface. The waters of the Oronoko, at one part of their course, lose themselves beneath huge granitic blocks, forming immense natural arches, under which the torrent pours with tremendous fury. In the year 1752, the bed of the Rio del Norte, in New Mexico, became suddenly dry to the extent of sixty leagues; the river had precipitated itself into a newly-formed chasm, and disappeared for a considerable time, till at last its subterranean course being stopped, the river returned to its former channel. About the beginning of the last century, the river Amazon exhibited a similar phenomenon.—For the effects produced by rivers in changing the face of a country, see the "Account of the Globe," No. 6 of this work.

Amongst other examples of the tendency of water to seek its level, cataracts and waterfalls exhibit some of the most striking. When a river in its progress to the sea meets with some abrupt declivity, it is precipitated over it with tremendous fury, forming what is called a cataract. These phenomena are amongst the most sublime and appalling of natural appearances. To witness the falls of the Niagara, in North America, say most of those who have enjoyed the spectacle, is an era in one's lifetime, an event never to be forgotten. This tremendous cataract falls 150 feet of perpendicular descent, and the sound of it is audible at thirteen miles' distance. The stream has a breadth of 400 yards immediately before the descent, and its depth is also considerable. The fall of such an enormous column of water may be conceived to produce a dreadful concussion. The celebrated cataract of Sequandama, formed by the Rio Bogota, in South America, was long considered the grandest in the world, one traveller having estimated the height of its fall at 1500 feet; but Humboldt, who has conveyed to us so much correct information with respect to the southern portion of the New World, says that its descent does not exceed 600 feet. The stream, before it approaches the precipice, has a breadth of 140 feet, which immediately contracts, and at the edge of the abyss is reduced to 35 feet.

WAVES.

The surface of the land displays every variety of hill and valley, here heaved up in immense mountain ridges, and there depressed into deep hollows, so that the mind, unenlightened by science, is almost justified in supposing that at one time it was a fluid mass, tossed like the sea into all fantastical forms by some primeval tempest, and that by the fiat of Almighty power it was consolidated in a moment, the hills and the vallies which it exhibited in the fluid state becoming permanently fixed. The reason why the earth does not assume the level surface which the sea exhibits, arises from the force of cohesion in solids resisting the power of gravity to separate their particles. The sea, like the land, exhibits at times great inequalities, but they are fluctuating continually, and this alternate depression and elevation of a liquid gives rise to a curious optical deception. The waves appear to have a progressive motion, and move as it were along the surface of the ocean from one end of it to the other. By a moment's reflection, however, we will soon be convinced that this idea is erroneous. Any body floating upon the surface of the water is not borne along by the wave, as would certainly be the case did the waters composing each wave move along with the undulation. For instance, the foam of the sea is an exceedingly light substance; and had the water, which composes a wave, a motion onwards equal to the speed of the undulation, the froth would undoubtedly be carried forward. But this is not the case. When water rises in the form of a billow, it is elevated upon its surface; and when the liquid is again depressed, it sinks into the hollow along with it. But a progressive motion appears to take place in something, whether it be the liquid or not, for we have the evidence of sight in proof of the fact. To what then does the motion belong? To the *form* of the wave, and not to the liquid which composes it. Dr Lardner, in his work on Hydrostatics, gives the following explanation of this phenomenon:—

Fig. 5.



"Let the undulating line in *fig.* 5 be supposed to represent the surface of the sea, and let A B C be the crests of three successive waves, and *a b c* the intermediate vallies: Let L M represent the bottom of the sea at A, the depth of the water is represented by the line A K; take any point near A, as *m*, and the depth here is represented by *m* K', the summit of the wave being A; the depth at A is greater than the depth at *m*, the pressure of the column A K being greater than that of *m* K, the point A has a tendency to fall, and the point *m* to rise, by reason of this excess of pressure; therefore *m* will rise to the point A, while A sinks to the level *m*. Thus the points A and *m* have interchanged levels, the point *m* being now raised to as great a height above the bottom L M, as the point A had before the change, and the point A having fallen to the height which *m* had. In like manner, it will be found that for every point in the first position of the wave, there is another point in the second position, with which it interchanges elevations. If these circumstances be closely considered, it will not be difficult to perceive that in the interval which we have supposed, the various points on the surface of the water, such as *m*, which were before on the sloping sides of the waves, have now become their summits A' B' C', &c. Not that the points A' B' C', &c. have advanced to A B C, &c., but that they have fallen from their former elevations, while the latter have risen. It appears, therefore, that the undulations of the surface are produced by its different points ascending and descending alternately in a perpendicular direction, without any kind of progressive motion.

To make this still more clear, let us suppose that perpendicular lines be drawn from every part of the surface A *a*, B *b*, C *c*, &c. to the corresponding points in the surface A'*a*', B'*b*', C'*c*', &c., and let the interval between the periods at which the surface of the liquid assumes these two forms be conceived to be one second; in that time the several points of the first surface which are marked by the letters *p*, fall in the direction of the dotted lines perpendicularly downwards to the points marked *p*', and the points marked *q* rise perpendicularly upwards, in the directions marked by the dotted lines, to the positions indicated by the letters *q*'. Between the two positions A and A', the points of the surface between A and *m*' have both risen and fallen during the second; they have first risen to an elevation equal to that of A, and have for an instant in their turn formed the crest of the wave, but, before the expiration of the second, have again fallen perpendicularly to their position in the dotted line. It will thus, it is hoped, be understood how the *form* of a wave may actually have a progressive motion, while the water which composes it is stationary.

If a cloth be loosely laid over a number of parallel rollers, at such a distance asunder as to allow the cloth to fall between them, the shape of waves will be exhibited; if a progressive motion be now given to the rollers, the cloth being kept stationary, the progressive motion of waves will be produced as the cloth will appear to advance. It is the same cause which makes a revolving corkscrew, held in a fixed position, seem to be advancing in that direction in which it would actually advance if the worm were passing through a cork. That point which is nearest to the eye, and which corresponds to the crest of the wave in the former example, continually occupies a different point of the worm, and continually advances towards its extremity. This property has lately been prettily applied in ornamental clocks. A piece of glass, twisted so that its surface acquires a ridge in the form of a screw, is inserted in the mouth of some figure designed to represent a fountain; one end of the glass is attached to the axle of a wheel which the clockwork keeps in a state of constant rotation, and the other end is concealed in a vessel designed to represent a reservoir or basin; the continual rotation of the twisted glass produces the appearance of a progressive motion, as already explained, and a stream of water continually appears to flow from the fountain into the basin."

CANALS AND SUPPLY OF WATER FOR TOWNS.

Every one knows that a canal is a long artificial hollow filled with water, and, passing over the surface of a country, serves to facilitate the intercourse of one part of it with another. Canals generally communicate with the sea at one end, whence they derive the water with which they are filled; sometimes they communicate with it at both ends; and occasionally the water is derived from lakes and other sheets of water. The methods of conducting a canal through a country depend upon the property of fluids to find a level. From the inequalities which the surface of a country presents, the course of a canal is necessarily divided into levels of various lengths, like the steps of a stair. At each level there is what is called a lock; that is merely a part of the low level sufficiently large to contain the vessel, and furnished with high walls and flood-gates at both ends. When the gates below are shut, and water is introduced from above, the boat of course rises to the high level. When the upper flood-gates are shut, and the water is gradually allowed to escape from the lock, it becomes a part again of the low level, and a boat may go in or come out by its lower gates. It is evident, whether a vessel ascend or descend, that a certain quantity of water must necessarily be lost, which of course is to be supplied. The objections urged against locks are the delay which they necessarily occasion, and the expense of their construction, their repairs, and their management. Thus, then, where it is practicable, it is advisable to take a circuitous route, rather than be subjected to these inconveniences. In countries such as our own, railroads, which are now becoming so common, appear to be in many respects preferable to canals. By a knowledge of the fact that water has a tendency to maintain its level, or to rise again through any channel, such as a pipe, to the level of its source, the moderns have been enabled to construct the admirable apparatus by which towns are supplied with water. In these a reservoir is constructed, in a situation more elevated than any to which we wish to conduct the water; the reservoir may be supplied by natural or artificial means; it may either be replenished from a higher part of the country, or forced up by pumps. From the reservoir many pipes lead off, from which, again, smaller ones ramify through all the intricate windings of a town, dwelling-house, or manufactory. As long as there is water in the reservoir, these will continue to be supplied, provided they do not rise above the level of the source from which they are fed. Whether the ancients were ignorant of the principle of water rising to its level or not, at all events they made no use of it, as their immense aqueducts for supplying cities with water, sufficiently prove.

LEVELLING.

In another place it was observed, that every surface of water was not, strictly speaking, a "level," but described a portion of a sphere, which, if extended, would complete a globe equal in dimensions to the earth. The reason of fluid bodies assuming the spherical form is, as was formerly mentioned, that the particles gravitate independently of each other. The point to which they are attracted is the earth's centre; and as at the surface they are all attracted with the same degree of force, no one part will stand higher than another, but the top layer of each column of particles will stand at exactly the same distance as the rest from the centre of the earth, and thus the sphericity of the earth is easily accounted for. In large bodies of water, such as the ocean, this is very perceptible. When a vessel departs from view, or comes into sight, the top of her mast in the first instance is the last, and in the second is the first visible, so that, as far as vision is concerned, she may be said to sail up or down hill, accordingly as she is coming to the spectator or leaving him. The swelling curve of the sea hides her hull, but as she rises over the bulging element, other parts besides her mast become gradually visible. But in a small portion of water this curvature is not discernible, so that, in a calm day, a lake appears to exhibit a plane surface, every part of it settling on the same level. The definition of the equilibrium of a fluid is, that every part of the surface is equally distant from the centre of the earth.

Upon the tendency of fluids to dispose themselves in a surface, such as we have described, depends the making of *levelling* instruments, or those by which we ascertain whether a surface is level, or a plane horizontal, or if two points are on the same level; that is, equally distant from the centre of the earth. The simplest form of these is what is called a spirit-level, which is represented by the following figure:—

Fig. 6.

It consists of a cylindrical glass tube *a c*, filled with alcohol or spirit of wine, except a small bubble of air *b*. The ends are closely sealed, to prevent the escape of the liquid. In whatever position the tube may be placed, the bubble of air will always tend to the highest part of it; when placed in a perfectly horizontal position, the bubble will stand in the middle, the tube having a slight convexity upwards. When used, it is generally fixed in a brass case, having an opening at the top, exactly in the centre of which the air will appear when the case lies in a perfectly horizontal position. If one of its ends be lower than the other, it will not be seen there, and the end must accordingly be raised, the space necessary for bringing the bubble to the middle being exactly that which the one extremity of the instrument, or rather the surface which supports it, wants of being on a level with that which supports the other. There are other more complicated instruments, but the above is sufficient to show the principles of levelling.

IMMERSION OF SOLIDS IN LIQUIDS.

When a solid is immersed in a liquid, it displaces exactly its own bulk of the fluid; and this method of ascertaining the solid contents of a body is resorted to when the figure of the body is so irregular as to be incapable of geometrical measurement. Let the reader suppose a glass vessel before him, say a common tumbler, having divisions marked upon its exterior surface, by parallel lines extending from top to bottom being drawn either all round or to a certain extent round it. These divisions indicate a certain quantity of water, say the twelfth part of a cubic inch. If the tumbler then be half filled with water, and the body which we wish to know the solid contents of immersed, this will be shown by the number of lines which it raises the water above the level which it had before the introduction of the solid substance. If it be raised say eighteen divisions, then the magnitude of the body is one and a half cubic inches. It is evidently necessary to correctness that the sides of the vessel should be truly perpendicular, and free from all inequalities. The fact that a solid, when plunged into a liquid, displaces exactly its own bulk of the liquid, was discovered by Archimedes, one of the greatest mathematicians of ancient times. Hiero, king of Syracuse, himself an eminent philosopher, had given a certain quantity of gold to an artist for the purpose of making a crown; and suspecting, from the lightness of the diadem, that the fabricator had adulterated his gold with silver, he required of his friend Archimedes to solve the difficulty. Whilst this great man was intent upon the question, he one day observed, whilst he was bathing, that on the immersion of his body the water ran over the sides of the bath, and finding by calculation that the quantity corresponded to the bulk of his body, the idea of specific gravity immediately flashed upon his mind, and he rushed out of the chamber, exclaiming, as he passed along, "I have found it! I have found it!"

Having seen the effects which the immersion of a solid in a liquid has upon its volume, let us now ascertain what effect is produced upon its apparent weight. If into each of the scales of a weigh-beam we place a tumbler such as that we have described, half filled with water, they will of course exactly equalise or balance each other. If in one of them we suspend by a horse hair a cubic inch of gold, the metal being completely immersed, but not touching the bottom of the vessel, the scale in which that tumbler is placed will outweigh the other. If, then, into the other tumbler water be poured, so as to restore the equilibrium of the scales, the fluid will be found to rise to exactly the same height as it stands in that in which the gold is immersed, as will be seen by the graduated scales of the vessels. For any other substance, no matter what its weight may be, provided its magnitude be the same as that of the gold, the same quantity of water is required to balance the scales. If the body be lighter, but pressed down by a piece of thin rigid wire, the same results will take place; and if only half of the body be immersed, just half the quantity of water is required in the opposite scale to restore them to a level with each other. The facts may be summed up in two propositions:—1. That the apparent weight of the liquid is increased, and the apparent weight of the solid diminished, by immersion. 2. That the apparent weight of the liquid is increased in a proportion of itself exactly corresponding to the magnitude of the body introduced, whilst the apparent weight of the body is diminished to an extent exactly equal to the difference between its specific gravity and that of the liquid.

FLUID SUPPORT.

We have almost daily illustration of the fact that a body specifically lighter than water floats upon it; unless, indeed, it be also lighter than air, when it rises above the surface of the earth altogether; and from what we have said above, the fact is likewise clear, that although bodies which are heavier than water sink down through that fluid, they are yet to a certain extent lifted up in it, by which we mean that they are rendered lighter there. Thus, a stone which it would be impossible to move out of the water, when immersed in it can be borne along with ease. This is experienced in a particular manner by those who are enabled to work under water by means of the diving-bell. Those who practise angling must often have observed the difference of weight of a fish whilst it was dragged along under the surface of the water, and after it had been raised above it. Indeed, the ease with which it is carried along in the liquid gives rise to a deception which an unpractised fisher often suffers from. If rapidly pulled out of the water, the sudden jerk which the line receives, when the fish passes from its native element into the atmosphere, often snaps it through, and the prey is lost.

In floods which carry away bridges, and bear immense blocks of stone to a great distance, much wonder is excited at the force exerted by water on such occasions. But our surprise is materially lessened when we consider that most stones in water do not weigh much more than half what they do when out of it, and can thus be more easily carried forward.

When a solid body floats in a liquid, it displaces as much of the liquid as is equivalent to its own weight. If for instance the body weigh one hundredweight, no matter whether it be a log of dense wood or a hollow vessel made of the lightest material, such as cork, still just one hundredweight of water would be displaced. [illegible] easily proved by trying the experiment [illegible] scale, in a vessel so graduated at the side [illegible]ate how much the water which it contains is [illegible]y the immersion of any body in it. Although every body which is specifically heavier than water sinks in it, yet the heaviest bodies can be made to float upon any liquid, however light. This is done by giving it such a shape as will enable it to displace a quantity of liquid which is as many times greater than its absolute bulk as its weight is greater than that of an equal bulk of the liquid. Thus, a metallic or earthenware bowl will float upon water if it be placed upon it with the convex end downwards. There are a great variety of shapes by means of which a very heavy body may be rendered buoyant, but they must all be formed upon this principle, that when the vessel is immersed in water, there will be, below the level of the liquid, some space in it occupied by air, or by some substance lighter than the liquid. Iron boats are now used for various purposes, particularly, we believe, in canal navigation; and a species of timber called Indian teak, which in the form of a log sinks in water, is now used in building vessels.

When the human body is in a state of ordinary health, with the chest full of air, it is lighter than water—a fact which, if it were more generally known and credited, would lead to the saving of many lives. When the body is as we have described, it floats with a bulk of about half the head above water; and thus a person who cannot swim may live and breathe, until chilled or otherwise paralysed, by simply exerting volition sufficient to keep the face uppermost. There are various kinds of apparatus for preventing drowning, called life-preservers. The most common are those which consist of pieces of cork or other very light material attached to the upper part of the body. But air-tight bags are preferable, as they may be said scarcely to encumber the body when empty, and, as danger approaches, they can be inflated with ease by being blown into. Life-boats have large quantities of cork in their structure, and also air-tight vessels made of thin metallic plates; so that, even when filled with water, a considerable portion of the boat still floats above the general surface. The bodies of some animals, as sea-fowl and many other species of birds, are considerably lighter than water. The feathers with which they are covered add very much to their buoyancy. Quadrupeds swim much easier than men, because the natural motion of their legs in walking or running is that which best fits them for swimming. Fishes are enabled to change their specific gravity by means of an air-bag with which they are provided. When the air-bag is distended, they rise to the surface; and when it is contracted, they descend to the bottom.

STABILITY OF FLOATING BODIES.

"A floating body," says Dr Arnott, "to be stable in its position, must either have its *centre of gravity* below the *centre of buoyancy*, that is, the centre of gravity of the fluid which it displaces, in which case it resembles a pendulum; or it must have a very broad bearing on the water, so that any inclination may cause the centre of gravity to ascend, in which case it resembles a cradle or rocking-horse."

That the centre of gravity of a floating body, in order to secure stability, should, to speak familiarly, be as far as possible below the surface of the water, is obvious. A body which is equally dense throughout its whole bulk, may be so shaped as to float upon water in every possible position in which it may be placed, without having any tendency to alter it of itself. Its centre of gravity must therefore be that part of it which is equidistant from every point of its surface, that is, the centre of its own mass. If, however, there be introduced into it, and placed a little on either side of this centre, a heavy substance, such as a lead bullet, that half of the body in which the weight is, will have a tendency to keep undermost, and this will increase the farther it is removed from the centre towards any of the sides; for in doing this, we are always depressing the centre of gravity. Hence any body, the parts of which have different weight, will only float steadily when the heavier parts are immersed, for among these or near them the centre of gravity is always to be found. In the stowing of a ship's cargo, care is generally taken to put the heaviest part of the merchandise undermost, and it is usual to have heavy ballast placed beneath all. It is on account of these circumstances not being attended to that vessels are frequently overset in squalls of wind. The whole case reduces itself to a simple one of mechanics. The masts of the ship with its sails are the long arm of the lever; the ship with its cargo is the short arm of the lever; the wind is the force applied to lift these, the fulcrum being the centre of buoyancy of the water. Now, it is evident that the farther the weight to be raised by the lever is removed from the fulcrum, the more difficultly will the task be accomplished. If, for instance, there be fifty tons equally distributed between the fulcrum and the extremity of the short arm of the lever, which is say twenty feet in length, it would be far more easily raised than if the fifty tons were all concentrated within ten feet of the lowest part of the vessel or the keel. When a ship is empty, she floats high in the water, thus raising the centre of gravity; and if the weight of the masts and rigging be considerable, they also assist in elevating it, so that the equilibrium is rendered unstable. In reference to the lever, we see the danger of having the masts too high, for the power of the lever is increased, without a proportionate degree of force for the impulsion of the vessel forward in the water being generated. The equilibrium of a boat may be rendered unstable by the passengers standing up in her; they thus raise the centre of gravity, so that, in certain circumstances, the slightest disturbance would overturn the boat. In other words, and to continue our simile of the lever, whilst the fulcrum remains the same, a portion of the weight to be lifted is brought nearer it, whilst other parts of it are removed farther up the long arm, thus materially increasing its power.

It is customary with those who are learning to swim to use bladders; but this is a very dangerous practice, unless these supports be very firmly attached to the upper part of the body. Should they shift downwards, and be yet so fixed as not to be easily got rid of, they will raise the lower part of the body, and the head will inevitably sink. Dr Arnott relates some anecdotes of an amusing description connected with this subject. A gentleman believing that he had made the great discovery of walking on water, invited the public to witness his first trip on the fickle element. He stepped with infinite confidence and self-complacency into the water, equipped in a pair of bulky cork boots, which he had previously tried in a large vessel of water at home. But, after having got fairly to sea, the law of nature took effect, and all that could be seen of the doughty experimenter was a pair of legs sticking out of the water. He was, however, happily rescued from his precarious situation.

It is well known that liquids are not all of the same specific gravity, and that some of them are considerably lighter than others. Thus, oil swims on water, and water on mercury. Oil sinks in alcohol and ether. The term *proof spirit* means spirit light enough for oil to sink in it, the strength of spirit being in proportion to its lightness. If wine be very slowly and carefully poured upon water, it will float on it. Sea water is more buoyant than fresh water; hence, bodies float easier on it. After these observations, it is scarcely necessary to observe, that, on any liquid lighter than water, a body will sink deeper in it; and on any one heavier than water, it will be buoyed higher up, and more of it will be seen above the surface of the liquid.

SPECIFIC GRAVITIES.

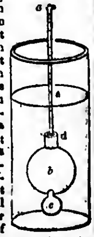
The meaning of the term specific gravity was explained in a note at the end of the number upon Chemistry. When bodies are to be compared to each other, in respect to one common quality, a standard of comparison is absolutely necessary. The standard which has been chosen is water; and it is to be preferred to every thing else, because it can be easily procured in a pure state, and is, therefore, uniform in all situations. The specific gravity of water is estimated at unity; and when we say that the specific gravity of a body is, for instance, 10, we mean to say that, bulk for bulk, this substance is ten times heavier than water. The specific gravity of a solid heavier than water is ascertained by the weight it loses by immersion in that fluid. The proportion which this weight bears to the actual weight of the solid will determine the specific gravity. For instance, if a piece of pure gold weighs 77 grains in the air, and only 73 when immersed in water, it therefore displaces four grains of water. The proportion, then, of the weights of equal magnitudes of the metal in the water is 77 to 4, or 19¼ to 1; hence, 19¼, or 19.250, is the specific gravity of gold. The instrument by which bodies are thus weighed is called the hydrostatic balance, which is simply a delicate weighing beam, with a water vessel below one of the scales. The specific gravities of bodies insoluble in water, and heavier than it, such as the metals, &c., are easily ascertained. They are merely suspended by a thread of hair, which has nearly the specific gravity of water, to one scale of the hydrostatic balance, and allowed to descend until completely immersed in the water of the vessel below. Solids lighter than water are weighed in it by fixing them to a rigid wire attached to the bottom of the scale, which keeps them below the surface of the water, the weight necessary to do this showing how much lighter they are than water.

There is another method of ascertaining the specific gravity of solids lighter than water; it is by loading them with a known weight of some substance heavier than water, which may cause them to sink, and then making an allowance for the load's difference of weight in air and water. A solid soluble in water, such as a crystal of any salt, may be protected by being previously covered by a thin coating of melted wax, or it may be weighed in some liquid which does not dissolve it, allowance being made for the difference between the weight of such a liquid and water.

The specific gravities of different fluids are ascertained by the same principle. If a substance be weighed in two fluids, the weight which it loses in each is as the specific gravity of that fluid. Thus, a cubic inch of lead loses 253 grains when weighed in water, and only 209 grains when weighed in rectified spirit; therefore, a cubic inch of rectified spirit weighs 209 grains, an equal bulk of water weighing 253; and so the specific gravity of water is about a fourth greater than that of the spirit.

The instrument called a *hydrometer* is constructed upon this principle. Its name is derived from two Greek words, signifying measure of water; but it is of course used for ascertaining the density of all kinds of liquids. There are various kinds of hydrometers. One of them consists of a glass or copper ball with a stem, on which is marked a scale of equal parts or degrees. When immersed in any fluid, the stem sinks to a certain depth, which is indicated by the graduated scale. The length to which it sinks in the standard of comparison being known, we can thus easily ascertain how much it is specifically heavier or lighter than it. Much in the same manner is constructed another hydrometer of great delicacy and exactness. It consists of a ball of glass about three inches diameter, with another joined to it and opening into it of one inch diameter, *b c*, fig. 7. and a brass neck *d*, into which is screwed a wire *a e*, divided into inches and tenths of an inch, about ten inches long and one-fortieth of an inch in diameter. The whole weight of the instrument is 4000 grains when loaded with small weights, such as shot, in the lower ball *c*. When plunged into water in the jar, this instrument is found to sink an inch if a single grain be laid upon the top *a*; hence a tenth of a grain sinks it a tenth of an inch. So great is the delicacy of this hydrometer, that the difference in specific gravity of one part in 40,000 can be detected. Its total weight of 4000 grains is convenient for comparing water; but the quantity of shot in the lower ball can be varied, so as to adapt the instrument to measure the specific gravities of fluids lighter or heavier than the standard of comparison.

Fig. 7.



There is another very simple hydrometer, which consists of a number of glass beads of different weights, but whose proportions are known, and the beads marked accordingly. These are dropped into the fluid under examination, until one is found which neither sinks to the bottom nor swims upon the surface, but remains at rest wherever it is placed in the liquid; and this bead being numbered, indicates the specific gravity.

The *areometer* is more simple than the hydrometer represented by fig. 7, although it much resembles it. A glass phial, about two inches diameter, and seven or eight long, with a plane or round bottom, is corked tight, and into the cork is fixed a straight wire about one-twelfth of an inch in diameter, and thirty inches long. The phial is loaded with shot so as to make it sink in the heaviest liquid, the wire being left immediately below the surface. The liquor to be examined is placed in a glass cylinder three or four feet long, and some three or four inches in diameter. It is furnished with a scale of equal parts on the side, to indicate the depth to which the top of the wire sinks. This instrument is so delicate, that if the sun's rays fall upon a fluid whilst under examination, the slight increase of temperature which it receives will cause the wire to sink several inches—heat, it is well known, by its expanding power, rendering bodies specifically lighter. A pinch of salt or sugar thrown into the liquid, by making it slightly denser, causes the instrument, on the other hand, to rise some inches.

The principal use of the hydrometer is to ascertain the specific gravity of distilled spirits, such as whisky, rum, brandy, &c.; but it is applicable to all fluids, and in Switzerland is used for ascertaining the purity of milk brought every evening to a common dairy where cheese is made.

Where extreme accuracy is required in scientific investigations, the specific gravity of a liquid is ascertained in the following manner:—A glass vessel of a determinate size and ascertained weight is filled with the fluid under investigation, and carefully stopped. It is first weighed in air, and then in water, and the loss of weight observed. From this loss let the loss of weight sustained by the glass alone be subtracted, and the remainder will be the weight of a quantity of water equal in bulk to the liquid contained in the bottle. The specific gravity of the liquid may thus be inferred in the same manner as if it were a solid.

The specific gravity of *aëriform* substances is ascertained in much the same manner. A glass flask of known size, and furnished with a stopcock, is first weighed when emptied by the air-pump, and afterwards, when filled successively with water, and with the different airs or gases. Comparison of the weights gives the specific gravities as already described.

As the specific gravity of every body depends upon the density or the closeness with which the particles composing it approximate to each other, care must be taken, when experiments are made, that the density of the body has not by any means been altered. Heat is the great agent in the expansion of bodies, which, by increasing their bulk, decreases their specific gravity. The temperature should therefore be carefully discriminated, else the results will not be correct. A cubic foot of distilled water at 40° Fahrenheit, weighs 1000 ounces avordupois. It is then at its least dimensions; for if it either sinks below or rises above that temperature, it expands in bulk. At 40° Fahrenheit, its state is independent of time, place, or other circumstances; it is the same at all parts of the earth, and under whatever circumstances it may be submitted to experiment. It is not, however, always convenient to obtain water at this temperature when experiments on specific gravity are made, so that it is necessary to have numerical tables expressing the change of weight which a given bulk of water sustains with every change of temperature; and thus, when the specific gravity of any substance has been found, with reference to water, at any proposed temperature, it may be reduced by a simple process of arithmetic to that which would have resulted, had it been compared, in the first instance, with water at the temperature corresponding to the state of greatest condensation.

Besides the temperature, there are other causes of fallacy in the results obtained by means of the hydrometer and hydrostatic balance. The internal structure of bodies is frequently altered by their union with each other, so that the measure of the compound is sometimes less, sometimes greater, than twice the measure of the bodies not so combined. Thus, the specific gravity of the compound formed, is not a medium or average specific gravity of the specific gravities of the two bodies in a simple state. In a mass of gold, a piece of silver may be inserted to fill up a cavity, and this weighed in water could be easily detected; but if the two metals were melted together, and chemically united, it is quite possible that they might form a compound having a specific gravity greater or less than the medium of the specific gravities of the gold and silver separate. This is the case with regard to copper. A cubic inch of gold mixed with a cubic inch of copper produces a mass of metal measuring less than two cubic inches. Thus, then, the component parts of these bodies have penetrated the dimensions of each other's mass, or the attractive affinities awakened by the process of melting have caused the particles to come closer together and occupy less space. The same occurs with regard to fluids. A pint of pure water and a pint of sulphuric acid, when mixed together, measure less than a quart. Before, therefore, placing implicit reliance upon the results obtained by the instruments above described, trials should be made with the simple substances and their compounds in known proportions. The effects of the mixture being thus ascertained in these cases, the weight becomes an accurate test of the degree of adulteration; because we know what allowance to make for the effects of chemical combination.

SPRINGS, FOUNTAINS, &c.

We have already observed that springs are to be accounted for on the principle of water seeking its level. In percolating through the earth, after having fallen in the shape of rain, dew, &c., water sometimes meets with strata of earth or stone, which will not permit of its passing downwards. Its progress therefore is stopped, and a reservoir of the liquid is formed, giving rise to various kinds of springs, which will be better understood by a figure. But first let us describe the syphon, an instrument which acts a conspicuous part in the natural phenomena of certain kinds of springs. A syphon is simply a tube bent in the manner represented in fig. 8. If it be filled with water and inverted, so as to turn the two orifices downwards, the liquid will not run out, but remain suspended in the tube, because the pressure of the column of water within is not so great as the pressure of the air without, and thus its escape outwards is prevented. If one end of it be put into a vessel of water, it will empty it down to a level with the orifice. It is evident that, when one end of the syphon is inserted in water, the pressure of the atmosphere upon the surface of the water impels the liquid through the tube, and it could be forced upwards to an elevation of above thirty feet, the height to which water rises in a vacuum, as will be afterwards described. The diagram represents an instrument of this kind furnished with two cups, firmly attached to the ends, which, by retaining a portion of the liquid, keeps the syphon always full and ready for use.

Fig. 8.

Fig. 9.

Let A B C, fig. 9, represent a mountain, and D E F a hollow in its centre containing water *G*, which flows to it through several small ducts, H H H H. Let I I' be a natural syphon, one end of which is connected with the water at *a*, and the other ramifies into diverse branches, issuing from the mountain at *b b b b*. Let K be also another stream issuing from the hill at L, but which, for the present, we shall suppose is closed at E. Now, if the hollow cavern be filled to the height M by the rivulets H H H H, it is evident that, on the principle of the syphon above described, the hollow will be emptied to the level N; and the water thus withdrawn will emerge from the mountain in the form of springs *b b b b*, because they are all at a lower level than that to which the water rises in the syphon at I'. When the whole has run off, they will then cease to flow until the hollow is refilled to the level M, when it will flow again, and thus the process goes on. This is what is termed an *intermitting spring*. Some springs, called *variable* or *reciprocating*, do not cease to flow, but only discharge a much smaller quantity of water for a certain time, and then give out a greater quantity. This arises from there being two hollows, one above the other, in the bosom of the mountain, the highest one having a runner which joins the stream of the lower one beyond the bend, or inflection, I'. This runner keeps the stream always supplied to a certain degree, although the lower cavity be dry. But when it is filled to M, the current is of course greatly augmented, which augmentation continues until the under hollow is again drained.

In some places there are springs which run freely in summer, or in dry weather, and almost stop in winter, or in wet weather. This is explained in the following manner:—Suppose the passage K L to be now open at E, and the water in the hollow to be very low, as it is in summer, or in dry weather—so low indeed that none can escape through the syphon I I'—then the spring at L will flow constantly. If during wet weather, however, the cavern be filled to the level M, the syphon will act, and drain off the water; and if we suppose the mouth of the syphon to be lower than the outlet at E, and to drain off as much as the runners H H H H supply, it will allow none to issue from the orifice at L at all.

The orifice at L, supposing there was no other outlet from the mountain, may be taken as an instance of those springs, most common, which flow continually. The reservoir from which these are supplied is generally to be traced to some hill or range of hills in the neighbourhood, which, from the quantity of rain, &c. collected by them, keep the internal cavity continually full or nearly so. Springs cannot rise higher than the reservoir from which they are supplied, and fountains, which are springs that burst out at a level considerably lower than the water in the reservoir, do not rise so high, because when they issue from the orifice, they have the resistance of the air to overcome, which retards their ascent. The current also branches out laterally, and thus the force which impels it upwards is partly expended in giving it an oblique direction.

In some parts, intermitting springs have afforded an opportunity for designing individuals imposing upon the credulous. Taking advantage of the flowing and stopping of those water-runs, these charlatans have gained credit to themselves by predicting the period when the events would happen, which, from a few years' observation, would soon be learned. In superstitious times the whole was ascribed to witchcraft; and even yet, in some places the ignorant still retain, with some slight modifications, the ancient belief of their fathers.

CAPILLARY ATTRACTION.

If we take an open tube of a very small bore, and place one of the ends upon the surface of a liquid, the latter will be found to stand somewhat higher in the inside than on the outside of the tube. If a smaller tube be taken, it will rise higher, the amount of elevation being always in an inverse ratio of the diameter. Tubes so small in the bore are called *capillary*, from a Latin word which signifies hair, because they are small like hairs. If the diameter of the tube is the fiftieth part of an inch, the water will rise to the height of one inch; if the one-hundredth part of an inch, it will rise two inches; if the two-hundredth part of an inch, it will rise four inches, and so on; always increasing in height with the smallness of the bore of the tube. The facts above stated are well ascertained; but upon what principle they are to be explained, it is difficult to determine. By some it has been asserted that the water is raised and supported by the attraction of the ring of glass immediately above the water's surface; but as an objection to that hypothesis it may be urged, that the ring immediately below the surface ought to draw it down as much as the ring immediately above it draws it up. Those who have not tubes small enough for the experiment may use instead of them square plates of glass. If one of the ends of each of the plates be placed close together upon the surface of water, and the other ends be made to approach each other gradually, but not to touch, the water will be seen to rise between the plates, forming itself into a curve line. All fluids which rise do not rise to the same height, and this is independent of their specific gravity. If the plates or tubes be made of grease or wax, the water will not rise in them; if glass plates or tubes be oiled or waxed over, watery fluids do not rise at all in them; neither does mercury nor melted lead.

In regard to an explanation of the phenomenon, nothing satisfactory has yet been advanced. That wax and grease should destroy the power which plates of glass and some other substances have of attracting and raising water, seems very extraordinary. It is commonly said that the liquid will not *stick* to these, and hence they will not rise. This seems to be a very clumsy explanation; and the cause appears to us to lie a little farther from the surface. May capillary attraction not be one of the various ways in which electricity developes itself? That chemical attraction results from bodies being in opposite states of electricity, has now been rendered highly probable; indeed, a majority of European philosophers are of this opinion, and it seems quite philosophical to bring it forward as explanatory of these kinds of attraction. But it is impossible to pursue the subject farther in this place.

HYDRAULICS.

The division of science which we have endeavoured to present a view of in the foregoing pages, is so closely or rather so inseparably connected with that upon which we are now about to enter, that part of what properly belongs to Hydraulics it was found necessary, for the sake of clearness, to give under Hydrostatics; whilst parts of the subject which ought, in a strict division of the science of watery fluids, to have appeared under Hydrostatics, will now be found under Hydraulics. But it should ever be kept in mind by the general reader, as well as by the student, that these sciences ought always to be studied together, and with reference to each other, else only a very superficial knowledge of either of them will be obtained. Hydraulics, then, being the science of fluids in motion, has for its object the investigation of the motions of such fluids as water, the methods by which these are effected, the laws which regulate their production, and the results of their impact either with themselves or with solids. The particles of liquids having little cohesion, a mass of fluid, such as water, cannot assume any particular form without some external support, but always takes that of the vessel which contines it. From this cause arises the difference which exists between their pressure and motion, and that of solids. A solid "moveth all together if it move at all," and can only produce a pressure downwards, upwards, or laterally, according to the direction in which it may be impelled, and in only one of these directions at once. If it be at rest, its pressure is downwards; but a fluid at rest presses in every direction at the same instant, and a part of a fluid mass may then be in motion, whilst other parts of it are perfectly quiescent. This constitutes the principal difference between the motions of solids and fluids. The subject seems to be naturally divided into three distinct heads:—1. The natural motions of fluids in ducts and channels, independent of mechanical contrivances. 2. The artificial motions of fluids, as produced by pumps and other hydraulic machines. And, 3. The power generated by fluids flowing under either of these circumstances.

The following facts, already stated under Hydrostatics, it will be necessary to recall to recollection:—That the particles of fluids flow over or amongst themselves with less friction and impediment to motion than when they have to pass over solid substances. That all fluids, when in a state of perfect rest, have level surfaces; that is, not a level plane, but a surface every point of which is equidistant from the centre of the earth, to which every particle tends by the power of gravitation. That fluids have a natural tendency to assume this level; and that the weight or pressure of fluids is simply as their quantities or heights. Thus, if a perpendicular pipe, three inches in diameter and three feet in length, contains nine pounds of water, it will exert a pressure of nine pounds upon any valve or stopper of any description, which is three inches in diameter, and placed in the bottom of the pipe; and that, if the pipe be made twice as high, twice the pressure will be exerted; if three times the length, three times the pressure, and so on. This is a circumstance of great consequence in the construction of pumps and engines for raising water.

FLOW OF WATER FROM A VESSEL.

When a vessel containing water is pierced at the side or bottom, the water flows out with a certain degree of velocity, in accordance with the law by which it seeks its level. In flowing out, those particles which were in immediate contact with the hole will be first discharged, creating for an instant a vacuum or void space above the hole; but the particles of fluids moving easily amongst themselves, it is immediately filled. The pressure is not that of a perpendicular column of particles, for the fluid pressing in all directions alike, there is from all parts of the vessel a general rush as it were to the outlet, thus putting the whole mass in motion. But the rapidity with which water thus set free flows, depends upon the depth. Thus, if a vessel ten feet high be penetrated at the side on a level with the bottom, and the water stand at two feet and a half within, it will issue outwards with a certain degree of velocity. If the height of the water be quadrupled, that is, if the vessel be filled, the velocity will be doubled. In order to obtain a threefold velocity, a ninefold depth is necessary, for a fourfold velocity sixteen times the depth is required, and so on. In fact, in whatever proportion the velocity of efflux is increased, the quantity of liquid discharged in a given time must be also increased; hence the pressure or the depth must be increased in proportion to the quantity discharged, as well as in proportion to the velocity. There is here a striking coincidence between the descent of water and the relation which exists between the height from which a body falls and the velocity acquired at the end of the fall, as described in Natural Philosophy.—*See that article.*

The motion of a solid down an inclined plane can be easily calculated, but that of a fluid moving in the same manner—that is, in the ordinary bed of a river, from a higher to a lower level—is very difficult to ascertain. Indeed, the results of theoretical computation are so very uncertain, that little or no dependence can be placed upon them. It is easy to find out the amount of friction between a solid and the surface upon which it moves; not so that of a fluid. When a solid is set in motion, all the parts move with the same degree of velocity, but in a mass of moving water, such as a river, some parts of it move with greater velocity than others; some are almost stationary, and occasionally there is a current at the sides moving in a contrary direction altogether. In all rivers there is a main current in the centre, which flows with greater rapidity than the water at the sides; and this is also the case with water in pipes. The fluid which is in contact with the pipe moves with more resistance than that at the centre, by which the calculated discharge of any given pipe of considerable length becomes much less than is due to its magnitude; hence the propriety of always making the conveying pipe of larger dimensions than would otherwise be necessary were there no obstruction from friction. Other circumstances also retard the motion of running water, such as sharp or right-angled turns, which form eddies or currents. It is therefore always proper in conducting water by means of pipes to any place, when it is necessary to bend the pipe, to make the curve as large and gradual as possible. And care should be taken not only to have the pipe of dimensions sufficiently capacious to afford the necessary supply, but also to have it of an equal bore throughout, and free from all projections and irregularities. These subjects have been particularly investigated and examined by Newton, Bernoulli d'Alembert, De Buat Robeson, Venturi, Dr Young, and many others; and the following important practical results obtained from their labours are highly worthy of attention:—First, the friction of water in rivers or channels increases as the square of the velocity. Second, although the sides of a pipe must in every case produce a certain degree of friction, yet that defect is frequently overbalanced by a duly-proportioned size of pipe properly fixed, giving a moving direction to the fluid which it would not otherwise obtain, and by which a greater quantity of discharge is produced than could otherwise take place. Thus, for example, a vessel or reservoir, having a thin bottom of tin, with a smooth circular hole formed therein, might be supposed most capable of parting rapidly with its water, because the fluid in running out has no continued length of substance to rub against, and consequently it might be imagined that very little friction could be generated; but M. Venturi found, by his experiments, that such a vessel did not discharge its water so rapidly as another containing the same height of water and area of hole to which a short pipe of the same diameter as the hole was applied; and by varying the length of pipe, he ascertained, that, when its length was equal to twice its diameter, it produced the most rapid discharge; for, being so circumstanced, it discharged eighty-two quarts of water in one hundred seconds, whilst the hole without the pipe discharged in the same time only sixty-two quarts. He also found, that if the pipe, instead of being flush or level with the bottom of the reservoir, entered into it to some distance, it had the effect of making the flow of water even less than that which issued through the simple hole without any pipe. The singular fact of a pipe and hole of the same dimensions discharging different quantities of water under different circumstances, whilst the head of pressure remains the same, must be accounted for by their being cross or opposing currents created by the rush which all fluids make to the orifice. Currents will thus form from the top and sides of the containing vessel, and by their inertia they will cross each other, and thus impede the descent of the perpendicular column, causing the water which issues to run in a screw-like form; this, however, is in a great measure obviated by the application of a short tube below the hole, such as we have described. That the projection of the tube too far into the interior of the vessel should make the flow less than if there were no pipe at all, may be thus explained:—The columns which descend from near the outside of the vessel, by turning up again to reach the discharging orifice, come into more direct opposition to the motion of the central descending columns, whilst they are at the same time themselves compelled to turn suddenly in opposition to their own inertia before they can enter the pipe. Thus, the discharge is more effectually impeded than if it were proceeding from a mere hole in the bottom of the vessel.

It was discovered by Sir Isaac Newton that the figure formed by fluids flowing to a common centre or orifice, such as we have described, was what is technically called a hyperboloid of the fourth order; and Venturi, after ascertaining the facts already mentioned, applied a pipe of the natural form of running water to the bottom of a reservoir, and found, that, although the external orifice was the same as before, the discharge was increased to 98 quarts in the same period of time. He also conjectured that the curve which water assumes in running was continued beyond the point of discharge, and, accordingly, enlarged or opened up the lower end, from which he obtained the maximum quantity of water that could be delivered from a vessel in a given time by a given orifice. To obtain these results, the discharging-pipe must be bell or trumpet-mouthed, or funnel-shaped, both internally and externally. Thus, by the simplest means possible, the flow of water from a reservoir may be increased or impeded in practice. Running fluids communicate a lateral motion to the bodies through which they flow. Thus, when a river runs through a sheet of water in a quiescent state, it loses a part of its own motion, which is communicated to the waters of the lake, and the current is thus retarded in its progress. Nor is this motion imparted confined to a fluid of the same kind as that from which the impulse is received. A column of water in its descent through the atmosphere in the form of a cataract, produces in some instances a current of air which can scarcely be withstood. This lateral communication of motion, combined with the irregularities in the shape of beds and banks of rivers, produces those eddies and petty whirlpools which are so frequently observed. It is also obvious that these irregularities in the bottoms and sides of rivers necessarily retard their currents; and although water in descending follows the same laws as solid bodies, and has its motion accelerated on account of this friction, it is impossible to calculate with any degree of certainty the exact velocity of rivers.

FLUID RESISTANCE.

With regard to the resistance which a fluid offers to a solid body which is impelled through it, one proposition will be obvious to every one, that the resistance will be greater the denser the fluid, and the larger the surface is which moves in it. It is also very clear that the figure of the body has a very material influence upon the amount of resistance offered to it. Thus, a wedge impelled by the sharp end will move far more easily through water than if the broad extremity were pushed forward in the liquid. Bossut instituted several experiments for the purpose of determining the absolute resistance sustained by a solid moving in a fluid. He found, that if a flat board were moved perpendicularly against a liquid, it would suffer a resistance equal to the weight of a column of the fluid, the base of which is equal to the board, and its height equal to the height from which a body should fall, in order to acquire the velocity with which the board is moved against the liquid. Of course it follows, that the resistance of a fluid will depend upon its specific gravity. When a jet of liquid strikes a solid at rest, it is found that the absolute resistance is different, but that its variation depends upon the same laws. In this case, the force sustained by the solid is equal to the weight of a column of the liquid whose height is double the height from which a body should fall to acquire the velocity. Hence it follows, that a column of liquid striking a solid with a certain degree of velocity, produces an effect amounting to double that which would be produced by moving the solid with the same velocity in a similar liquid at rest.

That a body which moves through the water with a given speed, and meets a given resistance, should, when moved twice as fast, just meet with double the former resistance, seems at a first glance to be a very obvious conclusion. But this is not the case; the resistance is four times greater with a double rate. The fact is thus easily explained: A vessel moving at the rate of one mile per hour displaces a certain quantity of water, and with a certain velocity; if it moves twice as fast, it of course displaces twice as many particles in the same time, and requires to be moved by twice the force on that account; but it also displaces every particle with a double velocity, and requires another doubling of the power on this account; the power thus twice doubled, becomes a power of four. When the body is moved with a speed of three or four, a force of nine or sixteen is wanted, and so on. Thus, in the language of mathematics, the resistance increases as the square of the speed.

This important law suggests many practical hints of very considerable importance. For instance, in steam navigation, if an engine of fifty horse power impel a vessel at the rate of seven miles an hour, it would require two of the same power to drive her ten miles an hour, and three such to drive her twelve miles an hour. Hence the enormous expense of fuel attending the gaining of a high degree of velocity; and in steam-vessels which sail to distant parts, it is better that the speed be medium than great; because as in these the fuel necessary for the voyage is a principal consideration, nothing would be saved by the celerity with which the vessel gained her destination; the immense space necessary for the additional coal required would far more than counterbalance any thing gained in time by increased velocity.

The law above explained holds equally in the case of a fluid moving against a solid. If a current be moving against a ship at the rate of four miles an hour, the strain upon her cable is not one-fourth part so great as it would be were the current flowing at the rate of eight miles per hour; and the same may be said of the force of the winds.

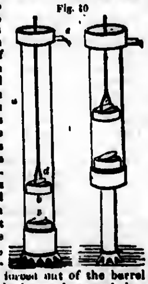
We have said that the resistance between a fluid and a solid is influenced by the shape of the solid. A flat or plane surface moved in water throws the particles of a fluid almost directly outwards from its centre to its circumference, whilst a concave or wedge-like surface, although it displaces them just as far, does so more slowly and with a less expenditure of force, and this in proportion as the tapering point is in advance of the broadest extremity. Obliquity of surface in a solid which is to move through water is therefore an important consideration in the construction of vessels of all kinds. We see in nature many instances of a wise provision of this kind in the shape of animals. Birds, and especially those of rapid flight, have a neck and breast tapering from before, and increasing by slow degrees towards the thicker part of the body, thus considerably diminishing the resistance of the air. Fishes have also been fashioned with a due regard to this principle.

PUMPS AND MACHINES FOR RAISING WATER.

There are various kinds of machines for elevating water above the level at which it stands in a reservoir. Those first used were wrought by mechanical force, without reference to atmospheric pressure. The most celebrated of these simple machines are the screw of Archimedes and the Persian wheel. The former consists of a long hollow tube, twisted into a spiral form, with an axle at the upper end, to which is attached a handle for the purpose of winding round the screw. The machine is laid in the water intended to be raised, at an angle of about forty-five degrees, the lower end dipping into it at every turn made by the handle. By this means a quantity of water passes into the hollow tube, which, being forced upwards into a higher convolution of the pipe at every revolution, is at last ejected at the upper end, where it can be caught in a vessel, or carried off by means of a spout. The Persian wheel consists of a rim or circle of wood of considerable diameter. It is provided with a number of iron bolts projecting outwards, firmly fixed, to which are attached a number of buckets. When the wheel is driven round, these buckets dip into the water or mud which is intended to be raised; and since they turn in the bolts (as long as they are not in contact with any thing) so as to keep the open end always upwards, they are elevated with the wheel, until coming in contact with a cistern at the top, they are tilted up, and discharge their contents into it. Going down empty on the other side, they are again filled and raised as before. The *bucket-engine* and *chain-pump* are but modifications of the above described machines, and are very useful in particular situations.

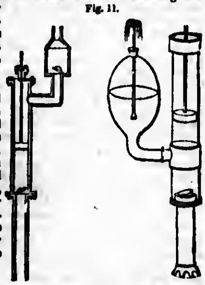
The next class of machines are those in which the water is raised by the pressure of the atmosphere, and to which the name of *pump* is applied. They act upon the principle of removing the pressure of the atmosphere from the surface of the water; when this is effected, water will rise independently of any other artificial contrivance, to the height of about thirty-two feet. The principle upon which this is effected will be fully explained in one sheet upon the properties of Air, or Pneumatics. In the accompanying diagram are shown two forms of the common sucking-pump. It consists of a cylinder *a*, furnished with a piston *b*, made to fit air-tight. When the piston is raised, a vacuum is formed in that portion of the cylinder through which it has moved upwards, and the pressure of the air upon the surface of the water on the outside of the tube forces the fluid into it. The valve *c*, which opens upwards, is lifted, and the water rushes in above it. When the upward stroke of the piston is complete, it is again depressed—the water passes through the valve *d*; and on the next stroke, it is discharged at the spout *e*. It is evident, that, when the piston is sunk downwards, the water cannot be forced out of the barrel again, because the valve at the bottom is pressed close down, and prevents its escape.

Fig. 10



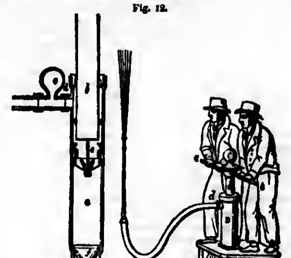
The force-pump is of more universal application than the above. It consists of a cylinder and piston, as in the former case, but the latter is constructed without a valve. In the right-hand figure of the following engraving, the piston sucks the water by its upward motion; but, on depressing it, the water passes by the side-pipe, and enters the air-vessel. The pipe placed in the centre serves to discharge the water, and the air by its elasticity ensures a continuous flow. In the left-hand figure, the piston is pierced for a valve, which would be too small to be indicated in the engraving, and when the water is above the piston, it is discharged by the air-vessel placed at the top, as in the former case. In this arrangement of the pump, the water may be raised to any required height.

Fig. 11.



Mr Perkins has made numerous improvements upon the forcing-pump. These may be enumerated under three heads. 1st, The enlargement of the bottom of the pump, or suction-pipe, which is so contrived as to allow all bodies heavier than water, as sand, stones, pieces of iron, &c., to subside by their own gravity, so as to prevent the inconvenience of the pumps choking, as frequently occurs on shipboard under circumstances of extreme danger. 2dly, The combination of the plunger and the pump-box, so as to produce a forcing stroke both by the ascent and descent of the plunger. And, 3dly, The separation of the valves from the stuffing of the pump-box, by which means a much larger water-way is effected than in any pump of similar size hitherto produced.

Fig. 12.



The left-hand figure exhibits a section of a fixed pump for raising water from wells, or out of the hold of a ship, which is also capable of being converted into a forcing-pump, for extinguishing fire, &c. *a* is the chamber or working barrel of the pump, and *b* a plunger, smaller than the calibre of the barrel, working up and down through a stuffing-box; *c* is an air vessel, which may be attached to the nozzle *d*, when it is required to be converted into a forcing-pump or fire engine, in which case the hose is to be connected to the end of the nozzle; *e*, the valve-box, which is made water-tight by fitting accurately in the barrel; the bottom of the pump may be enlarged, as shown in the right-hand figure at *f*, in order to prevent all heavy substances from coming up with the water, and getting into the pump barrel.

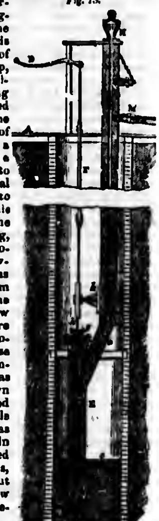
The right-hand figure represents a portable forcing-pump, to be employed either as a garden engine or fire engine, in which *a* is the chamber, *b* the plunger, passing through the stuffing-box, the interior parts of which are shown in the left-hand figure. In this portable pump, however, it is to be particularly remarked that the plunger *b* is made hollow, for the purpose of allowing the water to rise within it up into an air vessel *c*, at the top of the plunger; *e e* are the handles by which the plunger is to be raised and depressed by the men standing upon a platform.

Wooden pumps may sometimes be employed with advantage, though they seldom last more than forty or fifty years. The figure at the top of the next column represents one of the best forms of this pump.

A represents the surface of the ground, and B B the section of the brickwork forming the wall. The water stands at the ordinary level *c*. D is the lever or handle of the pump, which has the rod F jointed to it, and descending to the pump; the rod is made of wood, in several lengths, which are united by joints of iron; the wooden rods being capped with iron forks, which include the ends of them, and are rivetted fast; the ends of the forks are jointed together to connect the several lengths.

E is the working barrel or chamber of the pump in which the bucket *d* works; this part is formed of a tree bored through, and having a projecting branch *e*, which is bored obliquely to the barrel, and forms the forcing-pipe; in the bottom of the barrel the suction valve *f* is situated, being at the top of the suction part of the pump, which is bored with a smaller auger than the working chamber, which is also lined with a brass tube where the bucket works. The top of the barrel is covered by a metal lid *g*, which has a stuffing-box in the centre to receive the metal cylindrical part of the pump-rod *h*; to the lower extremity of this the bucket *d* is fixed. The metal lid consists of a ring, which is screwed to the wooden barrel by five screw-bolts passing through as many ears, projecting from the circumference of the ring; they have eyes below to hook upon pins which are fixed in the wood, but project sufficiently for these bolts to hold, and are formed into screws above, so as to hold the ring firmly down by means of nuts screwed upon them. The moveable lid of the pump, which has the stuffing-box *g* formed in the centre of it, is screwed to the ring by five screws, and these can be taken out to remove the lid and draw up the bucket when it requires to be leathered.

Fig. 13.



k is the forcing-pipe, formed of as many pieces of wooden pipes as are required to make up the length; they are united together by making the upper ends conical to enter a similar cavity made in the lower end of the next pipe; the lowest piece fits upon the extremity of the projecting branch *e*, and a valve is proposed to be put in the pipe at this joint to prevent the return of the water and bear part of the weight of the column from the lowest valve at *f*; the upper length of the pipe has a spout *i*, at which the water is delivered.

M is a second spout, fixed into the pipe lower than the former; it has a screw by which it can be united to a hole or leather pipe to convey the water to a distance; or by means of a jet, or branch-pipe, to throw it in the manner of a fire engine; in this case the upper spout *i* must be stopped up, by a screw, plug, or cap; and there is a copper air-tight vessel H, situated at the top of the wooden pipe, to equalise the pulsative motion of the water, as thrown by the pump.

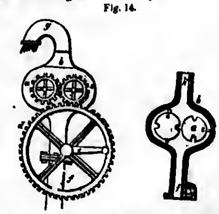
There is a bracket fixed to the pipe *k*, and projecting over the centre of the pump, where it has a hole to receive the pump-rod *h*, and guide it steadily in its motion up and down, that it may not wear the stuffing-box away on one side. As the wooden tubes of which this forcing pump is composed may be made from waste or crooked timber, it makes a great difference between the low price of such, and that of the straight trees necessary for common pumps.

A wooden plug may be chained to the pump betwixt the spouts or nozzles M and *i*, so as to be ready to stop that which is not wanted in use.

Mr Stephens, who was rewarded by the Society of Arts for this arrangement of the pump, is of opinion that it is better to place the valve *f* beneath the level of the water in the well.

There is a valuable rotatory pump invented by Mr Eve, which nearly resembles one form of the steam-engine. The two figures beneath will serve to show the general arrangements of its parts.

Fig. 14.



The left-hand figure represents an external view of the pump. Two cylinders turning on axles are placed in contact, and made to revolve in opposite directions in an outer case *a b c*, through the ends of which the axles protrude; each cylinder has two wings, leaves, or pistons, *c c*, shown in the next figure, and two recesses; and, in revolving, the wing or leaf of one cylinder falls regularly into the recess of the other, where their peripheries touch, and so on alternately. The equal motions of these cylinders are regulated by a pair of wheels *a a*, gearing into each other, placed outside the case, and affixed to the projecting axles. The speed of the wheels which drive the cylinders round is increased by a larger toothed wheel *d*, to be worked by a common handle *e*. The pump-case is connected by means of flanches and screws to a pipe *f*, leading down to the well. The two cylinders above described are three inches and a half in diameter, by six inches long, and the wings three quarters of an inch. The quantity of water pumped up by two men placed at the handle of the multiplying wheel, would be half a ton in three minutes.

Rotatory motion being given by means of the winch *e* to the large wheel, the teeth upon that wheel take into and actuate the pair of small toothed-wheels *a a*, which work into each other; and these, being affixed to the axles of the cylinder *a*, cause them to revolve with their peripheries in contact. The outer edges of the leaves *c* slide round against the circular parts of the interior of the box *b*, and by creating a partial vacuum, in the first instance, in the rising main *f*, causes the water to flow into the box. As the cylinders revolve, the leaves *c*, now lifting the volumes of water which encompass the outer halves of the peripheries of the cylinders *a*, force it to the upper part of the box, and thence through the discharge-pipe *g*. This pump possesses many advantages over the ordinary reciprocating pump.

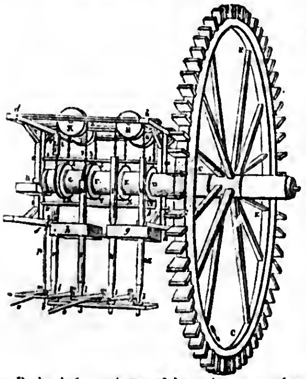
The operation of the *double plunger-pump* is entirely independent of pneumatic pressure, and is well calculated, both from its simplicity and effect, for raising large quantities of water to small heights. It is made by fitting two upright beams or plungers, of equal thickness throughout, into cavities nearly of the same size, allowing them only room to move without friction, and connecting the plungers by a horizontal beam moving on a pivot, as shown in

Fig. 15.

The water, being admitted during the ascent of each plunger through a large valve in the bottom of the cavity, is forced, when the plunger descends, to escape through a second valve in the side of the cavity, and to ascend by a wide pipe to the level of the beam. The plungers ought not to be in any degree tapered, on account of the great force which would be unnecessarily consumed in continually throwing out the water with great velocity as they descend, from the interstice formed by their elevation. This pump may be worked by a labourer walking backwards and forwards, either on the beam or on a board suspended below it.

The *compound plunger-pump* was formerly employed in almost all large water-works; and one of the best specimens is delineated beneath.

Fig. 16.



B, the shaft or axle-tree of the engine, twenty-four feet long, and twenty-four inches diameter.

C C C C, an undershot water-wheel thirty feet diameter; its vanes eighteen inches broad. The water-way eighteen inches broad and twelve deep. The fall seven feet. D E F G, four moveable rings or collars placed on the shaft, about three feet in diameter, and six inches broad.

H I K L, four forcers, rising and falling alternately by means of the collars having four chains fastened to the collars and the tops of the forcers, as W X Y Z represents. The forcer L is cut off, to show the chain more plain. As the collar G moves (with the wheel and axle) half round, the chain Z fixed at one end to the lower part of the collar G at 2, and its other end at the top of the forcer L l, will pull down the forcer L l four feet and a half, and at the same time a chain 1 to the head of the forcer L l, going over a pulley R, and to the head of K, pulls up the forcer K four feet and a half, by which time the collar G will have carried its trigger 2 up to the bar 1, 1, which will unlock its trigger, and the trigger 3 in the collar F will be brought backwards down to Y, and there lock the collar F. Then, the movement continuing, K will be depressed four feet and a half, and the chain 1, 1, over the pulley R, will raise four feet and a half. And thus these two forcers and collars continue rising and falling, moving forwards and backwards, locking and unlocking alternately. And in like manner the other two collars D and E move with their forcers H and I.

But to prevent one collar moving the backward way faster than the other moves forward, there is a guage-chain 4 fixed to the collar G, passing over another pulley T to the collar F at 5, which regulates their motions. These chains are lengthened or shortened by screws as occasion requires.

M N O P, four brass cylinders or pumps, seven feet long; the bores of M and N six inches diameter, and O P seven inches and a quarter; having at *l l l l* each a valve below, which are for taking in the water; and at *m m m m* valves in the horizontal parts.

The branches *n n*, *n n*, communicate the water of their two forcers together by *o o*, and so into one pipe *o*. Then O is joined to *o* coming from the other two, so the whole water is forced along one pipe.

g h are two cisterns supplied by a pipe in *p*, to keep the forcers or pistons always wet.

a b c d e f is a frame of wood to carry the pulleys Q R S T, and the bars *i i*, *k k*.*

HYDRAULIC MACHINES.

As a mover of machinery, water has been employed from a very early period. Water-wheels vary in their construction; the chief forms which they assume are denominated overshot, undershot, and breast-wheels.

Undershot-Wheel.—A common water-wheel must have been so often seen by every one, that any pictorial representation of it is unnecessary in this place. All water-wheels consist in common of a hollow cylinder or drum revolving on a central axle or spindle, from which the power to be used is communicated, while their exterior surface is covered with vanes, float-boards, or cavities, upon which the water is to act. The undershot, tide, or stream-wheel, is by far the oldest construction of the kind in use, and was for a long time the most common. It is the cheapest and simplest of water-wheels, and consists of a large drum, such as we have described, having vanes or float-boards projecting outwards. The toothed-wheel of any machine exactly represents a common undershot-wheel. Suppose this placed upon a stream of running water, so that these broad vanes of wood or float-boards dip to a short depth in the water, it is evident that the wheel will be driven round by the force of the water which flows against them. As this kind of wheel requires no other fall in the water than that which is necessary to produce a rapid progressive motion in it, and as it acts chiefly by the momentum of the water, its positive weight being scarcely called at all into action, it is only fit to be used when there is a profusion of water always in motion. Hence, it is more applicable to rivers in their natural state than any other form. As it works equally well upon either side of its float-boards, it is particularly applicable to tide-rivers, where the current sometimes runs in one direction, and at other times in an opposite course. Advantages are gained by not making the float-boards point to the centre of the wheel, but giving them a sloping or oblique direction a slight inclination from the centre. The following observations are from the pen, we believe, of Lord Brougham:—

"As action and reaction are always equal, but in contrary directions, of course it is the same thing whether the power of the moving water be applied to the float-boards of a wheel which revolves in a fixed building, or whether any extraneous force be applied to the axle of a wheel to cause it to move in still water. In the first case, the power of the water will be transferred to the axle of the wheel, and is applicable to the driving or moving of machinery; while, in the second case, the power applied to the axle will be resisted by the quiescent water, and will be converted into so much power for moving the building or boat in which the wheel is placed; and upon this principle depends the action of those steam-boats which are impelled through the water by means of water-wheels driven round by the power of steam-engines applied to their axles, instead of permitting the water to move the float-boards, and transfer its power to the axle.

Whenever the weight and motion of water can be made use of, as well as its momentum, much greater effects can be produced than the last described machine is capable of, and with a much less lavish expenditure of the fluid, for then its utmost powers of action are brought into play at once; and accordingly those water-wheels that are distinguished by the names of breast-wheels and overshot-wheels, will produce much greater power with a much less supply of water than the undershot-wheel already described. The overshot water-wheel, which of all others gives the greatest power with the least expense of water, requires a fall in the stream equal to rather more than its own diameter; therefore it is customary to give this description of wheel a greater length in proportion to its height than is given to any other, by which an equality of power is obtained. In the construction of the overshot-wheel, a hollow cylinder or drum, that is impervious to water, is fit prepared, and hung upon a proper central axis. A number of narrow troughs or cells, generally formed of thin plates of metal, extending from one end of the drum to the other, are next fixed round the outside of the wheel, so as to give a transverse section through the middle of the wheel. The water is conducted by a level trough of the same width as the wheel over its top, and is discharged into the buckets or cells placed round the wheel to receive it. From the particular form of these buckets, they retain the water thus thrown into them, until by their motion they descend towards the bottom, when their mouths being turned downwards, they discharge their contents into the tail-stream, where the water runs to waste. The buckets on the opposite side of the wheel descend with their mouths downwards, and thus remain empty, until they arrive under the end of the water-trough to be refilled, where there is a penstock or sluice for regulating the quantity of water and preventing waste. The overshot-wheel acts by the gravity or weight of the water contained in the buckets for nearly one-third of its circumference; and from the experiments of Mr Smeaton, which were made with great accuracy, it appears that the dimensions, quantity of water, and height of fall being the same, the overshot-wheel will produce double the effect of the undershot.

The breast-wheel is by far the most common, and may be considered as a mean between the two varieties before mentioned. In this, the water, instead of passing over the top of the wheel, or entirely beneath it, is delivered about half-way up it, or rather below the level of the axis, and the race or brickwork upon which the water descends is built in a circular form, having the same common centre with the wheel itself, so as to make it parallel to the exterior edges of the float-boards or extreme circumference of the wheel. It is formed with float-boards in the same manner as the undershot-wheel; but instead of the water acting upon its lower part, it is introduced upon it at the middle by the sluice or penstock, which, by rising or falling, permits a greater or less quantity of water to act on the wheel; and as the float-boards are made to fit as accurately as possible, without contact, into a circular hollow of brickwork, no water can escape past the wheel without producing its proportionate effect.

Mr Smeaton makes no observations on the nature of breast-wheels in his valuable papers on the subject, except to state that all wheels by which the water is prevented from descending, unless the wheel moves therewith, are to be considered of the nature of overshot-wheels, having power in proportion to the perpendicular height from which the water descends; while all those that receive the impulse or shock of the water, whether in an horizontal, perpendicular, or oblique direction, are to be considered as undershot. The breast-wheel is nearly allied to the overshot; for, notwithstanding it has only float-boards instead of buckets, yet as the mill-course is made concentric to the outside of the wheel, and is not only there, but at the two sides made as close as convenient, so as to prevent the escape of water as effectually as possible, the spaces between one float-board and another become buckets for the time being, and retain the water; and thus the breast-wheel is not only impelled by the weight of water, but by its impetus or momentum also, for the water is so confined as to be incapable of splashing or being lost, and consequently its moving force may be exerted to great advantage. Notwithstanding this apparent superiority, still the breast-wheel is, in effect, vastly inferior to the overshot-wheel, not only on account of the smaller height at which the water is supplied, but from the waste with which it must always be attended, even under circumstances of the most perfect workmanship."

There is a water-mill known by the name of Barker's centrifugal mill. It consists of a hollow upright tube of metal, terminating at the upper end in a funnel, and attached to an upright axle having a toothed-wheel, from which motion may be communicated to any machinery. The lower end, which is closed, turns in a socket, a little above which there passes through the hollow upright tube another at right angles to it, having a communication with it, and opening into it in the inside. Each extremity of this horizontal tube is perforated on opposite sides as near the end as possible, so that water issuing out of them horizontally, and spouting in opposite directions, drives the machine round. The motion results principally from the centrifugal force, which is generated in the horizontal pipe, and not, as is generally stated, from the resistance of the air, for the machine will move in a vacuum.

No. 40 PRICE 1½d.

HISTORY AND PRESENT STATE OF EDUCATION.

GENERAL HISTORY.*

As the object of education is to make the rising generation as well-informed, or as capable of receiving information, as that which has given it birth, by which means the disadvantage arising from the perpetual renewing of the human race may be obviated, it is natural to suppose that, as soon as there was any knowledge in the world, and the state of things had become in other respects suitable, there would be establishments for the instruction of youth. There was some knowledge in the world at a very early period—something even like literature from fifteen hundred to two thousand years before the birth of Christ. Knowledge, however, was in those days confined to narrow classes: the blessed light had no sooner sprung up, than it became a matter of monopoly, and an instrument of power. Schools were accordingly established only for the sons of the great, and for priests. Moses was educated in a priestly school in Egypt, Cyrus at a seminary connected with the Persian court; the Indian brahmins imparted instruction in secret schools; in Palestine, those conversant with the Scriptures taught in the schools of the prophets, at later periods in the synagogues and the schools of the rabbies. The advantages of these schools were attainable by few; the means of learning were limited to conversation, reading, committing to memory, and hearing the explanation of sacred books. The very difficulty of putting knowledge into a written shape must have operated powerfully in those days against its being communicated to youth.

In Greece there were schools almost from the dawn of letters, and in Rome from the year 300 before Christ. These, however, did little for any except the higher class of youths, and nothing whatever for children who resided in the country. From the age of Cæsar, Rome had the higher class of teachers called grammarians, who taught Greek and Latin systematically, and from whose hands the youth of best talent were transferred to the rhetoricians, who qualified them for speaking in public. Till the time of Vespasian, near the close of the first century, the Roman schools were matters of private enterprise alone; and it was only from Cæsar that teachers acquired the rights of citizenship. Vespasian for the first time established public professorships for grammar and rhetoric, with fixed salaries attached to them, for the education of young men for the public service; and about the year 150, Antoninus Pius founded what were called imperial schools in the larger cities of the empire. Though there was no systematic cooperation among the various professors, the imperial school at Rome, after the organisation which it received, in 370, from Valentinian, approached near in character to the modern German universities. In the lower schools of the ancient Romans, the rod was not spared; and Ovid is not the only one who complained of the severity of an Orbilius.

Christianity by degrees gave a new turn to education. In the East, it came gradually into the hands of the clergy, and under their superintendence. Schools were instituted in the cities and villages for teaching religion to youth catechetically, and in some capitals there were others for the instruction of clergymen: that of Alexandria was, from the second to the fourth century, the most prosperous of all the academies of the latter description. Rather apparently from the accident of schools having thus fallen at first under the care of ecclesiastics, than any other cause, it has been impossible, ever since that early time, in any country, to obtain a secular education at a public school, without at the same time imbibing or at least submitting to the dogmas of a religious party. From the fifth century, the clergy were chiefly taught at the episcopal schools, where, besides theology, the seven liberal arts—grammar, logic, rhetoric (these three formed what was called the *trivium*), arithmetic, geometry, astronomy, and music (these four were termed the *quadrivium*)—were taught from the *Encyclopædia* of Marcianus Capella, a poor compendium which appeared at Rome in 470, and continued for upwards of a thousand years to be the common text-book of the schools of Europe. Gradually, as the Roman empire declined, the imperial schools sunk also; and as Christianity rose on the ruins of the empire, so were schools under the charge of the Christian clergy established in their place. At these institutions, boys of all classes were instructed in reading and writing, which were generally followed by the *trivium* (grammar, logic, and rhetoric): hence the appellation of Trivial Schools, which came to be applied to such seminaries.

Throughout the middle ages, learning and religion are always found together: there is nowhere the one without the other. About the seventh century, a new class of schools rose into importance, but still in connection with devotion. They were originally designed to prepare persons for the monastic life, which now began to be followed in many places, but gradually became seats of instruction for laymen also. From their always being connected with convents, they were called Conventual Schools. The Benedictine convents, which flourished in England, Ireland, France, and Germany, from the sixth to the eleventh century, forming a bright though slender link between the civilisation of ancient and modern times, were the chief seats of these seminaries. The discipline was severe and monkish; but the instruction was generally better than in other institutions, partly on account of the many distinguished literary men who embraced the monastic life, and partly on account of the superior collections of books which they possessed. The conventual schools at Canterbury, Westminster, and York; at Armagh and Clogher; at Paris, Tours, Rheims, and Clermont; at Salzburg, Ratisbon, Hersfeld, Corvey, &c. were particularly famous. These are "the schools" so frequently alluded to in modern literature as the birthplace of the scholastic philosophy, which may be said to have consisted in an endless wrangling misuse of the philosophy of Aristotle—the apparition of reasoning, without the body of reason.

Charlemagne, who in 789 issued a decree for the improvement of the schools throughout his extensive dominions, was the first modern sovereign who thought of lending state influence to the noble cause of education. This illustrious man, after placing himself at a school which he established for the use of his court, undertook the superintendence of the seminaries throughout his empire, had reports sent to him, made examinations, and, by every means in his power, endeavoured to enlighten the nations under his sway. Alfred of England made similar exertions for the promotion of education; but scarcely had these great men passed away, when the tide of barbarism, like the waters of the Red Sea after the passage of the Israelites, resumed its usual flow, and obliterated all their efforts. Learning was not as yet able to exist, except where it was protected under the robe of religion.

The ninth century is the era of the Cathedral Schools. The clergy of the bishops' churches then adopted the canonical life, and at the same time commenced seminaries for the education of the clerical order, of which the schools of St Paul's, Winchester, and others, may be considered as surviving specimens or relics. About the same period, Jewish and Arabian teachers were introducing ancient literature into the south of Europe, as well as a knowledge of mathematics, of medicine, and of natural history.

Schools for instruction in law were now established in several parts of the Continent. That of Bologna was perhaps the most famous; and the privileges which it received in 1158 from the Emperor Frederick I., became the foundation of the constitution of the Universities, which originated in this and the subsequent centuries.

From this time, on account of the inactivity and luxury of the clergy, the Cathedral and Conventual Schools began to decline; but still, wherever there were places for instruction, this class of men maintained a controlling, and in too many instances a counteracting, power. The monks intruded even into the universities, where they laboured to augment the importance of their various orders, and the power of the Pope. In the upper schools, they caused the scholars to waste most of their time in copying the manuals: in the lower, they would not permit the pupils to learn writing at all, being desirous to confine the art, which was highly lucrative, to themselves. The exercises were mere matters of parrot-song, without any care being taken that the pupils understood what they learned. For a long time, the privilege of establishing writing-schools for the children of citizens could not be obtained by magistrates except by special agreement with the clergy; but at length, as the cities increased in independence, the magistrates took this as well as other branches of instruction under their own charge, though they could hardly obtain teachers who were not of the clerical order. It is surprising how long mankind were in seeing the necessity of a distinct profession of teaching. Luther, in the sixteenth century, complains of the wretched characters of the teachers, which he ascribes to the circumstance of the more learned youths being attracted to the church. A set of upper pupils, called *vocantivi*, or idlers, went about seeking employment as schoolmasters, and were almost the only professors of that art who could be obtained: they seem to have been mere vagrants, equally ready to act as mummers and as teachers, and subsisting by begging and plunder when other means failed.

Unique in its kind, in the history of the schools of this period, was the pious fraternity of the Jeronymites. They consisted of clergymen and laymen, who lived together, occupied partly with mechanical arts, partly with the instruction of girls and boys, to whom they taught reading, writing, and useful arts. For boys of talent and diligence, there were Latin classes. On the model of these schools, others were established in the Netherlands, on the Rhine, and in Northern Germany. These soon came into communication with the Greeks who had fled to Italy; and thus the study of the classics became more cultivated. Through the efforts of such men as Thomas à Kempis, Erasmus, and Melanchthon, a liberal study of the remains of classic antiquity was commenced. Much was done, in and after the latter half of the fourteenth century, to promote this object by Italian courts and universities, through the instrumentality of learned Greeks, and of the Platonic academy at Florence, and, towards the end of the fifteenth century, through the learned Rhenish Society, established by Conrad Celtes. It is curious that it cost as much pains to get this study introduced, as now, after its main utility is past, it will probably require to sink it to its proper place as only one of many branches of knowledge.

The Reformation gave a considerable impulse to education in almost every country where it took effect. Acting themselves under the influence of the light of knowledge, the reformers regarded the imparting of it to others as a sacred principle; nor did they fail to see, that, for a religious party to have the command of the schools where youth were taught, was the most effectual way of keeping that party dominant in the land. In Germany, the property of the convents, and of the church in general, which had been confiscated by the governments, was in most cases applied to the use of schools, the numbers of which were now greatly increased in this country, and their character elevated. Seminaries of a superior

* The Editors find it convenient to state in this place, that *elementary* education is the chief subject of the present sheet.

character, entitled gymnasia, were set up by most of the city corporations, and even in the villages instructors were appointed to teach the Catechism. So early as the year 1529, the reformers furnished a great example of the care which government should bestow on schools, by the visitations which they made of the schools in the electorate of Saxony. The example of Germany was, perhaps, more strictly followed in Scotland than in any other reformed country.

The invention of printing lent, as might be supposed, a great aid to the cause of education, not alone by the books of instruction which it more readily furnished to pupils, but by the force of that intellectual current to which it gave rise. About the end of the sixteenth century, education first became a subject of deep reflection among philosophical men. Bacon, and Amos Commenius, the exiled bishop of the Moravians, then made it the subject of treatises. During the seventeenth century, the Jesuits' schools attracted considerable notice, on account of the excellent education which they imparted to the youth of the superior orders, as well as to boys of talent selected from the humbler walks of life, for the service of the order. About the close of that century, the Pietists in Germany, and the Quietists in France—religious sects resembling the Methodists, who soon after sprung up in England—exercised a considerable influence of a beneficial kind upon education, though Latin and Greek still continued to be almost the only branches taught in any part of Europe. The idea of an education adapted to the nature and general destination of man, suggested by Bacon and Montaigne, received about this time a more complete developement from Locke: it was not practically introduced, however, till nearly a century later. The system of philanthropism, suggested by Basedow, which repudiated the rod, denounced the want of proper exercise for the children, and cried down the system of loading the memory without exercising the active faculties, then caused the establishment, in Germany, of schools, in which natural history, technology, civil arithmetic, &c., were taught, in addition to languages. The close of the eighteenth century is also the era of the system of Pestalozzi, a Swiss of simple manners and great enthusiasm, who adopted the idea of communicating all instruction by immediate address to the sensations or conceptions, and effecting the formation of the child by constantly calling all his powers into exercise, instead of making him a mere passive recipient; selecting the subjects of study, moreover, in such a way that each step should best aid the further progress of the pupil. We may only further observe, in the present department of our sheet, that education has now arrived at a point where the systems of comparatively unenlightened times are beginning to sink before a variety of new, but in almost every instance more promising, schemes; of which various scattered notices will be found in the chapters which follow.

ENGLAND.

Among the things incredible in Christendom—to use the forcible expression of a German writer—is the fact that England possesses no general system of elementary education. For the instruction of her clergy and gentry, she has several great public classical schools and two universities; but she has no national establishment, like that which exists in Prussia and other countries, to meet the convenience of the people at large, and enable every man in the kingdom to give his children the means of reading. Custom or chance has decreed that the landholders of England, instead of paying a comparative trifle to teach the lower orders, should be burdened with the enormous tax of seven millions annually to support a body of paupers, most of whom may be described as having sunk into that condition, or being born into it, through the effects of the low morality attendant upon ignorance.

To remedy as far as possible the want of a national establishment, two charitable associations have been in operation for some years, one of which is chiefly composed of friends of the church, and the other of dissenters; while the same purpose is served in some measure by the prevalence of Sunday Schools, first suggested by Mr Raikes of Gloucester about the year 1780, and of Infant Schools, recently brought into repute by the exertions of the ingenious Wilderspin. There had previously existed many private schools, which, however, were not adequate, either in number or in system, to supply elementary instruction to the people; while the boarding academies so prevalent throughout England were accessible only to the middle ranks, and chiefly aimed at giving a classical education. In 1818, there were in England 4167 endowed schools, 14,282 unendowed schools, and 5162 Sunday schools, educating 644,000, or one-sixteenth of the entire population, instead of the sixth, which Prussia has shown to be the proper amount of school-attenders. Thus England was shown to enjoy little more than a third part of the proper amount of education, even supposing the education she did enjoy to be good. Of the 11,000 parishes, 3500 were in 1820 without a school.

The system adopted by the two great associations just mentioned is the Monitorial, which was first practised by Dr Andrew Bell, at Madras, in the year 1786. Dr Bell was a native of St Andrews in Scotland, and at this time was one of the ministers of St Mary's, in Madras, and one of the chaplains of Fort George. With the spirit of a genuine philanthropist, he undertook the task of superintending a school established by the East India Company for one hundred orphans of the European soldiery, refusing the handsome salary of L.480 which was offered with the situation. At the opening of the school, the boys were in general stubborn, perverse, given to tricks, lying, and almost every vicious habit, insomuch that a single teacher could hardly expect to produce the least impression upon them. The difficulty of the circumstances suggested to Dr Bell that it would be necessary either to prepare a number of ushers, or a number of elder boys, to take charge of little detachments of the scholars. Finding most obstacles in the former mode, he finally adopted the latter; he succeeded beyond his hopes, and soon perceived that he had discovered an engine for increasing the impetus and abbreviating the labour of education, from which the greatest results were to be expected.

The first new practice which Dr Bell introduced into his school was that of teaching the letters, by making the pupils trace them in sand, as he had seen children do in a Malabar school. This mode of instruction has various advantages, besides the saving of expense. A distinct notion of the different forms of the letters is immediately obtained, and the difficulty of distinguishing those letters which closely resemble each other (b and d, p and q, for instance), by which children are so long perplexed, is removed at once. The scholar, at the same time, learns so much of the art of writing as materially to facilitate his progress when he arrives at that class wherein it is taught.

The next improvement of the Madras school was the practice of syllabic reading: the child, after he had learned to read and spell monosyllables, was not allowed to pronounce two syllables till he had acquired, by long practice, a perfect precision. Upon the old plan, children make continual blunders, in the beginning and middle, and more especially in the termination of words; to prevent this confusion, they were taught to read syl-la-ble by syl-la-ble, and, when so far advanced as to read sentences, to pause awhile at the end of a word. "So much," says Dr Bell, "for the first minutiæ; were I to pursue this subject through all its stages, I should fill a volume."

From the commencement of his experiment, he made the scholars, as far as possible, do every thing for themselves: they ruled their own paper, made their own pens, &c. with the direction only of their teacher. The maxim of the school was, that no boy could do any thing right the first time, but he must learn[a] when he first set about it, by means of his teacher, so as to be able to do it himself ever afterwards. Every boy kept a register of the amount of work which he performed, so that his diligence at different times might be compared. There was also a black-book in which all offences were recorded: this was examined once a-week; and Dr Bell's custom, in almost every case of ill behaviour, was to make the boys themselves judges of the offender: he never had reason, he says, to think their decision partial, biassed, or unjust, or to interfere with their award, otherwise than to mitigate or remit the punishment, when he thought the formality of the trial and of the sentence were sufficient to produce the effect required. But the business of the teachers was to preclude punishment by preventing faults; and so well was this object attained, that for months together it was not found necessary to inflict a single punishment. If a bad subject came to school, a good boy was chosen to take care of him, teach him right principles, treat him kindly, reconcile him to the school, and render him happy like the rest in his situation. The consequence of such a system was, that the boys, feeling themselves happy, felt also that their advantage was the only object which the master had in view: they were sure of his favour if they continued to do right, and of his disapprobation and displeasure if they offended; but knowing that he was just, and feeling that he was good, they regarded him as their friend, and benefactor, and common parent.

About the close of the eighteenth century, Dr Bell returned to Europe on account of his health, published an account of his system, and was gratified by seeing two experiments made upon his plan in England. Some short time before, Mr Joseph Lancaster, a Quaker teacher, began to make experiments of a similar kind; and on being made acquainted with Dr Bell's plan, eagerly added it to his own. Lancaster's improvements, with the addition of Bell's, were gradually brought into repute, and, by the aid of the Quakers, schools, upon what was called the Lancasterian plan, were introduced in many parts of the kingdom. The partisans of the church first despised and then condemned this educational project of a body dissenting from them, and finally were obliged to set up something of the same kind themselves, as the only available means of defending the interests of the establishment. Two rival associations, denominated the British and Foreign School Society, and the National School Society, the former composed chiefly of the liberal and dissenting party, and the latter under the patronage of the crown and church, now endeavoured to anticipate each other in the planting of monitorial schools in every cluster of population throughout England; and thus were the people indebted for once to party spirit for one of the greatest boons they ever received.

Notwithstanding the very great, and, in general, very useful exertions of these societies, a vast field of ignorance still remains. In many seats of population, a large proportion of the people know not one letter from another. The metropolis alone contains 150,000 persons, or a tenth of the whole population, to whom the means of education are not accessible. Two out of the fourteen millions of the entire national population are calculated to be in the same wretched state.

While such is the general condition of the country in respect of popular education, there are several features in the case which must cheer every heart. The system of teaching by real knowledge has at least been exemplified in various parts of the country, particularly in Dr Mayo's school at Cheam in Surrey, the establishments of the Messrs Hill at Hazelwood, near Birmingham, and Bruce Castle, near Tottenham, which have now fully acquired, as they eminently deserve, the confidence of the public. In Mr Bruce's academy at Newcastle-upon-Tyne, in addition to the usual branches, the following philosophical courses are taught:—Chemistry, electricity, magnetism, and pneumatics, as connected with physical geography, meteorology, &c.; natural history, with reference especially to the mechanism and physiology of the human frame—making Paley's Natural Theology the text-book—mental philosophy, the evidences of Christianity, &c. There is a seminary in Bath, under the direction of Messrs Clark, which bears a close resemblance to that of Mr Bruce. It is agreeable also to know that the government has at length taken up the subject of popular instruction, with every appearance of a desire to extend its blessings throughout the land. In the session of 1833, a grant of L.20,000 was voted by Parliament in aid of general education; and already has an account been rendered of the appropriation of that sum, an additional grant made to the same amount, and a select committee of the House of Commons charged with an inquiry into the state of education among the poorer classes in England and Wales.

The object of the grant of 1833 was the erection of schoolhouses, and the principle adopted in apportioning it was, that no aid should be given till one-half of the estimated expense was raised by private contribution. Upon this excellent arrangement, 98 schoolhouses were built within eight months, at the joint cost of L.46,000, by which many populous districts will be for the first time furnished with the means of instruction. A prospect is held out that, by the farther grant of L.20,000, no fewer than 187 other schoolhouses will be added to the above number. If to these exertions were added the establishment of a few schools for the instruction of teachers in the improved plans of education—moral, intellectual, and physical—the educational philanthropist might be content to wait with patience till the public mind shall become a little more alive to the subject.

INFANT SCHOOLS.

It has long been admitted as an abstract proposition, that in early childhood the mind is more pliable, and habits are more easily formed, than at any other period of life. "The little, or almost insensible, impressions on our tender infancies," says Locke, "have very important and lasting consequences: and there it is, as in the fountains of some rivers, where a gentle application of the hand turns the flexible waters into channels that make them take quite contrary courses; and by this direction, given them at first in the source, they receive different tendencies, and arrive at last at very remote and distant places. . . . . . The great mistake I have observed in people's breeding their children has been, that this has not been taken care enough of in its due season; that the mind has not been made obedient to discipline and pliant to reason, when at first it was most tender, most easy to be bowed."[a] Miss Edgeworth, to the same effect, observes, "Practical education begins very early, even in the nursery. Without the mountebank pretence that miracles can be performed by the turning of a straw, without the dictatorial anathematising tone which calls down vengeance upon those who do not follow to an iota the injunctions of a theorist, we may simply observe, that parents would save themselves a great deal of trouble, and their children some pain, if they would pay attention to their early education. The temper acquires habits much earlier than is usually apprehended; the first impressions which infants receive, and the first habits which they learn from their nurses, influence the temper and disposition long after the slight causes which produced them are forgotten." Yet these undeniable principles have not till the present generation begun to be systematically reduced to practice. It is only within the last few years that infant schools have appeared amongst us, and even yet their number is lamentably small. Mr Owen of New Lanark was the first in Britain who established what deserves the name of an infant school. Mr Brougham and some of his friends who had visited New Lanark, established, in 1819, an infant school at Brewer's Green, near Tothillfields, London, and transplanted thither the New Lanark teacher, Mr

[a] Locke observes with truth, that "some men's constitutions of body and mind are so vigorous and well framed by nature, that they need not much assistance from others; but, by the strength of their natural genius, they are, from their cradles, carried towards what is excellent; and, by the privilege of their happy constitutions, are able to do wonders." But what he adds is not less in accordance with fact, that "examples of this kind are but few;" and that, "of all the men we meet with, nine parts out of ten are what they are, good or evil, useful or not, by their education."—*Thoughts on Education*, § 1.——It must be kept in view that Locke uses the word *education* in its original and most comprehensive sense—training or bringing up.

Buchanan. The latter happened incidentally to meet Mr S. Wilderspin, then a young man, and had the merit of seeing his talent for the business of education, and of recommending him to the patrons. A new school was established at Spitalfields, at the expense of Joseph Wilson, Esq., of which Mr Wilderspin was appointed master. In his hands the system was rendered what it now is, and what has been adopted all over the country. Mr Wilderspin's method was the mere result of practice and observation; but at the same time it is perfectly sound in theory, and admirably adapted to human nature, as elucidated by philosophical writers. The London Infant School Society was instituted in 1824, and many similar bodies now exist in various parts of the United Kingdom. Infant schools are much more numerous in England than in Scotland, and we are sorry to say that Edinburgh possesses only one school conducted according to the method of Mr Wilderspin, and even that one is not fully appreciated by those for whose benefit it was established. Glasgow has several.

Education comprehends three great branches—physical, moral, and intellectual. Hitherto the two first have been deplorably neglected, and to the last alone almost exclusive attention has been paid in our schools. It is the object of physical education to promote the developement, consolidation, and strength of the body, and thus to prepare it for the exertions which it will be called on in future life to perform. Moral education has for its aim the cultivation and direction of the social, moral, and religious feelings, and the repression of the too great activity of the selfish propensities. Intellectual education exercises the understanding, and furnishes the mind with knowledge. All these are attended to in the infant schools. This, as well as other excellencies of the system, will be obvious from a statement of the objects of the London Infant School Society.

That society has been formed to promote the establishment of schools, or rather asylums, for the children of the poor, before the age at which they are capable of engaging in any profitable employment, or at which they may be received into the other schools, to which they are not usually admitted until the age of six; the proper objects of the society's care, therefore, are children of both sexes, from two to six years of age. It is well known that children of this age generally prove, during the working hours of the day, a heavy incumbrance on parents who are obliged to toil hard for a subsistence. One of the society's objects is to lighten the pressure of this inconvenience, and to leave the parents—particularly the mother—more fully at liberty to pursue some gainful occupation for the common benefit of the family. So convinced of this are the poor themselves in England, that, in numerous instances, Dames' Schools, as they are called, have been established, in which ten, twenty, or thirty infants are placed under the care of an old woman, by whom they are shut up, perhaps, in a close apartment, in order to be kept out of harm's way while the parents are at work. For this accommodation, parents are willing to pay from twopence to fourpence a-week for each child. The children are left with the dame, and remain under her care (with the exception, in most instances, of the dinner hour) until the evening.

Infant schools are intended for the reception of from two hundred to three hundred children, and, while they secure the same relief to parents, are made subservient to many other purposes, important not only to the children themselves, but through them to the parents, and to the community at large. The plan, therefore, is, in the first place, to provide an airy and spacious apartment, with a dry, and if possible large, play-ground attached to it, where, under the eye of a properly selected master and mistress, these infants may pass the hours during which their parents are at work; and, in the second place, to render this receptacle not a place of irksome restraint and confinement, but a school for the proper exercise of the body in cheerful sport, for the acquisition of useful knowledge, and for the attainment of habits of cleanliness and decorum, of cheerful and ready subordination, of courtesy, kindness, and forbearance, and of abstinence from every thing impure or profane; a scene, in short, at once of activity and amusement, of intellectual improvement, and of moral discipline. If the period of mere infancy is less fitted, comparatively speaking, for intellectual progress, yet curiosity is even then sufficiently active to enable the teacher to convey much useful knowledge to his pupils, by means which are calculated to call forth, *without oppressing*, their faculties. By means of pictures, models, and a museum of miscellaneous objects, it has been found possible, even in the case of very young children, to engage the attention, develope the faculties, and impart ideas, without the necessity either of resorting to any harsh expedients, or of imposing any strain on their minds. They are taught by easy lessons to read and calculate. But the first years of life are still more valuable, with a view to the formation of the temper and moral character of the future man. No doubt can be entertained both of the susceptibility of right impressions which belongs to the earliest age, and of the unhappy permanence of those vicious or selfish propensities, and of those peevish or violent tempers, which are then too often contracted; and which, when suffered to expand, lead in after-life to domestic misery, to profligacy, and to crime.

To counteract such propensities, and to prevent the growth of such tempers, is the prime object of the plan; and it is with a view to this object that the whole frame and discipline of infant schools ought to be regulated. Locke insists very strongly, in his work formerly quoted, on the paramount importance of this sort of training. "Seek out somebody," he advises, "that may know how discreetly to frame the manners of your son; place him in hands where you may as much as possible secure his innocence, cherish and nurse up the good, and gently correct and weed out any bad inclinations, and settle him in good habits. This is the main point; and this being provided for, learning may be had into the bargain." In like manner Lord Kames observes, "It appears unaccountable that our teachers have generally directed their instructions to the head, with very little attention to the heart. Surely, as man is intended to be more an active than a contemplative being, the educating of a young man to behave properly in society is of still greater importance than the making him even a Solomon for knowledge." At the infant schools it is not by precept merely that moral education is impressed; the children are trained to *act* in accordance with justice, and benevolence, and truth; and thus acquire the *habits* which it is desirable that they should possess in future life.

At present we behold many of the streets and lanes of cities—particularly those of London—crowded with squalid children, left to wallow in filth, to contract disease, and to acquire habits of idleness, violence, and vice. Almost the first language which many of them learn to lisp, is that of impurity and profaneness; almost the first science in which many of them are instructed is that of depredation. Abroad, they are exposed to every vicious seduction; at home, they suffer from the caprice or violence of parents who are incapable of giving them instruction, whose poverty makes them discontented and irritable, and who feel the very presence of their children to be a drawback on their efforts to earn a subsistence. From such a course of education, what can be expected but a proficiency in vicious propensities and criminal practices—what, in short, but that mass of juvenile delinquency, which in the present day we have been forced to witness and to deplore?

But if we contrast with this state of things the effect which may be anticipated from the general establishment of infant schools, conducted on the principles now explained, what heart but must exult in the prospect? Let all who regard such expectations as visionary, only take the pains of personally and minutely inspecting the schools already formed in different parts of the kingdom (our Edinburgh readers will find one in the Vennel, Grassmarket); let them view the children, clean, healthy, joyous, giving free scope to their buoyant spirits; their very plays made subservient to the correction of bad and the growth of good dispositions; the happiness they manifestly enjoy; and the habits of prompt and cheerful, of mutual kindness, of unceasing activity, of purity and decorum, which they acquire. And let them watch the return of these children to their homes, and witness the pleasurable sensations with which they are received, so different from the scowling looks and harsh tones with which their teasing importunities and interruptions, during the hours of labour, are apt to be met. And let them, moreover, contemplate the striking reaction of the improved manners and habits of the infants on the older branches of the family. Let them view and consider all this, and they will no longer doubt the beneficial influence of these institutions.*

SCHOOLS OF INDUSTRY.

The object of schools of industry is to combine with the ordinary elements of school education, instruction in such manual labours as the poor are generally called upon to perform. There are not many such schools in Britain, but their utility cannot fail to render them much more numerous in the course of a few years. The establishment of Mr Montagu Burgoyne, at Potton, in Bedfordshire, may be taken as an example. The children, besides being instructed in reading, writing, and arithmetic, are employed during half of the school-hours in works of useful labour and industry. The boys mend their own clothes; they clean and mend their own shoes, and are taught to clean knives, to use the hammer, to dig and cultivate a garden, to hedge and ditch, and even to plough. The girls are accustomed to the most useful kinds of needlework, are required to mend their own clothes, and learn the business of a house and dairy. This preparation tends to enable both the boys and girls, when they leave school at fourteen years of age, to earn an honest living. The boys will be active and useful farming servants, or grooms, or coachmen, or valets, or gardeners, or apprentices to different trades; and the girls will be clever housemaids, dairymaids, or cookmaids, and, when they marry, will be able assistants to their husbands, and acquainted with the best way of preparing food and clothing for a young family.

SCOTLAND.

Previously to the Reformation, Scotland was in much the same condition as to education as the other Christian countries of Europe, with perhaps some inferiority on account of its remote situation and narrow resources. The grammar schools, by which Latin is taught in the principal towns, are in several instances of considerable antiquity; and, in 1496, an act of the legislature endeavoured to *enforce* the attendance of the sons of landowners at these institutions, with a view to the better administration of the laws, which was then entrusted to that class of society, and for more than two centuries later, as a matter of hereditary right. There were also *lecture-schools*, in which children learnt to read the vernacular language. The Scottish reformers, following the example of their German predecessors, endeavoured to obtain a part of the confiscated funds of the church for the support of schools, of which they wished to have one in every parish, under the immediate charge of the clergy, in order that each successive generation might be inspired with an attachment to "the trew religioun." Though they did not succeed in obtaining any considerable part of the church funds for this or any other pious purpose, a considerable portion of the people of Scotland seem to have enjoyed the blessings of education, during the latter part of the sixteenth and early part of the seventeenth centuries. In 1616 and 1633, while the church was Episcopal, efforts were made, in the first instance through the Privy Council, and in the second by an act of Estates, to establish a school in each parish; throughout the subsequent struggles of the Presbyterians for ascendancy, the same object was kept in view; and the latter form of church government had hardly gained its final ascendancy at the Revolution, when the long-contemplated plan was at length accomplished, and the education of the people put upon its present footing. By an act of the Estates in 1696, it was provided that there should be *a parochial school and schoolmaster in every parish of the kingdom*, with a fixed salary, not under L.5, 11s. 1d., nor above L.11, 2s. 2d., payable by the heritors or proprietors of the parish, in proportion to the extent of their property, who should have the power of drawing one-half of the outlay from their tenants. The duty of planting the school was imposed on the heritors; and the appointment of the teacher, and supervision of the whole school, were entrusted to the presbyteries—district church-courts, which in Scotland exercise nearly the same ecclesiastical powers as in other countries are consigned to bishops.

In consequence of this public endowment, which never, so far as we have observed, was grudged by those from whose pockets it proceeded, each parish in the kingdom, except some of those in the large towns, was furnished with a school, in which reading, writing, and arithmetic, and, in some instances, classical literature, were to be learned. The fees were generally—for English, 1s. 6d., for arithmetic, 2s., for Latin, 2s. 6d., per quarter; the poor being admitted at about two-thirds of these rates. The system thus avoided at once the disadvantage of high fees, and that of an indiscriminate gratuitous admission, which, unless where the support is derived from the national funds, is so apt to lessen the value of instruction in the eyes of the lower orders. One prominent department of education in these seminaries was religion. The primer was prefixed to, and inseparable from, the Catechism approved of by the Westminster Assembly of Divines; and the first lessons in reading were from that venerated abridgement of Calvinistic divinity. The Bible was the only other text-book of importance; and thus almost the only ideas obtained at school were those of religion. To these causes, so early put into force, the uncommon diffusion of pious feeling and observance, and of a certain extent of acquirements in literature, which forms so striking a feature in the national circumstances, is generally ascribed.

On account of the decline in the value of money, it was felt, towards the end of the eighteenth century, that the fixed incomes of the parochial schoolmasters ought to be advanced; and, accordingly, in 1803, an act of the legislature provided that the salaries should not thenceforward be under L.16, 13s. 4d., nor above L.22, 4s. 5d., with a free house; the salaries more recently have been respectively elevated to L.17, 2s. 2d. and L.34, 4s. 4d. These emoluments, to which there are generally added others arising from the duties of session-clerk, precentor, and manager of militia-returns, are found, in populous parishes, where a considerable amount of fees is received, to secure the services of men of respectable acquirements—many of them disappointed aspirants for church preferment; but in many remote and more thinly-peopled situations, the remuneration altogether fails to attract properly qualified persons. An idea very generally prevails, and nowhere more generally than in the country itself, where its falsehood might be most readily detected, that Scotland is remarkably fortunate in respect of education. In reality, its parochial system is so very defective, that, considering the difficulty there is always found in reforming any old institution, it is questionable if the country would not have been better with a school establishment yet to be commenced. In 1818, there were 942 parochial schools, attended by 54,161 children, and drawing a gross revenue of L.29,611. Thus it appears that only 1 in every 36 persons was provided for by the schools of the establishment, while in Prussia there are government schools for 1 out of every 6 persons, and a greatly superior system of education. The average of stipends in 1818 was L.22 per school;

* For farther details we refer to Mr Wilderspin's work on Infant Education. Though written in a plain style, it contains matter of deep importance to society

and an inquirer in 1827 calculated that a full half of the teachers did not enjoy gross incomes above L.45, while a full third had from L.25 to L.35. These incomes are in all instances so very humble, that, upon fair consideration of circumstances, we are entitled to assume a very low standard indeed for the character and attainments of a vast proportion of the teachers.

In 1824, the General Assembly of the Church of Scotland appointed a committee for the purpose of increasing the means of education throughout the kingdom, wherever those means might appear to be deficient. This committee, after an inquiry occupying two years, reported that the means of elementary education appeared to be within the reach of the entire population, excepting in the Highlands and Islands, where, owing to the extent of the parishes and other causes, there were not less than 50,000 persons unable to read, or to obtain instruction. The Assembly, by means of charitable collections, was able, before 1833, to establish eighty-six schools in these districts; but it was found, by an apparently more searching inquiry in the latter year, that there were 83,397 persons above six years of age, out of a population of 504,955, who could not read either in Gaelic or English, and had no means of school-instruction within their reach. In some districts, the proportion of the ignorant to the instructed is a full fourth; in the Presbytery of Mull it is a third; in Uist, more than a half. Be it also remarked, a vast proportion of those who can read are unable to write or cypher; while the reading itself goes little way beyond a mere power to spell through a Bible or a Catechism, and can only be compared to an instrument, which, though possessed, is not used. Only 6443 pupils were attending the Assembly's schools in 1832, being less than a thirteenth part of those who require instruction; so that, without aid from the national purse, there is little reason to hope for the speedy universality of education in this part of the empire.

The branches taught at the Highland charity schools are Gaelic and English reading, writing, arithmetic, geography, and Latin. It is curious that the people in general prefer the English to the Gaelic, though there is great reason to fear that all their acquirements in that foreign tongue are only so much parrot learning. There are some other schools, opened upon private adventure, but of the most miserable kind, the teacher being generally a boy, an aged female, a retired soldier, an innkeeper, or a fisherman, and the emoluments seldom exceeding ten pounds a-year—in some cases, only three or four. But even the parochial schools in this department of the kingdom are in too many instances upon a footing inferior to that of the Lowland seminaries. The legal salaries are in many places evaded by compact, and the schoolhouses and abodes for the teachers not provided. In eleven parishes in Argyleshire, the stipends are divided into three, so as not to amount, probably, to ten or eleven pounds each.

The present state of Scotland as to elementary education may be thus briefly summed:—There are 1005 parish schools, being a few more than the entire number of parishes. In the Highlands, besides 171 parish schools, there are, or were at a recent period, 324, supported by the Society for Promoting Christian Knowledge, and other charitable associations, and eighty-six planted by the General Assembly. Throughout the whole country, but especially in the more populous parts, and in large towns, there is a great number of private schools: in 1818, the number was 2222, instructing 100,027 children, nearly double the amount of those who were then reared in the established parochial schools. In the year just mentioned, the county of Lanark, including Glasgow, contained fifty-six parochial schools, attended by 3437 children, and 307 private schools, attended by 18,270 children. Mid-Lothian, including Edinburgh and other populous towns, had twenty-five parish schools, attended by 1704 children, and ninety-seven unendowed schools with 4312 children. In Renfrewshire the numbers were twenty-one parish schools, with 1630 children, and 137 unendowed schools, with 8690 children. It is indeed apparent to the most superficial inquirer that the parochial establishment has fallen completely behind the population, and only accomplishes in a small degree the purposes for which it was intended. The idea of the Reformers in the sixteenth century seems to have been that there should be a minister, a catechist, and a schoolmaster, for every 1000 of the population: were the same principle now followed, there would be 2300 instead of 1005 endowed teachers.

The success or efficiancy of these means of instruction is very various. In the 143 parishes of the Highlands, as already stated, even after the establishment of 86 charity schools, there are above 83,000 persons who, from local circumstances, have no means of instruction within their reach. In the 132 parishes of Aberdeen, Banff, and Elgin, the average attendance at school is one-eleventh of the whole population, which is little above one half of the Prussian amount. The average in other districts ranges from this to one-twentieth, which last must be considered as deplorably low. It has been stated that one parish, Fossaway, has one-fourth of the population at school; two parishes, Comrie and Midcalder, one-fifth; four parishes, Colinton, Ruthwell, Kirkwall, and Tongue, one-sixth; so that it appears as if only a mere scantling of the Scottish parishes are in a proper condition as to education. The country parishes, from their extent and other local peculiarities, and the large towns, from the absolute want of cheap seminaries, and the demoralisation that is so apt to beset large masses of population, are alike ill provided. In Edinburgh there are no parish schools; nor till lately were there seminaries of any kind accessible to the poor: hence, a very great number of the children of the lower orders grow up without education. In Glasgow, 20,000 persons are in this condition, so ominous of moral degradation, turbulence, and crime. In Paisley, where, thirty years ago, the artisans were an enlightened and virtuous body of men, there are now 3000 families into which education does not enter. The proportion of the population which attends school in Glasgow is one fourteenth; in Dundee, one-fifteenth; Perth, under one-fifteenth; Old Aberdeen, one-twenty-fifth; Paisley Abbey Parish, one-twentieth. Yet in one of these instances—Dundee—it cannot be said that the object is overlooked. In that thriving town, besides a grammar school with two masters, an English public school with two masters, and an academy with four masters, who teach mathematics, natural philosophy, chemistry, moral philosophy, logic, drawing, and the modern languages, there are no fewer than 77 private schools, several of which are supported and partly taught by the masters of factories. As there is thus a school for every 570 of the population—which cannot be considered a mean allowance—it follows that much of the fault lies in the short attendance of each individual. A child learns to read, and no more is supposed to be required. He is hurried off to the factories, with his faculties still in a great measure dormant. But it is not alone among the working classes of large towns that an ability to read is supposed to be a sufficient education.

The writer of the late statistical account of Dundee states, that hardly any individual above six years of age is found unable to read, though a vast number of the working people have not learned to write. It may be conceived, then, since a sixth of every population is at the school-going age (between seven and fourteen), and since only a fifteenth are at school in Dundee, that the period of attendance is very far from perfect. Every thing, indeed, tends to show that the sneer of Dr Johnson as to Scottish education is now realised—all get a mouthful, but none a bellyful. In Scotland, the monitorial and intellectual systems have as yet been very partially adopted. One teacher in general superintends the tuition of a large number of boys, only a few of whom can at one time be getting any benefit from his exertions. The period of attendance is short, and the impression of school-learning upon the mind very slight: even the Catechism is learnt only by rote, and, at a very fair computation, not understood, even glimmeringly, by one in a hundred pupils. The private teachers are, in a vast proportion of cases, women, or else males of very humble accomplishments; a result of the extremely slender emoluments, which range from L.4 to L.25, the latter sum being very rarely exceeded. Altogether, the system is a starveling one—starveling in its provisions for both teacher and taught—and a disgrace rather than an honour to the nation.

IRELAND.

In the dark ages, Ireland was remarkable above the most of other countries for the number and excellence of its schools, which were then resorted to by students from various parts of Europe. Under the domination of the English, however, this, as well as every other matter connected with good government, has been, till a very recent period, neglected. An act of Henry VIII., indeed, imposed on the vicar or rector of every parish the duty and cost of keeping up a parochial school, in order to instruct the natives in the English tongue, as the existence of the Irish was considered a main obstacle to the progress of civilisation, and to the establishment of English and Protestant supremacy. This, however, though confirmed by an act of William III., was never more than a dead letter. The clergy regularly, among other oaths, swore at admission that they would support an English parochial school; but nothing of the kind was ever done. At the same time that the keeping of Protestant schools was thus evaded or found impracticable, the same act of William III. forbade Catholics to keep schools, under a penalty of twenty pounds and three months' imprisonment. The Catholic Irish, however, who are nationally characterised by an anxiety to give their children education, have all along contrived to maintain a great number of the mean establishments called *hedge schools*, where a slender and imperfect degree of instruction was conferred on a considerable portion of the rising generation.

During the century between 1731 and 1831, various attempts were made by private associations, generally with the aid of government, to educate the people of Ireland. Almost every one of them, however, went to wreck upon the fatal principle that the religious instruction should be exclusively Protestant. The celebrated Charter School Society, commenced at the first of these dates, has continued up till a recent period to spend vast sums in the vain attempt to proselytise by means of education. Their plan was to get hold of children—the term is quite appropriate—to catch them, if possible, wild, or transfer them from the Foundling Hospital, and to immure them in schools where they also got food and clothing, so that they should never come in contact with their parents or with the Catholic religion, till they should be firmly established in the Protestant faith. As hardly any Catholic families would allow their children to be taken from them for such a purpose, the system has been signally unsuccessful. The society has never had above 50 schools or 2000 scholars, more generally about 40 schools and 1400 scholars; an amount so trifling as compared with the whole population, that it would not be worth mentioning, if it were not for the instructive lesson which the failure of such a plan holds forth. The expense of these few schools has been enormous. Besides all the private contributions, about L.10,000 per annum has been voted to them by Parliament; the whole grants of public money amounting to L.1,105,869. It is also alleged that the few scholars thus reared were striking examples of the utter folly of such an attempt. A horrible system of cruelty and coercion prevailed in the schools; all the natural affections of the pupils were suppressed; they were forbidden to see any human being related to them; and they grew up in total ignorance of nature and society. Hence, when they were sent abroad, they appeared stunted both in body and mind, and were found totally unfit to make their way in the world. In 1824, the society was found maintaining no fewer than 706 grown individuals, or about a half of their usual number of pupils, who had been unfitted, by their system, for procuring a maintenance in any other way. A more deplorable instance of human folly could not easily be found in any part of the world, than what is presented by the Charter School Society of Ireland.

The Incorporated Association for Discountenancing Vice, commenced in 1792, was the second of these societies, and made a great improvement upon the first. In the schools established by it, whilst the Church Catechism was used for Protestant children, nothing was required from those of Catholic parents but to read the Scriptures. In November 1819, it numbered 110 schools, attended by 4460 Protestants and 4360 Catholics; in 1824, 9578 of the former, and 6344 of the latter. The London Hibernian Society, established in 1806, was less liberal in its plan, and has not done so much good among the Catholics. In 1823, it had 653 schools, attended by 61,387 scholars; besides which, it had many Sunday schools.

In 1812, a society was formed, under the sanction of a Parliamentary committee, for the education of the Irish poor: it is usually called the Kildare Place Society, from the street in Dublin where its chief establishment has been built. Its grand principle was to afford education to every description of the lower class of the people, keeping clear of all interferenc with the particular tenets of any; and its specific o' jects were—to aid in the founding of new schools the improvement of old ones, provided the prine of the society were adopted; to maintain two n schools for the exhibition of their plan, and the t... ing of teachers; and to publish moral, instructive, and entertaining books, fitted to supersede the objectionable works then in use. The Kildare Place Society began to operate in 1817, and had prospered so much before 1825, that it then had 1490 schools, attended by about 100,000 scholars; in 1830, 1620 schools (two-thirds of them in Ulster), and 132,573 scholars. The system of instruction was a combination from those of Bell, Lancaster, and Pestalozzi. Each child attending the model schools in Kildare Place paid one penny per week. In the course of the seven years ending 1824, the society had published fifty-two small treatises, of which the total issue had been 956,702 volumes; the loss upon the sale L.650 per annum. Up to 1828, the Kildare Place Society had received L.170,508 from the public funds, and there has since been a grant of L.30,000, making the whole L.200,508.

During the same recent period, something has been done for the instruction of the poor in Ireland by the Baptist Society, the Irish Society, and the Sunday School Society. The last has been particularly efficient.

From inquiries made in 1828, it appears that there were in Ireland 11,823 elementary schools, of which no less than eight-elevenths were pay-schools, conducted by private enterprise, and altogether unconnected with either the clergy or charitable societies. The number of scholars in 1824 was 560,549, of whom 394,730 (Protestants 87,326, and Catholics 307,402) paid for their education. The number of masters and mistresses in 1826 was 12,530, of whom 3098 professed the established religion, 1056 the Presbyterian, and 8300 the Catholic, while of seventy-four the religious denomination was not ascertained. Upon the whole, the proportion of school-attenders to the total population shows rather better in Ireland than in England; a fact probably attributable to the higher sense of the value of education which is allowed to prevail among the common people in the former country.

Such was the state of education in Ireland, when, in 1831, the government resolved to commence a national system, avoiding various errors which had operated against all former attempts. Perceiving that the usefulness of the Kildare Place Society had been much impaired by its introduction of the Bible without notes, to which there was a constantly increasing opposition on the part of the Catholic clergy, the liberal administration of Earl Grey determined that the religious part of education should be kept separate from the literary, and be entirely under the control of the various denominations of clergy. Among the books to be employed in the literary education, they contemplated such extracts from Scripture as all creeds could sanction; but the great business of religious instruction was to be prosecuted on one or two days of the week set apart for the purpose. A commission was appointed by the Lord Lieutenant, consisting of the Protestant and Catholic archbishops of Dublin, a Presbyterian clergyman of high character, and a few other individuals, who were to form a board of superintendence, and whose various creeds should form a guarantee for the liberal intentions of the government. As yet the scheme has been prosecuted only as an experiment; but it has met with considerable success even in that limited character, and this in the face of a vigorous opposition from the church-ascendancy party. From the report of March 3, 1834, it appears that, from January 1832, 1548 applications had been made for aid towards schools, of which 789 had been attended to. The schools now in operation afford the benefits of education to about 140,000 children. The members of the board have conducted the business in perfect harmony. They have published several class-books, two of which contain Scriptural extracts. One day of the week besides Sunday is set apart for religious instruction, which is conducted by such pastors as are approved of by the parents and guardians of the children. "It shall be, as it has ever been," says the report in conclusion, "our constant object so to administer the system of education committed to our charge, as to make it acceptable and beneficial to the whole of his Majesty's subjects; to train up and unite, through it, the youth of the country together, whatever their religious differences may be, in feelings and habits of attachment and friendship towards each other, and thus to render it the means of promoting charity and good-will among all classes of the people."

FRANCE.

Previously to the (first) Revolution in this country, there were, besides Episcopal seminaries and conventual schools, lyceums and colleges in the cities, where young persons were prepared, under a system of monastic discipline, for the higher seminaries. The government did nothing for the education of the people at large, and the clergy, though possessing so large a share of all the property in France, and having the instruction of the people under their especial care, left them in utter ignorance; whence the horrid outrages that disfigured the early part of the Revolution. Some elementary schools were supported, here and there, by religious orders, or private persons; but the instruction was scanty, and, in all the institutions of education, was behind the age. During the Revolution, the schools were declared to be under the care of the state, but no plan for their proper management was adopted. Napoleon established several military schools, and others for instruction in trades and arts, and an imperial university was created, to have the supreme direction of instruction in France. But the plan was on a military principle, and as little fitted to promote the true purposes of education as the monastic narrowness of former ages. It failed entirely, so far as primary or elementary education was concerned.

Since the restoration of public tranquillity in 1815, the business of education has been well attended to in France, though it is only now on the point of being fully and properly established. Public instruction is there a department of the business of the state, being entrusted to a train of officers of various ranks, who preside over its various divisions, and the chief of whom, under the title of the Minister of Public Instruction, has a seat in the cabinet. The elementary schools are placed under the superintendence of committees, one of which is established in every canton of the kingdom, and watches over the progress of instruction in that canton. The number of members composing each committee varies according to the population and extent of the district. The ex-officio members are the curé, the justice of peace, and the principal of the college, if there be one in the canton; the other members are chosen by the rector upon the approbation of the prefect. Elementary schools are of three degrees, according to the nature of the education given in them; and while some are supported upon the voluntary principle, others are maintained by associations, charitable and otherwise; but whatever be the nature of the school, it has hitherto been impossible for any candidate to obtain the mastership of it, without a patent, certifying his qualifications, which he can only obtain, after a severe examination, from a superior functionary. Within the last three or four years, normal schools have been established all over France, for the preparation of teachers according to a regular system. In March 1834, there were 62, which served for 73 out of the 86 departments, and the number of pupils was 1944. The whole annual expense of these institutions is £60,000, great part of which is defrayed by voluntary local assessment. The young men are accomplished in, 1, Moral and religious instruction; 2, Reading; 3, Arithmetic; 4, Linear drawing; 5, Elements of physical science, with a special view to the purposes of ordinary life; 6, Music; 7, Gymnastics; 8, Geography and history; 9, Gardening; 10, the preparation of the simpler legal forms and civil deeds. The systems of mutual instruction and of simultaneous instruction have been very extensively introduced in France, and with the best effects. In 1815, there were 22,348 elementary schools, educating 737,369 pupils; in 1819, the number of pupils had advanced to 1,130,000, or one for every twenty-five of the population. In 1828, there were 1,500,000 in the way of being instructed, being double the amount of 1815, though still very far short of the number which, according to the most approved calculations, ought to have been at school. The population of France was, in the latter year, above 30,000,000; and hence there ought to have been at least 5,000,000 at school. It is gratifying, however, to know that the number of the educated is increasing at a much more rapid rate than the population, and that the French government is not only making liberal grants for schools, but is about to establish a state system, which shall provide for the education of the whole community. When such a system shall have got into full operation, and the generation which has first experienced its benefits have entered into life, a great change may be looked for in the national mind of France. It has been calculated that a third of the population of this fine country—the proportion being greater in the south than in the north—are unable to read or write: when all are able to do so, and have undergone the moralising influence of literature, the French people cannot fail to exhibit an improved general aspect.

SPAIN.

There are few establishments in Spain for the diffusion of the first rudiments of knowledge. The lower classes seldom learn to read and write: those above them are seldom instructed in any thing but these two accomplishments, and the elements of arithmetic. Such as are intended for the learned professions attend a Latin school for three or four years. Since the expulsion of the Jesuits, these schools are not numerous. The Spaniards are among the most ignorant and bigoted nations in Europe.

DENMARK AND THE NETHERLANDS.

Denmark and Holland strive to keep pace with Germany. In the former country there have been normal schools for the last forty years; and the monitorial system has been recently introduced, and has met with surprising success. Out of a single monitorial school, founded in the early part of 1819, seven had sprung up before it closed; in 1820, the number had increased to 11; in 1821, to 15; in 1822, to 35; in 1823, to 244; in 1824, to 605; in 1825, to 1143; in 1826, to 1545; in 1827, to 2003; in 1828, to 2302; and at the end of 1820, to 2646! In Holland, one-fifth of the population is stated to be at school, and the elementary seminaries are placed under a good organisation. In Belgium, education is too much in the hands of the priests to be in a good condition.

SWITZERLAND.

In the Protestant cantons of Switzerland, elementary education is in a flourishing state, the schools being attended by from one-sixth to one-tenth of the population. In the Catholic cantons, chiefly through unfavourable local circumstances, education is not in so satisfactory a condition, and is chiefly in the hands of the clergy. In several of the cantons, the Lancasterian method has been adopted, and Sunday schools are now becoming common. The new systems introduced by Pestalozzi and de Fellenberg, both of whom were Swiss, and commenced their operations in this country, are also producing some visible benefit, especially the latter, which is exemplified at Hofwyl to 6000 students, not to speak of an academy for the instruction of teachers, conducted at the same place. In Switzerland, education is partly supported and superintended by the various local governments; and in several cantons there are public institutions for the training of teachers.

NORWAY.

In Norway there are public schools for the lower orders, of which each parish necessarily has one, the teachers being appointed by the bishops of their respective dioceses. Children are compelled by law to attend these seminaries, where they are instructed in reading, combined with intellectual exercises, religion and bible-history, singing from the psalm-book, arithmetic and writing. The period of attendance is from seven years till the time of confirmation, which generally takes place at about sixteen or seventeen; and parents who withdraw their children during that period are liable to a fine. The teachers are partly supported by a fixed piece of land, and partly from a fund raised by local taxation.

SWEDEN.

In Sweden, the schools are much on the same footing as they were in the seventeenth century among the German Protestants. The clergy, in the possession of the church property of their Catholic predecessors, show little disposition to apply a part of it to the public instruction; and the government is too poor and too jealous to admit many improvements from foreign countries.

ICELAND.

This remote country is literally a chain of immense rocks, the summits of which are covered with snow. Situated in a climate where the ground is frozen during the greater part of the year, and where the sun for a long period hardly appears above the horizon, it affords to the inhabitants comparatively little occupation out of doors, and they have betaken themselves for amusement to intellectual pursuits. Dr Henderson, who recently visited Iceland, gives the following statement:—"On inquiring into the state of mental cultivation in Iceland, we are struck with the universal diffusion of the general principles of knowledge among its inhabitants. Though there be only one school in Iceland, and that solitary school is exclusively designed for the education of such as are afterwards to fill offices in church or state, yet it is exceedingly rare to meet with a boy or girl who has attained the age of nine or ten years, that cannot read and write with ease. Domestic education is most rigidly attended to; and I scarcely ever recollect entering a hut where I did not find some individual or another capable of entering into conversation with me on topics which would be reckoned altogether above the understandings of people in the same rank of society in other countries of Europe."

POLAND.

Poland, where formerly the nobility only were instructed by the members of religious orders, had, before its partition, some gymnasia, founded towards the end of the eighteenth century, and some common and country schools, but no well-arranged school system. In 1830, the number of pupils in the elementary schools was calculated at only 28,000, in a population of nearly four millions! After the close of the late insurrection against the Russian power, the schools called gymnasia were re-organised; but there no longer exists an university, or any other institution for the higher branches of learning. Twenty-two district schools have been instituted, and in the system of education appointed for them great care has been taken at least to inculcate sentiments of loyalty to the imperial devastator of this fine country.

RUSSIA.

The government of the vast Russian empire has directed its attention to a system of schools for a hundred years past, before which there were only conventual schools for the clergy, and some institutions for the sons of the great, established—almost by force—by Wladimir the Great. According to the decrees of the Emperor Alexander, schools for the circles, districts, and parishes, were to be instituted throughout the empire, in order to strike an effectual blow at the deep ignorance of the Russian people. The circle schools exist at present on the pattern of the German gymnasia, in most of the capital cities of the governments; the district schools are found in some towns of a middling size; the parish schools, however, in very few villages; and the greatest and best part of this plan remains as yet unexecuted. Somewhat earlier, there existed, in the German provinces of Russia, good gymnasia, and some common and country schools; but the latter are still in a very low condition. The education of Catholic youth was attended to by the Jesuits, who were admitted by Catharine II. into White Russia.

PRUSSIA.

The provisions made by government for the instruction of the people in Prussia have justly attracted the admiration of surrounding nations, and are certainly far superior to those which exist in Britain. There is a minister of public instruction, whose duty it is to superintend the national education, the religious establishment, the secondary medical schools, all institutions relating to public health, and all scientific institutions—as academies, libraries, botanical gardens, museums, &c.—every thing, in short, which concerns the moral and intellectual advancement of the people. This minister is the head of a council or board for the whole kingdom; under it there are councils for every province, and under these are the parish committees, who superintend the primary schools. In Prussia, as in the other states of Germany, all parents are bound by law to send their children to the public elementary schools, or to satisfy the authorities that their education is sufficiently provided for at home. This regulation is of considerable antiquity. It was confirmed by Frederick the Great in 1763, and was introduced into the Prussian code in 1794, and finally it was adopted in the law of 1819, which forms the basis of the actual system of Prussia. The obligation extends not only to parents and guardians, but to all persons who have power over children, such as manufacturers and masters of apprentices, and applies to children of both sexes, between the seventh and fourteenth year. If the parents omit to send their children to school, the clergyman is first to acquaint them with the importance of the duty which they neglect; and if his exhortation is not sufficient, the school committee may summon and remonstrate with them severely. If all remonstrances fail, the children may be taken to school by a policeman; or the parents, guardians, or masters, brought before the committee, and fined or imprisoned in default of payment, or condemned to hard labour for the benefit of the commune or parish. Every commune is required by law to have a complete *elementary school*, and every town containing more than fifteen hundred inhabitants to have at least one *town school*. In order to carry this law into effect, it is enacted that the inhabitants of every rural commune shall, under the direction of the public authorities, form themselves into a society composed of all the landed proprietors, and all the fathers of families not landed proprietors, resident in the commune. In general, every village is required to maintain its school. Several villages, however, may have one in common, if each is unable to support the expense of a separate school; provided that the distance from the common school is not greater than two miles in a flat country, or one mile in a hilly country; that the communication is not interrupted by marshes or rivers impassable at certain seasons of the year; and that the number of children is not too large—that is, more than one hundred for one master. For the support of the schools, the law provides—1. A suitable salary to the schoolmasters and schoolmistresses, and maintenance for them when they become incapable of performing their duties. 2. A schoolhouse, properly constructed, kept in repair, and heated. 3. Furniture, books, pictures, instruments, and means requisite for instruction and exercise. 4. The aid to be given to needy scholars. The *first* provision is considered by the law as the most important of all, and the local authorities are enjoined to raise the schoolmaster's salary as high as possible. In regard to the *second*, schoolhouses are to be in a healthy situation, of sufficient size, well aired, &c.; hereafter, they are to be built and repaired in conformity to general models. Attached, must be a garden of suitable size, &c., and applicable to the instruction of the pupils; and, where possible, before the schoolhouse, a gravelled play-ground, and place for gymnastic exercises. The *third* provision comprises a complement of books for the use of master and scholar, according to the degree of the school; a collection of maps, geographical instruments, models for drawing and writing, music, &c.; instruments and collections for natural history and mathematics; the apparatus for gymnastic exercises; and, where instruction is given in the arts, the requisite tools and machines. In regard to the *fourth*, if there be no charity school specially provided, every public school is bound to afford to the poor instruction wholly or in part gratuitous, as likewise the books and other necessaries of education.

The object of these elementary schools is the developement of the human faculties—intellectual, moral, and physical—through an instruction in those common branches of knowledge which are indispensable or useful to the lower orders both of town and country. The *town* or *burgher schools* which the law has provided, carry on the child until he is capable of manifesting a desire for a classical education, or for a particular profession. The gymnasia, a still higher class of seminaries, continue this education until the youth is prepared either to commence his practical duties in common life, or his higher and special scientific studies at the university.

In every complete elementary school in Prussia, the branches taught are, religion; the German tongue, and in the Polish provinces the vernacular language; the elements of geometry and general principles of drawing; arithmetic; the elements of physics, of general history, and of the history of Prussia; singing; writing; gymnastic exercises; the more simple manual labours; and some instruction in the relative country occupations. Every pupil on leaving school receives from his master and the committee of superintendence a certificate of his capacity, and of his moral and religious dispositions. This is produced on approaching the communion, and on entering into apprenticeship or service.

Seminaries for the instruction of teachers, both in the knowledge to be afterwards communicated by them and in the practical art of communicating it, form a very important appendage of the Prussian system of education. Without a proper training of schoolmasters, all public institutions for instruction must be comparatively inefficient. In Scotland, unfortunately, the matter is wholly neglected. On this subject, Professor Pillans has the following pertinent remarks:—"It is a curious fact in the history of our country (and we might extend the observation to more countries than our own), that, while ample provision is made for professional training in every other line, it never seems to have occurred to those whose business it was to make it, that any such provision was required for that profession in which I conceive it is quite as important and indispensable as in any other. In order to qualify a man to be a practising physician, lawyer, or divine, a long probation of preparatory discipline is very properly required. He must study the theory of his profession, and he must witness and engage in the experimental parts of it, before he is admitted to practise it publicly. Nay, more; there is scarcely a handicraft the aspirant to which is not bound to serve an apprenticeship of several years, in order to make himself acquainted with its mysteries. The precautions we take to have our medicines well compounded—our books well printed and well bound—nay, our very shoes well made—we utterly neglect when the question is whether our children shall be well taught. A certificate from a professor of some university, that the youth who bears it has attended a Greek or Humanity class, accompanied with a clergyman's attestation that he has been a regular hearer in his church, and has led a quiet life in his parish, are deemed ample proofs of his fitness to be a schoolmaster; and upon no better evidence are raw lads appointed every day to this difficult and delicate task, of which they have never thought seriously but as a means of subsistence." In Prussia there were, at the close of 1831, thirty-three seminaries for the training of primary instructors. The course of preparation lasts three years; in the first is contained the previous primary education of the pupil; the second is devoted to the special instruction of a higher order; and the third to practical exercises in the annexed primary school, and other establishments of the place.

The universality of the operation of the Prussian law will appear from the following statement:—According to the newest census, the population of Prussia amounts to 12,726,823 souls. Of this number, there were, in the year 1831, 4,767,072 children up to the age of fourteen years complete. Now, it is reckoned, that, out of 100 children from one day to fourteen years old, about 43 are between seven and fourteen—the legal age for attendance at school. Consequently, if all children of the required age attend the public schools, the number would be 2,043,030. Now, it appears from official returns, that, in 1831, the number of children attending the public primary schools was 2,021,421; leaving a deficiency of only 21,609, to embrace boys educated at home or at private schools.*

GERMAN STATES.

Ever since the Reformation, elementary education has been a leading object in the Protestant states of Germany, but comparatively neglected in the Catholic. It has of late years received a great additional impulse, and is now established in Wirtemberg, Baden, and Bavaria, on much the same principles, and to nearly the same extent, as in Prussia. In 1807-8, the Bavarian government established, besides the gymnasia for classical education, seminaries called *Real-Instituten*, where young persons who intend to become merchants, apothecaries, manufacturers, artists, &c. are instructed in those branches of knowledge which are of most general utility—in history, religion, modern languages, mathematics, and the natural sciences. A final reorganisation of the Bavarian system of education took place in 1825. In this kingdom there is a particular department in the ministry of the interior, to superintend the subject of education, whose authority extends to all the various schools and institutions.

Austria possesses a national or state system of education, with the advantages of normal schools, and other establishments, for the instruction of teachers. The groundwork was here laid for elementary instruction among the common people at a much earlier day than in most of the European states. At the beginning of the last century, there were not more than three out of twenty children who enjoyed the advantage of public education; whereas their numbers, at the present moment, are equal to two-thirds of all the young persons who are susceptible of instruction. Of this class there are two millions of individuals in the Austrian states, exclusive of Hungary; and out of these two millions there are nearly one million and a half on the books of the national schools. Deducting 1500 schools of industry and girls' schools, as well as 6000 supplementary schools, which exist in the Hungarian provinces, there are altogether 13,000 elementary and superior schools in the Austrian empire; the average result of which is, that there is one school to every 275 families. In Austria Proper, and the district of Saltzburg, there are 244,382 children of a teachable age, and 231,749 of them are under tuition; in the Tyrol, there are 99,463 children taught, out of 105,250; in Moravia and Silesia, 230,563 out of 250,749; in Dalmatia, 1460 out of 2249; in Styria, Carniola, Carinthia, and Illyria, only 98,150 out of 231,310; and in Gallicia, but 51,129 out of 444,044.

The smaller states of Germany, as Nassau, Lippe-Detmold, Anhalt-Dessau, and the Saxon dukedoms, have done much for schools. All have institutions for teachers, which is perhaps the most cheering feature in the whole system. The great variety of accomplishments which are conferred in the superior schools of Germany, has of late years attracted much attention in Britain, which is no more to be compared to that country in this valuable class of institutions, than Germany is to be compared to Britain in political circumstances. Hence it has now become a prevailing fashion, and one that will probably increase, to send young persons who are destined for liberal though not exactly learned professions, to the German schools. The writer of this sheet was recently informed of a Scottish family consisting of two sons, one of whom has been reared in his native country for the church, and has passed through the narrow and antiquated course of instruction which has been appointed for such individuals; while the other, educated in Germany for a mercantile career, though two years younger, is not only a tolerable classical scholar (and his brother is little more), but can speak in the French and German tongues, reads Italian, is a first-rate mathematician, and possesses a fund of general knowledge and an expandedness of mind, forming the most striking contrast to the acquirements of his brother. Owing in a great measure to the diffusion of education in Germany, the people at large are remarkable for their peaceable and orderly habits. Mr J. C. Loudon, well known for his able works on gardening and other useful arts, visited Wirtemberg, Baden, and Bavaria, a few years ago, and, in a pamphlet published at Paris, gave a highly agreeable account of his observations. "After what I have seen in Wirtemberg," says he, "and what I have observed with respect to its population, I am inclined to regard it as one of the most completely civilised countries in Europe, and I am persuaded that the end of government is more perfectly attained than in Great Britain; because, with an almost equal degree of individual liberty, there is an incomparably smaller amount of crime, misery, and poverty, and much more of politeness and cordiality." In Bavaria the beneficial consequences resulting from the establishment of a system of national education have been more signal than in any other European country. Half a century ago, the Bavarians were the most ignorant, debauched, and slovenly people between the Gulf of Genoa and the Baltic. That they are at present patterns of morality, intelligence, and cleanliness, it would be going too far to affirm; but perhaps no people has ever made a more rapid advancement in the career of civilisation than they have made during the last thirty years. One-eighth of the entire population is at school.

ITALY.

The northern provinces of this country, which are under the sway of Austria, partake of the improved system of elementary education now flourishing in the German states, and are therefore more fortunate in respect of early tuition than the southern states. The schoolmasters have from 250 to 400 Austrian livres of fixed salary, and the schools exhibit a well-organised system of progressive education. It was found a few years ago that in the Venetian part of Lombardy, which contains a population of 1,894,000, there were 1402 elementary schools, attended by 62,000 pupils, besides 29 female schools, attended by 2390 girls.

In the continental territories of the king of Sardinia, popular education is in a very poor condition; but in the island of Sardinia, which contains about half a million of inhabitants, every village or commune has now, by a recent decree, a gratuitous school, for reading, writing, arithmetic, religious instruction, and the elements of agriculture, while there is a normal school for each of the ten provinces into which the island is divided. A very few years since, the learning of reading and writing was forbidden to all who did not possess a capital of 1500 lire; since those horrible times, the number of murders in the island has been reduced from 150 annually to 90.

Popular education in the Papal states is in the hands of the clergy, and hence, though it is widely diffused, it is conducted on narrow principles. The same thing may be said of Naples, though it is admitted that a decided improvement is there taking place. Some attempts have been made to establish Lancasterian schools in Naples, and normal schools are already in existence. In Sicily, a still better prospect is held out. There are in that island both primary and secondary schools, which are encouraged by the government; and the system of mutual instruction has actually taken root in the island.

GREECE.

Since the revolution in this country, a very eager desire of instruction has been manifested by the people. It was stated in 1831, that there were about 400 elementary schools in the Peloponnesus and islands, attended by nearly eight thousand scholars, who were chiefly reared upon the plan of mutual instruction. The means of instruction were, however, very generally inadequate to the end. In many places, the scholars had to meet in the open air, and in some schools of forty pupils there was not one entire book. An institution called the Orphanotrophion has recently been built at Egina, at the expense of government, for the education of the children redeemed by the French government in Egypt, and orphans of the country, as well as the offspring of indigent parents. Here, in 1830, about three hundred children were instructed in the elementary branches of education, and afterwards taught the mechanical arts under another roof. The ancient Greek language is a favourite branch of education in modern Greece, and mathematics are taught in several places. Much has been done for education in Greece by American missionaries, and it is probable that the King of Bavaria, father of the young sovereign recently appointed to rule the country, will not long allow it to want that blessing in its full extent, which he has so liberally conferred on his own subjects. The most promising feature, however, in the prospects of Greece, so far as education is concerned, is the enthusiastic desire of the people themselves to become an enlightened nation.

IONIAN ISLANDS.

In this British dependency, besides an university and a preparatory school, both of which are well attended, there are 125 schools of mutual instruction for elementary education, attended by 4555 scholars. There is a central school in each island, and two in Cephalonia, and the master of each of these institutions inspects the village schools every three months. Slates, pencils, desks, and benches, with a few books, are supplied by the public, under certain conditions.

EGYPT.

The present pacha, Mohammed Ali, among other schemes for the improvement of his country, has established some elementary schools, one of which, at Cairo, has 600 pupils of Turkish and Arabian lineage, who are instructed in their own and the Italian languages, drawing, arithmetic, and geometry, military exercises, and the art of printing. At Dgiaad-Abad, he has also established a military college for the education of officers, and a medical school for the education of surgeons and physicians, for his army. The branches taught in these institutions are almost exactly the same as those which obtain in similar schools in Britain. The object of Mohammed, however, is stated to be less the enlightenment of the people at large, than the improvement of his military resources.

* Many additional particulars of great interest, respecting education in Prussia, will be found in Mrs Sarah Austin's translation of the report made upon this subject by M. Cousin, to Montalivet, the French Minister of Public Instruction, lately published; and in the Edinburgh Review, No. 116, and the Foreign Quarterly Review, No. 24; from which our own knowledge of the subject is derived.

UNITED STATES OF AMERICA.

No country in the world has made such advances in universal education as the United States of America. The tone imparted by the early colonists of the New England states, who were intelligent, educated men, has never been lost; and the principle which they established, that the education of the community should be conducted at the common expense, has never been abandoned in the states that they planted, and has been successively adopted by the states lately incorporated with the Union. There are three descriptions of public seminaries in the States: The first consists of the free schools, at which the elementary branches are taught; the second are the academies, incorporated by law, for giving instruction of a higher kind; and the third are the colleges—three classes of schools forming altogether a routine very much like that of Scotland, and conducted on very much the same plan of instruction.

With regard to the extensive establishment of free schools, one of the chief advantages of the system is, that the whole population is made to take a direct personal interest in the business of education, and to carry it on in the way best suited to supply the general wants. The people in their town meetings vote the assessments for the support of the schools, by their committees spend the money which is collected from this or other sources, and, by their children, get the benefit of the outlay. The process is thus essentially popular, and as free of jobbing as possibly may be. Another great advantage is, that the schools are supported by a tax on property, although there are exceptions to this rule in some of the states, in which a public fund assists in bearing a proportion of the expense. But every where in New England, except in Connecticut, they are supported by a tax on the property of all. It is therefore an arrangement eminently beneficial to the poorer classes of the community. In most towns, one-fifth of the inhabitants pay at least one-half of the tax, and instead of sending one-half of the scholars, do not send one-sixth. Of course the school-tax is substantially a tax on the wealthy to educate the children of the poor. Thus, a mutual benefit flows to both poor and rich. The poor are assured by law that their children shall be educated, and thus preserved from the greatest temptation to crime; while the rich are assured that they shall live in a community where the universal diffusion of education shall keep the foundations of society safe. The schools are in this light a great moral police, to preserve a decent, orderly, and respectable population; to teach men, from their earliest childhood, their duties and their rights; and by giving the whole mass of the community a sense of character and a general intelligence, make them understand the value of justice, order, and moral worth. The mode in which this system of popular education is carried into effect is perfectly simple, and is one principal cause of its practical efficiency. The New England states are all divided into territorial communities called *towns*, which have corporate privileges and duties, and whose affairs are managed by a sort of committee annually chosen by the inhabitants, called *selectmen*. These towns are of unequal size; but in the agricultural portions of the country, which contain four-fifths of the people, they are generally five or six miles square; and upon them, in their corporate capacity, rests the duty of making provision for the support of free schools. In all but the smallest towns, one school, at least, is kept through the whole year, in which whatever goes to constitute a common English education in reading, writing, geography, history, &c. are taught under the immediate superintendence of the selectman, or of a special committee appointed for the purpose. This, however, would not be carrying education near enough to the door of the people, in agricultural districts, to enable them fully to avail themselves of it, especially the poorer classes and the younger children. To meet this difficulty, all the towns are divided into districts, varying in number, in each town, from four to twelve, or even more, according to its necessities and conveniencies. Each district has its district school committee, and receives a part of the tax imposed for education; sometimes in proportion to the population of the district, but oftener to the number of children to be educated. The committee of the district determine where the school shall be kept, select its teacher, choose the books that shall be used, or delegate that power to the instructor, and, in short, are responsible in all particulars for the faithful fulfilment of the trust committed to them; the general system being, that a school is kept in each district during the long winter months, when the children of the farmers are unoccupied, by a male teacher, capable of instructing in reading, writing, and arithmetic, English grammar, geography, and history; while, in the same school-house, during the summer months, schools are kept by women, to instruct the smaller children in knowledge even more elementary. In this way, for the population of New England, consisting of two millions of souls, not less than from ten to twelve thousand free schools are open every year, or, on an average, one school to every two hundred souls—a proportion undoubtedly quite sufficient, and larger than would be necessary, if the population were not in many parts very much dispersed.

With respect to the academies, they are a superior kind of schools established in the larger towns for communicating instruction in the ancient and modern languages, the lower branches of mathematics, and natural philosophy. They are generally incorporated by the legislature at the instance of an association of individuals desirous of procuring better teaching for their children than can be had at the free schools. They sometimes receive grants of money from the public authorities; they are also occasionally founded by charitable donations from private individuals, and are supported in part by the tuition fees of the pupils, which are remarkably moderate. These seminaries, which amount to about five hundred in the country, act as preparatory institutions for the various universities or colleges.

MAINE—POPULATION 399,437.

Every town in this state is required by law to raise annually, for the support of common schools, a sum equal at least to 40 cents for each person in the town,* and to distribute this sum among the several school districts according to the number of scholars in each. According to the reports made in 1826, there were, in the state, 2499 school districts; 137,931 children between the ages of four and twenty-one; of which 101.325 usually attended school; the sum required by law to be annually raised D.119,334 (dollars); annual expenditure D.1?7,875.

NEW HAMPSHIRE—POPULATION 269,328.

Common or free schools are established throughout the state, and for their support, a sum, amounting each year since 1818 to D.90,000, is annually raised by a tax. This state has, besides, a literary fund, amounting to D.64 000, formed by a tax of one-half per cent. on the capital of the banks. The proceeds of this fund, and also an annual income of D.9000 derived from another kind of tax on banks, are appropriated to aid the support of schools.

VERMONT—POPULATION 280,657.

The money raised by the general law of this state for the support of schools amounts to about D.100,000, levied by a process of taxation. Besides this sum, the state has a literary fund, derived principally from a tax of six per cent. on the annual profits of the banks. In 1829, this state had a school-debt of upwards of D.23,00·

MASSACHUSETTS—POPULATION 610,408.

Schools and academies are well supported in this enterprising state. According to the report of the school committee of Boston, in 1829, the number of public schools in that city was 80; pupils 7430; expense of tuition, fuel, &c. D.52,500; the estimated rent of schoolhouses D.10,000; making the whole expense amount to D.62,500. Private schools in the city, 155; pupils, 4018. Besides the Harvard College at Cambridge, there are 56 incorporated academies in the state.

RHODE ISLAND—POPULATION 90,000.

The attention to education in this small state is on the increase. The sum of D.10,000 is now raised annually for the support of free schools, each town receiving a portion of the money according to population.

CONNECTICUT—POPULATION 297,675.

This state possesses an important school-fund, which was derived from the sale of lands, reserved by Connecticut, in the state of Ohio, and which amounted, in the year 1829, to D.1,882,261. The income of this fund is appropriated to the support of primary schools. In one year, up to March 1829, the sum of D.72,161 was divided among the different free schools throughout the state. The number of children between the ages of four and sixteen, in 1828, was 84,899; and the dividends amounted to eighty-five cents to each child.

NEW YORK STATE—POPULATION 1,918,608.

By the report presented in January 1829 to the legislature of this populous and flourishing state, by an official entitled the Superintendant of Common Schools, it appears the school-fund then belonging to the state amounted to D.1,661,081, in stocks and other securities, and 869,176 acres of land; that the revenue actually received into the treasury on account of this fund, in 1829, was D.9?,?26; that there were in the several towns in the state 8872 school districts, and of this number 8292 had complied with the condition of the statute, by having schools kept at least three months by an inspected teacher, and by making returns to the commissioners; that there were in the districts from which reports had been received, 468,257 children over five and under sixteen years of age; and that, in the common schools of the same districts, 480,041 scholars had been taught during the preceding year. "Our system of school instruction," continues the reporter, "is based on the principle that the state, or the school-fund, will pay only a share of the expense, and that the towns, by an assessment upon property, shall pay at least an equal share. The total amount paid this year by the patrons of the common schools for teachers' wages was D.297,048, which, added to the public money, makes an aggregate of D. ,878, paid for teachers' wages alone. Thus it will be seen, that, where the state or revenue of the school-fund pays one dollar for teachers' wages, the inhabitant of the town pays, by a tax on his town, and by voluntary contribution in his district, more than four dollars for the same object. This latter sum of four dollars is made up in the proportion of one dollar assessed upon property to three dollars paid by the scholar."

PENNSYLVANIA—POPULATION 1,348,233.

The law of this state provides for the most extensive system of free elementary education; so much so that the children of every poor man are educated free of all charge. The expenses attendant on the school establishments are defrayed by the county commissioners. The schools are superintended by gentlemen who serve without compensation; and the teachers, who are well qualified for their duties, are liberally remunerated. Stephen Girard, a wealthy merchant of Philadelphia, who died in 1831, bequeathed two millions of dollars (or more if necessary) to build and endow a college or school in that city for the education of orphans; which bequest has been acted upon, and now provides board and education to 300 children, who are taught reading, writing, grammar, arithmetic, geography, navigation, surveying, practical mathematics, astronomy, natural, chemical, and experimental philosophy; and the French and Spanish languages. Principles of morality are also inculcated; but, in the terms of the founder's will, "no ecclesiastic, missionary, or minister of any sect whatsoever, shall ever hold or exercise any station or duty whatever in said college; nor shall any such person ever be admitted within the premises appropriated to the purposes of said college."

DELAWARE—POPULATION 76,748.

There is a school-fund in this state, amounting to D.170,000, the interest of which, together with a small tax levied on each school district of four miles square, at the will of the majority of the taxable inhabitants, is put aside for the support of free schools. It is arranged that no district shall be entitled to any share of the school-fund, that will not raise by taxation a sum equal to its share of the revenue of the fund.

In Maryland, in Virginia, and in the southern as well as in those states lying in the valley of the Mississippi, there appear to be processes of education all less or more similar to the foregoing. In Virginia and some others there are school-funds raised by the sale of escheated property, and lands forfeited for nonpayment of taxes, confiscations, &c. What has been detailed is sufficient to show that the great principle on which the free educational system is based in the states, is the protrusion of schools into the most minute sections of the country, so as to bring education home to the door of every one, and on such a magnificent scheme of liberality that the very poorest person may have his children educated in a way fit to render them useful and intelligent members of society. Our information regarding the mode and extent of instruction in the free schools of the states is much less distinct; but from a personal knowledge of the vast number of excellent elementary, moral, and instructive works, which are now issuing from the American press, and which certainly surpass the antiquated collections, spelling-books, and school treatises in this country, we are inclined to suppose that the minds of the young must undergo a training exceedingly creditable to teachers and parents, and undoubtedly advantageous to the rising generation themselves.

LOWER CANADA.*

This important colony, according to a census taken in the summer of 1831, contains a population of 368,449 souls, which number is receiving constant augmentations by means of emigrants from the United Kingdom. It is gratifying to learn that amid the prosperity which the province is now experiencing, the subject of education is not forgotten or neglected; but that, on the contrary, much of the attention of the colonists and a large share of their public funds are applied to this all-important purpose.

The Royal Institution for the advancement of education, a board incorporated by an act of the Provincial Parliament, has under its management eighty-one schools, attended by 3578 scholars. This institution is supported by an annual grant of the Provincial Legislature, and is placed under the management of the Bishop of Quebec as the principal. The largest of the seminaries thus supported are, the free schools of Quebec and Montreal, the former having 222, and the latter 221 scholars. The board does not enjoin the adoption of any particular course of instruction, but contents itself with selecting competent masters for each school, and leaves to their discretion the choice of the system to be pursued. In addition to these eighty-one schools, the Royal Institution has under its management two grammar schools, one in Quebec and the other in Montreal, where the course of instruction pursued is the same with that followed in the generality of grammar-schools in England. Each of these schools has twenty free scholars, for whose instruction the sum of L.200 is annually assigned out of the revenues of the estates formerly belonging to the order of Jesuits; a further allowance is made of L.90 at Quebec, and L.50 at Montreal, for rent of schoolhouses. Other scholars are admitted to these grammar-schools, upon payment of L.12 annually for each.

* To comprehend the value of these expenses it may be explained that a dollar is worth 4s. 6d. sterling; and the dollar being divided into 100 parts or cents, a cent is thus worth rather more than a British halfpenny

* For this and the following article, as well as for much information in other departments of the present sheet, we are indebted to a work of superlative utility, the Useful Knowledge Society's Journal of Education, published quarterly.

The Royal Institution was established by an act of the Provincial Legislature in the year 1800, and it is probable that the provision then made for the advancement of education in the colony was sufficient at that time. The rapid increase of the population during the last few years, and the moral wants of its new inhabitants, have, however, forcibly called the attention of the colonists to the subject. Under the provisions of a provincial act (9 Geo. IV.), upwards of 1000 schools have been established since 1829 throughout the province; and these schools, according to the most recent accounts, are attended by 45,558 scholars of both sexes. These schools are placed under the management of trustees, who are elected annually by the inhabitants of the township or parish in which each is situated. The sum of L.20 is granted to the teacher of each school, when it is attended by at least twenty scholars. No particular course of instruction is followed, but the British or Lancasterian system has been introduced into many of the schools.

Several colleges are established in different parts of the province in connection with the Roman Catholic church, as well as many private seminaries in which the higher branches of education are taught to children of the richer Protestant inhabitants.

UPPER CANADA.

This province, which is divided into eleven districts, had, in 1831, a population of 211,567 souls. For the purposes of education, each district has an annual grant from the Provincial Legislature of L.90 appropriated towards defraying the expenses of a classical school, in addition to L.250 voted for the support of common schools: this money is distributed by trustees appointed under an act of the legislature. Besides these common schools for daily instruction, there are numerous Sunday schools established in every district of the province; and as the best effects are seen to result from their establishment, these schools are fast increasing in number.

In 1829, the board of trustees for the advancement of education in the province, computed that about 20,000 children of both sexes were provided with some kind of education in the schools of the different districts, and that as many more were without any means of instruction, the public provision made for the purpose being wholly inadequate to the wants of the colony. Since that time, the population of Upper Canada has received an important accession to its numbers, from classes to whom assistance of this kind is most necessary. May we not hope that the example set to its legislature by that of the adjoining province will not be lost; but that the good effects which cannot fail to manifest themselves in the condition of the rising generation in Lower Canada, will stimulate those who possess influence in the upper province to a similar course of action?

York, the capital of the province, has a school, supported by government, where gratuitous instruction is given on the Lancasterian system; this school is managed by a master and two assistants. York also contains the Upper Canada College, and Royal Grammar School, which is under the management of a principal and vice-principal, one mathematical and two classical professors, besides instructors in French, writing, arithmetic, and drawing. The course of studies pursued in this college comprises "the classics, mathematics, English composition and history, writing, arithmetic, geography, and the French language."

WEST INDIES.

Education may be described as in a low state in the West Indies. The children of the planters are generally sent home to Britain to be educated; and hence there are few whites at school in any part of these colonies. It is only within the few past years that the prejudices of the planters would allow any of their slaves to be subjected to school instruction; and, even now, out of a total of 697,418, only 9930, or about 1 in 70, of this unfortunate class, are taught to read, while but a tenth part of these are permitted to acquire writing and arithmetic. Some of the islands, however, are much more liberal in this respect than others. Out of 29,839 slaves, or what were lately slaves, in Antigua, 4451 are at school; out of 19,310 in St Christopher's, there are 1876; while in Jamaica, out of 322,421, only 521 enjoy the blessings of education, of whom but 17 learn writing and accounts. In Tobago, where there are 12,556 unfree people, only 7 are instructed; in St Vincent, out of 23,589, only 138. A greater proportion of the free coloured people are instructed: in Montserrat, out of 814, exactly a half are at school; in Grenada, out of 3786, there are 480. The proportion of school-attenders among the whites appears much below that of any other civilised country: Of 1980 in Antigua, only 39; of 840 in Dominica, only 7; of 322 in Tobago, only 2. Of 32,000 whites and free blacks in Jamaica, 1496 are at school; a proportion apparently above the average. Out of the total West India population of 831,274, the total of scholars is 19,406, of whom only 5864 learn to write.

Though education be thus low in these important colonies, it is constantly rising, and will probably, in a short space of time, be in a much more flourishing state. The schools have as yet depended solely upon private enterprise and private beneficence, and the methods of instruction are not good. But the attention of Parliament has been directed to the subject, and it will probably be deemed a necessary precaution, in anticipation of the manumission of the slaves, that all should be instructed.

CONCLUDING REMARKS.

The present sheet, for the first time it is believed, gives an outline of the state of education over the whole civilised world. The purpose of bringing these facts into one place, was to show how partial and imperfect education has as yet been, and is—how deplorably insufficient both in amount and in method. We are thus enabled to see at a glance, that, even in nations of good character, the mass of the common people are in one of two conditions, either in that of utter unacquaintance with letters, or at the most instructed in nothing besides letters—so that, while the upper classes enjoy a certain reputation for moral and intellectual refinement, the great bulk of the lower are confined to the developement of little more than those parts of their nature which they possess in common with ordinary animals. If the writer has succeeded in making out this case, he trusts that the most of his readers will be inspired with the wish which inspires himself, and which is now gaining ground every where, that fair play should at length be given, by means of a moral, intellectual, and physical education, to the better qualities of the whole of the human race. In the present sheet there is little room to argue upon the subject; but we shall employ the small space that remains to us, in stating what we conceive ought to be done by all nations in respect of education.

Education ought every where to be a matter of state-policy, in order that proper methods and qualified teachers should be attainable. The elementary parts of it ought to be accessible to all orders of the people, without money and without price—payable, however, not out of the national exchequer, but by local assessments.

It should be the first duty of each government to form a proper code of instruction—one calculated to develope and exercise the moral, intellectual, and physical faculties—which should be rendered imperative in all the schools under its protection. To render the system efficient, schools should be established in every considerable district for the instruction of masters in the branches of knowledge to be taught, and in the business of teaching; and a diploma from such an institution should be an indispensable passport to every school, public or private. The normal schools, as these are called, should be supported in the first place by government, while such fees ought to be exacted as may fully or nearly cover the expense.

Elementary education, with moral tuition, ought to be entirely free, because by no other method can the *whole* of the community be brought to school, and because, without the whole community being educated, the great end of education, as a system of moral police, would be defeated.

As curiosity respecting the natural world is the first part of the mental constitution which is developed, and as the success of instruction must greatly depend on the advantage which is taken of the natural dispositions and capacities of the pupil, it would be proper to commence education by introducing the young to natural objects and their various properties, which can be done by means of lively graphic representations. This part of education must be entrusted to what are called infant schools, to which the young should be initiated at about three years of age. It is also possible, in infant schools, to acquaint the children with the elements of arithmetic, and various other branches of knowledge, by means of sensible objects. While mere knowledge is given, it might be made the means of conveying religious impressions also. From the *objects* of nature, the reference to the *God* of nature is easy; and by directing attention perpetually to not only the excellent nature of every thing, but the admirable fitness of all things for each other, the elements of natural theology would be effectually impressed. The pupils must be kept in the constant *exercise* of the virtues—benevolence in thought and action, justice in dealing, truth in speech; and unceasing efforts must be made to repress the inferior feelings and propensities—selfishness, coarseness, cruelty, and improbity. Thus, the pupils, seeing virtue invariably commended in practice, and vice as invariably condemned, will acquire habits which can hardly fail to attend them, in a greater or less degree, through their subsequent years.

At five or six, the infant school period ceases, and the pupils may be properly introduced to the elements of literature. Much of simple reading must depend on the memory. The forms of the letters, and the appearances of these when combined into words, must be impressed on that sense before any progress be made. There is certainly no need, however, to load the memory with any thing beyond the elements of reading: spelling can be learned through the mere impression which the words make upon the eye in the course of reading, and all exercises which consist in the learning of pieces of prose or verse by heart, are only so much lost time, forming, even in their highest success, but an useless wonder to impress parents and visitors with the idea that the children are rendered *clever*. As soon as reading is mastered, it should be immediately employed in its legitimate ends, the introduction of the pupils to the stores of useful and elegant literature, in the acquisition of historical and geographical knowledge, and in the study of the physical sciences.

For reading, the monitorial system will always be found the most convenient and advantageous in large schools. It should be conducted on what is called the intellectual plan, by which it is meant that the pupils must be made to understand every word that occurs. Pictures of objects would also be of service, in the conveying, at least, of substantive ideas. With regard to the teaching of writing, we have no improvements to suggest upon the methods usually adopted; but it may be hinted that arithmetic ought to be explained philosophically, at the same time that its rules are made the subject of regular progressive exercise.

All kinds of knowledge that do not chiefly consist in substantive ideas, should be left to the latter part of the course. In their earlier years, children are capable of understanding very little beyond what can be seen and touched; and it is therefore necessary to wait for the developement of the faculties before any attempt be made to convey abstract ideas. Almost all the physical sciences consist in sensible ideas, and hence, with proper exemplifications, the most of them can be taught to pupils under ten years of age. Children at that period of life can be easily taught chemistry, geology, mechanics, the elements of geometry, natural history, including animal and vegetable physiology; and they *ought* to be taught those sciences. Simple classbooks should be prepared for the purpose, and, so far as possible, experimental apparatus should also be provided. Here, in our opinion, terminates the education which should be at the public expense.

In a more advanced order of schools, the teacher ought to proceed to abstract studies. Among these we would be disposed to include grammar, which cannot be fully comprehended by children under eleven or twelve years of age. To this time of life ought also to be postponed the study of foreign languages, living and dead, so far as these might be deemed necessary for particular pupils. The more necessary studies of this period are natural theology, the higher branches of mathematics, political economy, the principles of the constitution under which the pupils live, and a few simple views of the nature of the human mind. The whole course could easily be arranged in such a manner as to terminate at the age of fourteen, when the pupil would be sent out to the world, not confused with a few Latin and Greek words, as the scholar of the present day generally is, but fully acquainted with the world in which he is to live, and with his own constitution, mental and bodily; qualified to judge clearly between right and wrong; capable of protecting his own health and interest, and inspired with the best feelings towards his fellow-creatures; in short, a being whose natural properties had all been trained and improved to the best advantage, in obedience to what appears to have been the will and design of his Creator. The remaining years of youth, where the calls of a profession did not interfere, might be employed in an extended course of private reading, and in attendance on such academic or other classes as seemed likely to be advantageous.

Such is a brief and imperfect outline of a system of education, which appears to us to combine the best ideas of the most enlightened inquirers into this subject. It may be long before existing circumstances and prejudices will allow such a plan to be followed very generally; but that it will be eventually followed every where throughout what is called the civilised world; and that it will in time raise the moral and intellectual nature of man far above what it has ever been supposed capable of, we have no doubt. If the industrious classes in our own country had a true perception of their interests, they would take up the question with far more fervour than they have ever displayed in either political or trades' unions, and their aid would be of much service in promoting the cause. It is the master-key to all the difficulties and distresses of their situation. If their interests have been in any instance sacrificed or neglected, if their blood has been shed in wars, and their physical strength overtasked in toils on behalf of their superiors, it has only been owing to their ignorance. If they desire that their rights should be efficiently protected, they must cause themselves to be instructed, in order that they may become their own protectors. The improvement of their condition rests almost entirely with themselves, and education is the means by which they may be enabled to work that improvement.

PNEUMATICS, ACOUSTICS, AND AERONAUTICS.

PNEUMATICS.

PNEUMATICS is a term derived from a Greek word which signifies *breath* or *air*, and denotes the science which treats of the mechanical properties of elastic fluids, such as the air or atmosphere which we breathe. Reasoning by analogy, we conclude that all material substances are capable of existing in three different states, the solid, liquid, and aëriform; each state depending upon the quantity of heat which the body contains at the time. Thus, the liquid water, when deprived of a certain portion of heat, becomes the solid body ice; and when, on the other hand, a certain proportion of heat is imparted to it, it becomes the aëriform body steam. Steam, however, though a highly elastic body, and hence exactly similar in this respect to the aëriform fluids treated of under Pneumatics, differs from them in this, that it does not remain permanently elastic; that, in fact, at ordinary temperatures, it does not exhibit this form at all, but appears as the liquid water. The term vapour is usually applied to such bodies as are fluid at the ordinary temperature of the atmosphere, but can by natural or artificial heat be made to exist in the elastic form. To distinguish between fluids such as water and those similar to air, the former are sometimes called *inelastic*, and the latter *elastic*, fluids. But as water is compressible, and possesses the property of occupying the same space after the mechanical force by which it was condensed is withdrawn as it did before it was applied, these terms of distinction are in strict philosophical language incorrect. Air, or gas, which is a German word for air, differs from other fluids such as water in two circumstances, great lightness, tenuity, or thinness, and extreme elasticity. By extreme elasticity is meant that quality in virtue of which certain bodies are easily compressed into smaller bulk than they naturally possess, and as easily resume their former state when pressure is withdrawn from them. Indeed, so extremely compressible is common air in comparison with water, that did not the term inelastic, as applied to fluids such as water, convey an idea that it was impossible to make them occupy smaller space (they still of course retaining their liquid state), the words elastic and inelastic would admirably distinguish the two classes of fluids alluded to; and with this explanation we may occasionally employ them.

But there is another and a most important characteristic distinguishing fluids such as air from all others: it is, that the particles of which they are composed mutually repel each other. In water they are kept together by the attraction of cohesion; in the state of air there exists no cohesive attraction whatever, and the atmosphere is only prevented from dissipating itself throughout space, by the common attraction which each individual particle possesses for the earth. Elastic fluids differ materially in their chemical properties; but as atmospheric air exhibits all the mechanical properties which we shall have occasion to notice with reference to these bodies, our investigations are entirely confined to it.

THE ATMOSPHERE.

The atmosphere is that thin transparent fluid surrounding our globe to the height of about fifty miles. It is in this aërial medium that clouds, balloons, &c. float like light bodies in water, by which birds are enabled to fly, and of which we breathe. For its composition and chemical properties, see our number upon Chemistry. The air is sometimes said to be invisible, but this is not correct; it is an azure coloured fluid, as is proved when we turn our eyes to the firmament above us. The reason why we cannot perceive the atmospheric tint when we view only small quantities of air, is, that, from its extreme rarity, it reflects colour very faintly; and hence a great mass of the substance must be looked at before as many of the rays of light which it reflects can be concentrated upon the eye, so as to convey to it the sensation of colour. For instance, sea-water is green when we view an immense quantity of it, such as the German Ocean; but if we view it in a wine-glass, it appears perfectly colourless. On a dry clear day, the hills at only a few miles' distance appear of a bluish hue, not because they really are blue—for they are usually covered with green vegetation—but because they are seen through a blue medium; that is, the atmosphere.

Air possesses all those properties of matter which were described in Natural Philosophy; namely, impenetrability, inertia, gravity or weight, &c.

IMPENETRABILITY OF AIR.

The nature of this property was explained in Natural Philosophy; and that it is possessed by atmospheric air, is proved by numerous experiments. It is shown by a very simple one, in which a common tumbler is inverted over water. If this be done, the liquid will be found to rise a little in the inside of the tumbler; but it will stop there, and cannot be made to rise to the top, though it were sunk to the bottom of the Atlantic. If into a cylinder an air-tight piston be introduced, it can be pushed down to some extent, but no power or weight, however great, can compress it to the bottom. Before this could possibly take place, the cylinder would burst. These facts plainly prove that air is material, and that it possesses that property called impenetrability, by which it excludes every other body from the space which it occupies at any given time. It may be compressed to a great extent, but never into a space so small as to be below calculation. Additional proofs of the existence of this property will appear as we proceed with our subject.

INERTIA OF AIR.

It will be recollected that, by inertia, was meant that property of matter in virtue of which it requires a certain effort or force to produce motion if a body be at rest, and to destroy or modify that motion if it be not at rest. It was also stated, that, when one solid body puts another in motion, the former loses as much as the latter receives. The most familiar instance of the inertia of air is the wind, which is just air in motion. If a flat surface be presented to the wind, a power is exerted which will propel it forward in the direction in which the column of air is moving, the force being in proportion to the velocity of the latter. We see this illustrated in the case of ships, and also of balloons. However, where the surfaces are connected by arms with a moveable axle, as in the case of windmills, a rotatory motion is produced, and that, too, of a power sufficient to drive machinery of considerable extent. But the power exerted by air in motion, notwithstanding its extreme thinness, is evinced by the dreadful effects produced by hurricanes. These terrible visitations sometimes lay whole islands desolate. When the air is in a state of rest, the same fact is proved by moving forward in it a body presenting a broad surface. A degree of resistance is offered to its motion through it, which resistance is proportionate to the velocity with which the body moves. In walking at an ordinary pace on a calm day, this is not perceived; but those travelling with steam-coaches between Liverpool and Manchester, where the speed is very great, will readily distinguish it; and should the wind be blowing in a direction opposite to that in which the vehicle is moving, the resistance will be considerable. The observations which were made in the article Hydrostatics relative to the speed of steam-boats, are equally applicable to steam-carriages.

Before adverting to the weight or gravity of air, it will be necessary to treat of its elasticity.

THE ELASTICITY OF AIR.

By the term elasticity is signified that quality in virtue of which a body, when compressed into a smaller space than it naturally occupies, fills that space again when the power by which it was compressed is withdrawn. A small bladder of air may be squeezed between the hands so as to be considerably reduced in size; and on opening the hands again, and withdrawing the pressure, it will instantly resume its former bulk. If a metallic tube or barrel be fitted with a moveable plug or piston, which is made to work in it perfectly air-tight, the air which occupies the space between the top and the bottom of this barrel when the piston enters, can be compressed to a hundredth part, or even less, of its usual bulk. If the force, however, by which the piston is pushed down, be withdrawn, the air, by its elasticity, will force it up again with a power equal to that by which its descent was resisted. A uniform law governs the increase of elastic force, arising from the diminished bulk of the air, which is, that the elastic force, or the pressure exerted by the air against the sides of the vessel which contains it, is increased in precisely the same proportion as the space which it occupies is diminished. Thus, then, the remarkable law is established, that the elastic force of air is proportional to its density. This law, though generally true, is not found to be exact in extreme cases both of condensation and rarifaction. When a high degree of condensation is required, a greater degree of compressing force is found to be necessary than that which would result from the above law. If an external pressure of 15lbs. on each square inch be sufficient to confine atmospheric air in its ordinary state, it would only require a pressure of 150lbs. on the square inch to confine it when reduced to one-tenth of its bulk by compression; but by this law it is found to require a somewhat greater force. In other words, when a great degree of condensation is effected, the elasticity of air increases in a somewhat higher ratio than the density.

In like manner, we find that in high degrees of rarifaction the law is also not precise, highly rarified air having a less degree of elasticity than that which would be consistent with the law. This, indeed, is a necessary consequence of the former, or rather it may be considered as another way of expressing the same fact.

It must also be observed, that the above law can only hold true in cases where the temperature remains the same; for heat, whilst it decreases the density, increases the elasticity of air. Thus, a flaccid or partially filled bladder, if held to the fire, will expand so as to become perfectly filled, and have a tendency to burst. The elastic force of the air is beautifully illustrated by what is called the air-fountain.

Fig. 1.

There are two species of air-fountains. The most simple arrangement consists in employing the elastic force of the air compressed in a close vessel, and made to act on the surface of the water or in the pump. The second form is exhibited in the accompanying woodcut, and requires the aid of the air-pump to put it in motion. The receiver in which the fountain is seen to play must be made to fit air-tight on the ground brass plate beneath. The stopcock must then be screwed into the plate of the air-pump, and a vacuum formed. After turning the stopcock to prevent the entrance of the air, the lower extremity of the tube should be increased in a vessel of water, and, on again opening the communication, the water will be seen to rise in a continuous stream, forming a beautiful *jet d'eau*. The elevation of the water in this case is, it will be obvious, dependent on the pressure of the atmosphere. Other instances of the pressure of the atmosphere will occur as we proceed with our subject.

WEIGHT OF THE AIR.

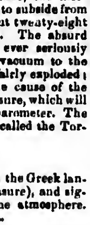
That the air possesses weight, and presses upon every object upon the surface of the earth with a certain degree of force, is a fact familiar to every one; but that, by means of this weight, some of the common mechanical phenomena are to be accounted for, is only of recent discovery. Amongst ancient philosophers, the idea was entertained that nature had an abhorrence of a vacuum; and that, when a vacuum was by any means formed, the air rushed in by virtue of this said repugnance of inert matter to the existence of a void space. The antipathy thus entertained by nature served the purposes of philosophy for two thousand years, when some engineers at Florence, in sinking pumps, had occasion to construct one to raise water from an unusually great depth. Upon working it, they found that the water would rise no higher than about thirty-two feet above the well. Galileo, the most celebrated philosopher of that day, was consulted in this difficulty, and it is said that his answer was, that "nature's abhorrence of a vacuum extended only to the height of thirty-two feet, but that beyond this her disinclination to an empty space did not extend." Some writers deny the fact of his having given this answer; others admit it, but take it to have been ironical. It has been more generally taken as a solution seriously intended. It appears, however, that Galileo, having his attention thus directed to the point, soon saw the absurdity of the maxim that "nature abhors a vacuum," and sought to account for the phenomenon in other ways. He attributed the elevation of the water to an attraction exerted upon that liquid by the piston. This attraction he considered to have a determinate intensity; and when such a column of water was raised as was equal in weight to the whole amount of the attraction, then any farther elevation of the water by the piston became impossible.

It is affirmed by some writers that Galileo, at the time when he was interrogated upon the subject, was aware of the true cause of the phenomenon, and only avoided a direct answer because he had not yet completed his investigations. This is generally supposed to be an unlikely circumstance. That he did not solve the problem, is certain; but that he had made some advances towards the solution of it, appears probable, from the fact that Torricelli, his pupil, directed his attention to the same subject, and came to the conclusion, that whatever be the cause which sustains a column of water in a pump, the measure and the energy of that power is the weight of the column of water; and that, if a liquid be heavier or lighter bulk for bulk than water, then the same force sustains a lesser or greater column of such liquid. He proved the fact by experimenting upon mercury, which, as is well known, remains fluid at ordinary temperatures, and is extremely heavy. A glass tube thirty inches in length, closed at one end and open at the other, he filled with mercury; and applying his finger to the open end to prevent the escape of the mercury, he plunged it into a cistern filled with the same fluid. No air was thus allowed to enter the tube, the mercury contained in which was observed to subside from the top and stand at the height of about twenty-eight inches, as Torricelli had anticipated. The absurd notion, therefore, if any such was ever seriously maintained, that nature abhorred a vacuum to the extent of about thirty-two feet, was fairly exploded; and Torricelli soon perceived the true cause of the phenomenon, namely, atmospheric pressure, which will be illustrated in the description of the barometer. The vacuum thus formed by Torricelli is called the Torricellian vacuum.

THE BAROMETER.

The term barometer is derived from the Greek language (*baros*, weight, and *metron*, measure), and signifies a measurer of the weight of the atmosphere. The following figure represents one:—

Fig. 2.



Let A B be a glass tube, upwards of thirty-two inches in length, closed at the extremity B, and open at the opposite end A. After the tube is carefully cleaned on the inside, let it be filled with mercury or quicksilver, which has been well cleansed, and freed from air by boiling. G H is a cistern also filled with mercury to the height C D. Let the finger be placed upon the open end A of the tube, which being turned downwards, is plunged into the cistern, and the finger removed when the orifice is below the surface of the liquid in the large vessel. The mercury in the tube will be found to fall to about the height of twenty nine or thirty inches, where, after a few vibrations, it will remain.

Now, the question arises, Why does the mercury in the tube not fall to the level of that in the cistern, instead of standing at the height E? The tube being closed at B, the space B E must be destitute of air or any other fluid, and is hence a vacuum. The column of mercury E P, therefore, presses with nothing but its own weight on the level C P D of the mercury in the cistern; for, since all air is excluded from the inside of the tube, there can be no atmospheric pressure. According to the universal law of hydrostatics, that pressure is transmitted in all directions, by the pressure of the column E P, exerted at P, it is transmitted to the whole surface, C P D, which accordingly has a tendency to rise with an equivalent force. But this tendency to rise is resisted by some other force which is exactly equal to the weight of the column of mercury. This is plainly the weight of the atmosphere which presses upon the surface of the quicksilver in the cistern, and prevents it from being elevated. An instrument constructed upon the above principles is a barometer.

If we suppose the base of the column P E to be equal to a square inch, it follows that the atmosphere presses on every square inch of the surface of the mercury in the cistern with a force equal to the weight of a column of mercury whose base is a square inch, and whose height is P E.

It might appear that in this experiment the weight of the column of mercury P E, suspended in the tube, must be equal to the total pressure on the surface of the mercury in the cistern, and that, therefore (supposing, as before, the base of the column in the tube to be equal to a square inch), this pressure being distributed over as many square inches as are in the surface of the mercury in the cistern, the proportion of pressure by which the ascent of each square inch must be resisted, is as many times less than the weight of the column P E, as the surface of the mercury in the cistern is greater than the base of the column. But this is not the case; for it is, as we have remarked, the peculiarity of fluids not merely to transmit pressure equally in every direction, but to transmit whatever pressure is exerted on any one part of its surface undiminished, to every part equal in magnitude with the first. That it is the weight of the atmosphere which, pressing on the surface of the mercury in the cistern, sustains the column of mercury in the tube, will be made manifest by breaking the upper end B of the tube, and admitting the air to press on the mercury E. The consequence will be, that the mercury in the tube will fall to the level P of the mercury in the cistern.

There is another very satisfactory proof that the weight of the atmosphere is the cause which sustains the mercury in the tube. If a tube of more than thirty-four feet long be immersed in a cistern of water, and the air be withdrawn from it, by means which shall be hereafter explained under the head Air-Pump, the water will rise according as the air is expelled, but the ascent of the water will be limited to about thirty-two perpendicular feet; at the same time it will be found that the column of mercury suspended in the barometric tube will be about twenty-eight perpendicular inches. If, then, the weight of the atmosphere be the cause which sustains both the water and the mercury, we may expect to find that a column of water thirty-two feet high, and a column of mercury twenty-eight inches high, ought to have the same weight when they have the same base. To determine whether this be the case, let equal measures of mercury and water be accurately weighed, and it will be found that the mercury is about thirteen and a half times heavier than the water. Hence we perceive that a column of water, whose base is a square inch, and whose height is thirteen inches and a half, will have the same weight as a column of mercury whose base is a square inch, and whose height is one inch. Hence it appears that columns of water and mercury with equal bases, will have equal weights, if the column of water be thirteen and a half times the height of the mercury. In the present instance, the height of the water is 32 feet, or 384 inches, and that of the mercury is 28 inches. If 384 be divided by 13½, the quotient will be nearly 28 inches. We may in general estimate the pressure nearly by allowing 1lb. for every two inches in the column; and thus, when the column is thirty inches in length, the atmospheric pressure is 15lbs. on every square inch.

In the construction of barometers, there are a few circumstances which must be attended to, in order to render the instrument a perfect indicator of atmospheric pressure. It is evident that the space E H, above the mercury in the tube, should be a perfect vacuum; for if it be occupied by any aërial fluid, the latter will of course press upon the mercury, and thus the real weight of the atmosphere will not be ascertained. To prevent this, the inside of the tube is made perfectly clean and smooth, and the mercury, before it is introduced into it, is boiled, for the purpose of expelling the air which it generally contains in its ordinary state. The tube is also freed from moisture by means of heat, and it will even contribute to the perfection of the instrument to boil the mercury in the tube. But notwithstanding every precaution and means employed to insure perfection in the instrument, even in the most perfect barometer an atmosphere of mercury occupies the upper part of the tube.

As the pressure of the atmosphere is subject to variations, the amount of pressure at any given time is determined by a scale marked upon the barometer; and this is one of the most interesting uses of the instrument. The weight of the superincumbent air is never less than what sustains a column of mercury at the height of twenty-eight inches, and never more than what supports one at the height of thirty-one inches. Indeed, the range of the fluid may be said to be confined to three inches. It is evident, that, as the pressure upon the surface P in the cistern is lessened, the mercury there will rise, and the top of the column E will fall; the surfaces of the two columns of mercury thus always moving simultaneously, and in opposite directions. Hence, if the scale by which the distance between these surfaces is measured be fixed, two observations would be necessary to determine the height of the column. This may be avoided to a certain extent by making the cistern large and the bore of the tube small, so that any change in the altitude of the latter can produce very little upon the level of the mercury in the former; but, for scientific purposes, several improvements have been made by which the inconvenience is obviated. Amongst these, the following may be noticed:—The glass tube containing the mercury is enclosed in one composed of brass, which has an opening at D E, fig. 3, sufficiently large to show the rise and fall of the mercury in the places where it is to be used. Upon this tube a scale is engraved for indicating the changes in the height of the column of mercury, and the whole is fixed in the cistern A B, which has a bottom B moveable by a screw V, by turning which, the level of the mercury in the cistern may be raised or depressed. An index of ivory is attached to the top of the cistern, furnished with a fine point P, for showing the level from which the divisions of the scale C F are measured. When observations are to be made, it is just necessary to turn the screw V, until the surface of the mercury meets the point P, and the divisions upon the scale C F represent the actual change of height in the barometric column. This is the usual form of a barometer mounted and provided with a scale. This scale C F may be furnished with a *vernier* or *nonius*, to give greater accuracy to the observation, and by which extremely small changes are indicated, as low indeed as the one-hundredth part of an inch.

Fig. 3.

The range of the mercury in the tube is sometimes increased by making it of a diagonal form, the diagonal bend of the tube commencing at a point rather lower than that which the mercury falls when it is at the greatest degree of depression, and rising to a height equal to that which it attains by ordinary atmospheric pressure. But the wheel barometer, another contrivance for enlarging the scale of the instrument, is more frequently used, and for common domestic purposes is attended with some convenience. It is represented in the following figure:—

Dr Lardner thus describes it:—"The barometric tube is here bent at its lower extremity B, and turned upwards towards E. The atmospheric pressure acts upon the surface F, and sustains a column of mercury in the tube B A, which is above the level of F. The bore of the tube being in this case equal in every part of its length, it is clear, that, through whatever space the surface E falls, the surface F will rise, and *vice versa*. Hence it is obvious that the variation in the height of the barometric column will always be double the change in the height of either surface E or F; for if the surface F fall, the surface E must rise through the same space. They are thus receding from each other at the same rate; and, therefore, their mutual distance will be increased by the space through which each moves, or by double the space through which one of them moves. In the same manner, if F rise, E must fall, the two points mutually approaching each other at the same rate; so that the distance between them will be diminished by the space through which each moves, or by double the space through which one of them moves. The change, therefore, in the height of the barometric column will always be double the change in the position of the level F. Upon the surface A F, there floats a small ball of iron suspended by a string, which is carried over a pulley or small wheel at P, and counterpoised by the weight at W, less in amount than the weight of the iron ball. When the surface F rises, the iron ball, being buoyant, will be raised with it, and the counterpoise W will fall; and when the surface F falls, the weight of the iron ball, being greater than the weight of the counterpoise, will cause it to descend with the descending surface, and to draw the counterpoise W up. It is evident, that, through whatever space the iron ball thus moves in ascending or descending, an equal length of the string will pass over the wheel P. Now, this string rests in a groove of the wheel, in such a manner that by its friction it causes the wheel to revolve; and, consequently, the revolution of this wheel indicates the length of string which passes over its groove, which length is equal to the change in the level of the surface F. Upon the centre of this wheel P, an index H is placed, which, like the hand of a watch, plays upon a graduated circular plate. Let us suppose that the circumference of the wheel P is two inches, then one complete revolution of this wheel will correspond to a change of two inches in the level F, and therefore to a change of four inches in the barometric column. But in one revolution of the wheel P, the hand or index H moves completely round the circle; hence the circumference of the circle corresponds to a change of four inches in the barometric column. Now, the circular plate may easily be made so that its circumference shall measure forty inches; consequently, ten inches of this circumference will correspond to one inch of the column, and one inch of the circumference will correspond to one-tenth of an inch of the column. In this way, variations in the height of the column, amounting to the tenth of an inch, are indicated by a motion of the hand H over one inch of the circumference of the plate. By further subdivision, a still greater accuracy may be obtained. In the form of the barometer, it is evident that the preponderance of the iron ball assists the atmospheric pressure in sustaining the column. This cause of error, however, may be diminished almost indefinitely by making the preponderance of the ball over the counterpoise W barely sufficient to overcome the friction of the wheel P. Again, when the atmosphere is diminished in weight, and when the

Fig. 4.

surface F has a tendency to rise, it is compelled to raise the ball—and there is the obvious limit to the indications of the instrument; namely, that a change so slight that the difference of pressure will not exceed the force necessary to elevate the ball, will fail to be indicated."

There are various other contrivances for enlarging the scale of the barometer, and insuring the accuracy of the results which it indicates.

WEATHER-GLASS.

From a long course of observation it has been found that changes in the atmospheric pressure are connected with changes of weather, and from this connection it has been attempted to establish rules by which *rainy*, *fair*, or *changeable* weather may be predicted, according to the variations in the altitude of the barometric column; hence the instrument has been designated a *weather-glass*. Perfect accuracy, however, cannot be looked for in these indications. The rule which seems most generally to obtain is, that the mercury is low in high winds; but even this often fails. Little attention is to be paid to the terms *rain*, *fair*, *changeable*, &c., usually engraved on the plates of these weather-glasses, for the changes of weather are not so much indicated by the actual height of the mercury as by its variations in height. We give the following as the most correct series of observations which have been made by means of this instrument:—

1. The barometer rising, may be considered as a general indication that the weather, comparatively with the state of it at the time of observation, is becoming clearer.

2. The atmosphere apparently becoming clearer, and the barometer above *rain*, and rising, show a disposition in the air for fair weather.

3. The atmosphere clearing, and the barometer above *changeable*, and rising, indicate fair weather.

4. The atmosphere clear, and the barometer near *fair*, and rising, denote continued fair weather.

5. Our prognostic of the weather is to be guided relatively, thus:—If, notwithstanding the sinking of the barometer, little or no rain follow, and it afterwards rise, we expect continued dry weather.

6. The weather for a short period—viz. from morning until evening—may commonly be foretold with a considerable degree of certainty. If the barometer has risen during the night, and is still rising, the clouds high and apparently dispersing, and the wind calm, especially if it be in or about the north or east points, a dry day may be confidently expected.

7. During the increase of the moon, there seems to be a greater disposition or effort in the air for fair or dry weather, than in the wane; but this disposition does not commence till three or four days after new moon, and ceases about four days after full moon.

8. The barometer should be observed occasionally—thrice in the day, or oftener, when the weather is changeable—in order to notice whether the mercury be stationary, rising, or sinking; for from this circumstance, together with the direction of the wind, and the apparent state of the air at the time, is information to be collected, and a continuance of the same, or a sudden change of the weather, to be foreseen.

Lastly, it is to be observed, that the higher the mercury stands in the scale in each instance, and the more regularly progressive its motion is, the stronger will be the indication. Likewise, the more the wind inclines towards the north or east points, the greater will be the disposition in the air for fair weather. It is obvious that the indications of rainy weather are the reverse of those which predict fair weather.*

MEASUREMENT OF HEIGHTS.

The barometer has been applied to the measurement of heights, and this is one of its most important uses. It is clear, that, as we ascend to great elevations, the pressure of the atmosphere will be diminished, there being a much less portion of it above us; and hence the altitude of the barometric column will be proportionally lessened. At the level of the sea, the medium height of the column of mercury is twenty eight inches; on the top of Mount St Bernard it is only the half of that; and in the balloon in which De Luc ascended, it fell as low as twelve inches. This elevation was upwards of 20,000 feet. A considerable degree of difficulty, however, attends the determining of heights by means of the barometer. If the atmosphere remained always in the same state, and, like water and other such fluids, had at all heights the same density, the experiment could be easily performed, and the barometer would become an accurate measure of the difference of level of two stations, or their perpendicular altitude above the level of the sea. But from the great compressibility or elasticity of air, each inferior stratum has a higher degree of density than that which is above it. Neither does this density increase or change according to any fixed and known law; for the temperature, which, as is well known, affects the density of bodies, is continually varying. Generally, the temperature decreases as the height of the station increases, but not according to any fixed rule. Thus, then, the irregular variation in temperature produces an irregular variation in density, and therefore produces an irregular variation in the change of the barometric column. Notwithstanding these irregularities, rules have been determined, by which the difference of level of two places may be computed when the heights of the barometer and thermometer at the two places are known.

We have already observed, that the atmosphere presses upon bodies with a force equal to 15lbs. for every square inch of surface. All bodies which exist at the surface of the earth are continually exposed to this pressure, and at first view it might be supposed that this great weight would produce very destructive effects. Thus, the body of a man, the surface of which amounts to 2000 square inches, sustains a pressure from the surrounding air (for like all fluids it transmits pressure in every direction) to the enormous amount of 30,000lbs. Such a weight, one would suppose without due consideration, would be capable of crushing him to atoms. But this we find is not the case, and men, as well as all other animals, move with perfect ease, and are for the most part scarcely conscious of the existence of an atmosphere at all. This is very easily accounted for. The internal parts of their bodies are filled with fluids, both in the liquid and gaseous states, which offer a pressure from within, exactly equivalent to the external pressure of the air. This is manifested by applying to the skin the mouth of a close vessel to which an exhausting syringe is attached. By this instrument the air may be confined in the vessel, and the atmospheric pressure consequently partially removed from the skin. Immediately the force of the fluid from within will swell the skin, and cause it to be sucked into the glass. This experiment may be performed by the mouth on the hand or arm. If the lips be applied to the flesh, and the breath drawn in so as to produce a partial vacuum in the mouth, the skin will be drawn or sucked into the mouth. This effect is produced in the same manner as in the former instance.

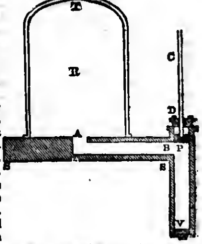
All cases of that class of effects which are commonly expressed by the word *suction*, are accounted for in the same manner. The flies and other insects which walk upon ceilings and other surfaces presented downwards, are enabled to do so from the peculiar formation of their feet, by which they form a vacuum. These act as suckers excluding the air between them and the surface with which they are in contact, and the atmospheric pressure keeps the animal in its position.

The effects of atmospheric pressure are presented to us in a great variety of natural phenomena, as well as artificial contrivances. In the act of breathing, the pressure and elasticity of the air are both engaged. The air enters the lungs on the same principle as it rushes into a vacuum. By the chest being expanded, an empty space is formed into which the external air forces itself; by a muscular action, the lungs again are compressed, so as to give the air a greater elasticity than the pressure of the external atmosphere. By the excess of this elasticity it is propelled, and escapes by the mouth and nose. The working of a pair of common bellows is precisely similar. The effect of atmospheric pressure is strikingly shown in the emptying of a cask filled with a liquid. It is well known that liquors are usually drawn off by a cock which enters the vessel near the bottom of one of the ends, and it is customary to make a vent-hole on the top of the cask, otherwise the liquid would not flow out so rapidly, and indeed would finally stop altogether; for as the cask empties, the air which may be confined in it becomes so rarified, that the external pressure upon the orifice of the cock counterbalances both the pressure of the column of water within, and also the confined air. When, however, the vent-peg is withdrawn from the hole, the external air rushes in. Thus, the pressure upon the orifice of the cock and the surface of the liquid in the vessel are equally balanced, whilst the weight of the column of the fluid upon the internal orifice of the cock forces the lower stratum forward, and thus the liquid escapes. It is upon this same principle that we see holes made in the tops of teapots, teakettles, and such like utensils. The gurgling noise which is produced in decanting wine and other liquors, arises from the pressure of the atmosphere forcing air into the interior of the bottle as it is emptied. What is termed the pneumatic trough used in the chemical laboratory, and the gas-holders or gasometers used in gas-works, depends upon atmospheric pressure. A vessel with its mouth upwards is completely filled with a liquid; the mouth is then stopped with a flat piece of glass or other smooth surface, and the vessel inverted, the mouth being plunged into a cistern filled with the same liquid. It is evident that although the body which covers the mouth of the vessel be withdrawn, provided the column of water within it do not rise to a height which more than balances the atmospheric weight, it will be retained in its place by the latter. The pneumatic trough is simply a large cistern filled with mercury, in which is placed, below the surface of the liquid, a shelf to support a receiver. If a vessel which has been plunged in the trough and filled be slowly raised, still keeping its mouth below the surface of the liquid, it will remain filled with mercury. The mouth may then be placed upon the shelf, and the greater part of the vessel remains above the surface. It is customary to introduce gases upon which chemists wish to experiment into vessels of this description. A flexible tube is introduced into the mouth of the vessel which is below the surface of the mercury; the gas flowing through this tube rises into the interior of the vessel, and, displacing the quicksilver, occupies its place. The gasometer used in gas-works is constructed on the same principles, but upon a different scale.

THE AIR-PUMP.

Air is capable of being either condensed or rarified to an almost indefinite extent. The methods by which rarifaction and condensation are effected we shall now explain. The air-pump is exhibited under various forms, each of which is attended with particular advantages, according to the purposes to which it is applied. There are, however, some general principles in which all modifications of this interesting machine agree, which we shall first explain. Let R, fig. 5, be the section of a glass vessel, closed at the top T, but open at the bottom, and having its lower edge ground smooth, so as to rest in close contact with a smooth brass plate, of which S S is a section. When the receiver R is thus placed upon the plate S S, it will, with the assistance of a little unctuous matter previously rubbed on the edge of the glass, be in air-tight contact. In the plate is a small aperture A, which communicates, by a tube A B, with a cylinder, in which a solid piston P is moved. The piston-rod C moves in an air-tight collar D, and a valve V is placed in the bottom of the cylinder, opening outwards.

Fig. 5.



Let the air in the receiver R, the exhausting tube A B, and the barrel S V, be first supposed to have the same density as the external air. Upon depressing the piston, after it has passed the aperture B, the air in the barrel S V will be compressed by the piston; its density, and therefore its elasticity, will be increased, and will become greater than that of the external air. This superior elastic force will open the valve V, through which, as the piston descends, the air in the barrel will be driven into the atmosphere. When the piston has reached the bottom of the cylinder, the valve V will be closed by a spring or otherwise, and will be pressed into its seat also by the atmospheric pressure. When the piston has thus arrived at the bottom of the barrel, the air which before filled the receiver R, and the exhausting tube A B, will have expanded by its elastic property, and diffused itself also through the barrel above the piston. But, upon again raising the piston, it will be forced back into its former bounds, until the piston has passed the aperture B. As the piston ascends, it leaves beneath it a vacuum, into which the external air is prevented from entering by the valve V. When, therefore, the piston has been raised beyond the aperture B, the air in the receiver R, and the exhausting tube A B, will expand once more, and also fill the barrel S V. Upon a second depression of the piston, the air which fills the barrel will be discharged, and similar effects will follow its ascent, and so the process may be continued at pleasure.—*Library of Useful Knowledge.*

After very slight consideration, it must appear evident that it is impossible to form a *perfect vacuum* by this means, for some air, however small the quantity may be, must necessarily remain in the receiver after every depression of the piston. When the elasticity of the air in the receiver is no longer sufficient to open the valve V, it is clear that no farther rarifaction can take place. Besides, it is to be observed, that, however accurately the piston when it is down may close upon the valve, yet a space, small indeed, but capable of containing air, must exist. The valves, also, have to open against atmospheric pressure, which the elastic force of the air in the receiver must soon fail to counterbalance. We can, however, attain a vacuum sufficient for merely practical purposes. The air-pump has been constructed in a great variety of ways; that in common use has two barrels and two pistons, the rods of which are furnished with teeth, and a wheel which works in them. By a half turn of this wheel one of the pistons is raised to the top of its barrel, and the

* There is one circumstance which must tend materially to invalidate the indications of the weather-glass, namely, the attraction of the moon. Since the moon has an influence upon water, a dense and heavy body, so as to cause great elevations in the sea at one part, and depressions at others, it will readily be conceded that so light a body as air will be considerably affected by it in the same manner. Thus, where the aerial tide is at the full, the barometer situated under it will be pressed by a column of air higher and heavier than it is pressed with when the moon is attracting another part of the earth's surface. These tides are certainly produced, and they are independent of temperature. The effect which they will have in rendering uncertain the indications of the weather-glass is obvious. For, at the time of this additional pressure, the mercury would rise, thus indicating that the weather was clearing; was, in reality, the very reverse of this may be the case. May the attraction of the moon, as exercised over the atmosphere, be the cause of that mysterious influence which our satellite ... over the weather itself? That, by drawing up the air in ... wave, as it were, in certain parts, it will destroy the ... of density, and thus cause the vapours which exist ... shape of clouds to change their relative position, ... to descend or to rise according to circumstances. The moon will also influence the clouds themselves, ... it may be, by attracting some of them, and drawing them into ... positions, perhaps in some degree attenuating ... rapid and almost unaccountable changes of ... experience. The position assumed is, that it ... by the moon over the atmosphere and many of the minor changes of weather.

other is depressed to the bottom of its barrel; thus a continual discharge of air goes on. There is also commonly a barometer made to communicate with the receiver, by which the degree of rarifaction obtained is estimated.

EXPERIMENTS WITH THE AIR-PUMP.

The various properties of air are capable of being strikingly illustrated by means of the air-pump. If an *egg*, having a small hole pierced in it, be placed beneath a receiver, and the air withdrawn, the contents of the egg will be seen to exude through the hole like gum from a tree. This arises from the air contained in the egg becoming more elastic when the external pressure is withdrawn (for it communicated with it by means of the perforation), and thus forces the matter out of the shell. Fruit, when dried and shrivelled, contains particles of air; and if placed beneath an exhausted receiver, these expand in the same manner; and where there is no opening in the skin, they will burst it. A shrivelled apple placed in these circumstances will appear to grow suddenly ripe, and a bunch of raisins will be converted into a bunch of ripe grapes. The experiment of the Magdeburgh hemispheres may be performed by means of an air-pump.

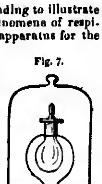
Fig. 6.

Two hollow hemispheres, *b d*, constructed of brass, as represented in fig. 6, are so formed, that, when placed mouth to mouth, they shall be in air-tight contact. They are furnished with handles, *c d*, one of which may be screwed off. In the neck to which this handle is screwed, is a tube furnished with a stopcock. The handle being screwed off, let the hemisphere be screwed on the pump plate, and the other hemisphere being placed over it, let the stopcock be opened so as to leave a free communication between the interior of the sphere and the exhausting tube of the air-pump. The pump being now worked, the interior of the sphere will form the receiver, from which all communication with the external air is cut off, and rarifaction will be produced in it to any degree which may be desired. This being affected, let the stopcock be closed, and let the sphere be detached from the pump plate, and the handle screwed upon it. If, then, the two handles be drawn in opposite directions, so as to pull the hemispheres from one another, it will be found that they will resist with considerable force. If the diameter of the sphere be 6 inches, its section through the centre will be about 28 square inches. The hemispheres will be pressed together by a force amounting to 15 pounds for every square inch in the section. If 28 be multiplied by 15, we shall obtain 420, which is the amount of the force with which the hemispheres will be held together. If one of the handles be placed on a strong hook, and a weight of 400 pounds be suspended from the other, the weight will be supported by the pressure of the atmosphere.

This is one of the earliest experiments in which the effects of atmospheric pressure were exhibited. Otto Guericke, the inventor of the air-pump, constructed, in 1654, a pair of such hemispheres one foot in diameter. The section through the centre of these was about 113 square inches, which, multiplied by 15, gives a pressure amounting to nearly 1700lbs. If the exhaustion were complete, the hemispheres would be held together by this force; but, even though incomplete, they were still able to resist a prodigious force tending to draw them asunder.

Another beautiful experiment, tending to illustrate the use of the air-pump and the phenomena of respiration, may now be noticed. The apparatus for the purpose is shown in fig. 7.

Fig. 7.



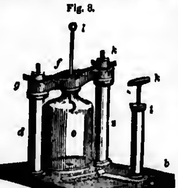
It consists of a receiver placed on the pump plate, and enclosing a globular-shaped glass vessel, within which is contained a bladder. Now, in the ordinary process of respiration, a partial vacuum is formed in the chest by the elevation of the ribs, and the air passing down by the ordinary passage of the mouth, enters the lungs. In the little apparatus above referred to, a vacuum is formed by the air-pump, and the bladder immediately expands; on the re-admission of the air, it returns to its original dimensions; so that a series of expansions and contractions may readily be produced very analogous to the operations of nature.

The fact that in a vacuum a piece of gold and any light substance, such as a feather, will descend with equal degrees of rapidity, is proved by dropping these bodies from the top of an exhausted receiver. That the presence of air is necessary for the production of sound, is also strikingly illustrated by means of the air-pump. If a bell be placed in a receiver in such a manner as to admit of being rung easily from the outside, without admitting air into the inside, whilst the receiver is full of air the sound of the bell will be distinctly heard; but after the receiver has been exhausted, and although the bell be struck with the same force, the sound will be inaudible, or nearly so. If a small portion of air be admitted, it will be faintly heard, and it will gradually increase, according to the quantity of air which is allowed to enter the receiver. The farther examination of this subject belongs to Acoustics, which see.

THE CONDENSER.

The condenser is the opposite of the air-pump, and a necessary accompaniment to it. It consists of a flat table *a b*, supporting a brass plate, and a glass receiver *c*. The columns *d e*, perpendicular to the table, serve, by the aid of a cross bar *f*, and screws *g h*, to hold the receiver down to the plate, and prevent the escape of air. The upright syringe *i*, with its piston and handle *k*, is used to inject air into the receiver *c*. In this instrument the valve opens *inwards*. Each time the piston is depressed, as much air is forced in as is equal to the internal dimensions of the tube. When it is raised, the valve opening inwards admits air into the piston, which being alternately raised and depressed, throws into the receiver an immense quantity of air. The wire and hook *l* serve to communicate with the interior during the performance of experiments. There is a guage at one side, to show the amount of condensation.

Fig. 8.



MACHINES FOR RAISING WATER.

After what has been stated respecting atmospheric pressure, the principle upon which all those machines called *pumps* are wrought will be easily understood. In our number of this work upon Hydrostatics, a variety of these engines were described, and it is unnecessary in this place to introduce accounts of any more of them. Water, we have more than once observed, rises to the height of about thirty-four feet, and cannot by any means be raised higher with an ordinary pump. The reason is, that a column of water of that height is exactly equal in weight to a column of air of the same diameter, but of the height of the atmosphere, and hence they equalise or balance each other. The pump-box or piston, it is well known, works air-tight in the pump; and when it is raised, a vacuum is created below. The pressure of the air upon the water without, forces the latter into the lower orifice of the pump, to fill the void space; and pressing upon a valve which opens upwards, and hence does not admit of its descent again, is thus raised to the height of thirty-four feet, by the alternate ascent and descent of the piston.

AIR-GUN.

The air-gun is an instrument for projecting balls and other missiles by the elastic power of highly condensed air. It will be easily understood from a short description. By means of a condenser, such as has been described, air is condensed in a strong receiver provided for the purpose, and furnished with a valve which opens inwards. This magazine of compressed air is affixed to the stock of the air-gun, in such a manner as to admit of a communication between the barrel and the condensed air, by opening a valve, by mechanism provided for the purpose. A bullet being placed in the barrel, the valve is opened, and the compressed air rushing out with great force, impels the missile forward with considerable velocity. The best air-gun is Martin's. It is furnished with stock, lock, barrel, ramrod, &c., similar to a common fowling-piece. The magazine for condensed air is a strong hollow copper ball, in which air is condensed by a syringe. If the air be highly condensed, this instrument will impel a ball sixty or seventy yards. A number of balls may be discharged in rapid succession without any further condensation in the magazine being required.

FIRE-ENGINE.

It is by means of condensed air that water is thrown upwards to a great height by fire engines, those machines so useful in checking conflagrations. They are subject to a great variety of forms, which all, however, agree in principle. They generally consist of a double forcing-pump, communicating with the same air-vessel, and, instead of a force-pipe, they are furnished with a flexible leather tube, which can easily be turned in any direction required. By means of the two forcing-pumps, the water, usually brought in buckets, and emptied into a reservoir or trough, is forced into the receiver, in which a portion of air is confined. Into this vessel the leather tube enters, and descends near to the bottom. As the water is injected by the force-pumps, and the vessel fills, the confined air becomes greatly condensed, and exerting a high degree of elastic power, impels the water upwards through the tube with great velocity and force. It is upon the principle of the simple pressure of the atmosphere that syphons work, as was explained in our article upon Hydrostatics.

ACOUSTICS.

The term Acoustics is derived from two Greek words which signify *I hear* and *an art*, and therefore designates that branch of natural philosophy which treats of the nature of sound, and the laws of its production and propagation. The sensation of sound is familiar to every one, and the sense of hearing is one of the most important of those links which connect matter and spirit—the thinking principle of man with the external world. A certain organisation is necessary before it is possible to communicate this sensation. For instance, we cannot hear with the arm or the hand, but only with the ear, which is constructed after a very peculiar manner. It was early observed, that when a sounding body was struck, a trembling or vibration, very often sensible to the touch, was observable. But that this same vibration communicated to the animal organ called the ear, whose structure is admirably adapted to be affected by the concussions or tremblings of surrounding objects, and that upon this circumstance depended the sense of hearing, was reserved for modern discovery. That an agitation or concussion takes place in bodies which are struck or from which sound issues, is a familiar fact. Every noise or sound is accompanied by such an action. The report of a cannon, the fall of the cataract, the rush of the wind or a wave upon the sea-shore, the thunder peal, or the blow of a hammer upon an anvil, the rattling of carriages, and an infinite diversity of other sounds which arise in general from the percussion of one body against another, all go to prove that a sensible and sometimes violent agitation takes place in the bodies from which the sounds proceed. In musical instruments, which are of a more delicate nature than any sounding body yet mentioned, the same fact is observable. If, for instance, we touch a harp-string which has been struck, a sensible tremor is communicated to the finger.* The question arises, by what means is this agitation or vibration in the particles of bodies communicated from a great distance to the ear, which is the organ of hearing? Simply through the medium of the atmosphere, which is an immense aërial ocean, in which all bodies at the surface of the earth are immersed. That this is an undoubted fact, is demonstrated by the experiment already alluded to, that a bell struck in the exhausted receiver of an air-pump will communicate no sound whatever, or at least one so faint as scarcely to be audible; the report of a gun on a lofty mountain top, and the sound of human voices, are much less loud than they are at the foot of the elevation; and in the condensed atmosphere of a diving-bell, a whisper is heard aloud.

Let us now consider by what means the surrounding atmosphere communicates sound. Let us take for illustration a series of balls arranged in a line upon a table, or suspended together by threads. If at one end of the line we take a ball, and impel it with force against that which is next to it, the effect is observed at the opposite extremity of the line; of course, the degree of effect produced must depend upon the length of the line, the number of balls, and the force employed to agitate them. In general, the ball which is at the extremity of the one receiving the impact, flies off from the rest, and leaves them almost stationary. Thus, the intermediate balls serve merely to transmit the impulse from the one end to the other of the series. In the same manner it is, that the agitation or impulse from which sound arises is transmitted in the air. This fluid, like every other body, consists of an infinite number of little particles, a single series of which may be represented to us by the balls in the above example. These particles are not even in contact with each other; they are separated by minute intervals, but are yet connected together by attractive and repulsive forces, which tend to retain them perpetually in equilibrio.

In every case, therefore, there is in reality a chain of such particles reaching from the sounding body to the ear. The former, by its agitation, strikes that particle which is next to it; the intermediate ones serve to convey the impression; and the last one flying off, strikes the sentient organ of hearing. The process is exactly similar to that of impulse along a series of balls; only that in the case of the air, the intermediate particles, instead of remaining at rest, move each of them backwards and forwards by a very minute interval—the first communicating its motion to the second, the second to the third, and so on to the last—each performing a slight oscillatory movement, which advances from the beginning to the end of the series. We thus see that the propagation of sound is not instantaneous; it requires time to advance from the sounding body to the ear, as is daily observed and illustrated in the discharge of fire-arms. If the distance be at all considerable, a sensible interval is always observed to elapse between the flash and the report. The light flies almost instantaneously, but the report is retarded according to the distance—a fact observable in many other cases which leave no doubt that sound advances only at a certain rate, and invariably requires time for its propagation; and the reason is, that each aërial particle in the chain of communication must have a certain time—minute, no doubt, but still definite—in which to perform its oscillation, and communicate its motion to the rest; and thus the advance of

* The reader has probably seen what is called by musicians a tuning or pitch-fork, a metallic instrument consisting of prongs, which, when struck, sound a certain note, from which the singer pitches his tune. If when the pitch-fork is vibrating the point of the finger is brought into contact with the fork, a singular sensation, similar to that of a very slight electric shock is communicated. We do not mean to infer from this that the pitch-fork is an inanimate torpedo, which gives an electric shock when touched; but may not at least part of the effects which electricity produces arise from the violent agitation into which it throws the particles of the body? This would certainly account for the resemblance of sensations to which we have alluded, and the conjecture seems by no means

the agitation and of the sound is retarded, and only sweeps with a regulated progression along the line.

It is not through one series of particles merely that the oscillatory motion is communicated. The sounding body having every part of it in a state of agitation, generally acts all round; but even though only one particle were originally affected, so intimately are they all connected together, and united into a system by their mutual attractions and repulsions, that this cannot advance in any degree forwards without affecting the particles on each side; these affect what are before and around them; and thus the impulse is communicated, and diffuses itself on all sides. These lateral impressions would appear to be necessarily somewhat enfeebled; yet it is one remarkable characteristic of such oscillatory movements, that, like the vibrations of a distended cord, or the oscillations of a pendulum in a cycloid, they are all performed in the same time, however minute, or however extended. The lateral impressions, therefore, though ever so feeble, are yet transmitted with the same rapidity as the direct; the sound may be weakened, and we often observe it so. A speaker, for example, is always best heard in front; the report of a cannon is also loudest in that direction, but still the sound is heard at the very same instant all round. It is owing to this diffusion of the agitation in all directions, the original impression being spread out, not merely in concentric circles, like the little waves in a pool when a stone is thrown into it, but expanding continually, if we can conceive it, into a wider and wider concentric sphere —it is owing to this that every sound decreases so rapidly as we recede from it, and at last dies away altogether in the distance of a mile; yet the guns of Edinburgh Castle have been heard at the distance of twenty miles. That this diffusion of the agitating impression is the true cause of the diminution of the sound, is proved in a remarkable manner by confining the air on all sides, as in a tube. M. Biot, in his Traité de Physique, gives an account of some very interesting experiments made by himself in the train of cast-iron pipes used for the conducting of water into Paris, and which extended about 2860 feet, thus including in their interior a cylindrical column of air upwards of half a mile in length; at which distance, a person standing at one end of the pipes, and speaking within, could be easily heard at the other. "The lowest voice," says he, "was heard at this distance, so as to distinguish completely the words, and to establish a continued conversation. I wished to ascertain at how low a tone the voice ceased to become audible, and I could not reach it. Words spoken as low as when one whispers in the ear of another, were heard and appreciated; so that, if we wished to speak so as not to be understood, there was only one way of doing it; and that was, not to speak at all." It is on this principle that depends the effect of those tubes which are now in such general use as modes of communication between distant apartments in houses and public offices. Hence, also, are performed many amusing tricks with statues or busts situated in different parts of a room, answering questions and speaking to one another; the figures being connected by tubes concealed under the walls or floor, or communicating with an apartment below, in which a speaker is stationed.

In regard to the actual velocity with which the impulse of sound advances, it appears, from the most accurate experiments on the discharge of pieces of ordnance, and marking the interval between the flash and the report, at a distance carefully measured, that in ordinary circumstances this amounts to no less than 1130 feet each second, which is nearly equal to the velocity of a cannon-ball the moment it issues from the piece. This last is very speedily retarded by the resistance of the air, but sound advances with undiminished velocity. Hence it will travel a mile in a little more than four seconds and a half, or 12$\frac{3}{4}$ miles per minute. On this depends an easy method of determining in many cases our distance from objects, and which may often prove useful, particularly in military operations. We have only to observe in seconds the interval between the flash and report of the cannon or musket, and allow 4$\frac{1}{2}$ seconds to every mile, or 1130 to every second.

It is remarkable, also, that all kinds of sounds, strong or weak, acute or grave, advance with the same velocity; and this arises from the circumstance already noticed, that all the oscillatory movements in the air, however minute, or however extended, are performed each in the very same interval of time. This effect was distinctly proved in the experiment made by Biot in the cast-iron pipe already noticed, by playing different airs on the flute at one of the extremities of the tube. Now, it is well known that a musical air is adapted to a certain measure or time, which regulates very nicely the intervals between the successive notes; consequently, if any of these were propagated more rapidly or more slowly than others, by the time they reached the ear these would have been confounded with what preceded or followed them; and the air would have appeared quite altered, in place of which it was uniformly regular, and in its natural time; whence it clearly followed that all sounds are propagated with equal velocity.*

All sounds, however, although they travel with the same velocity, do not travel to the same distance. Thus, in approaching an organ which is playing, the first tones heard are the bass notes, which, as is well known, are the lowest in a harmonised piece of music. The grave or low notes, therefore, are heard to a greater distance than those which are acute or high.

The loudness of sound depends upon the violence with which the sonorous body is struck; for we can produce from the same body sounds having very different degrees of loudness, by simply striking it gently or with force. Two bodies, composed of the same substance, and of a like figure, but differing as to the quantity of matter which they contain, if subjected to the same shock, give out sounds differing in their degree of loudness—that which has the greater mass sounding louder than the other. Again, bodies of like size and figure, but unlike in substance, generate sounds of different loudness when struck with the same degree of force. In this case, the loudness depends upon the quantity of elasticity possessed by the bodies. From these facts, it may be inferred that loudness depends upon the quantity of motion or sonorous vibration in which it originates. Its acuteness or pitch depends upon the frequency with which the concussions or vibrations of the sonorous body succeed each other. The frequency of vibrations in strings depends upon their shortness, lightness, and tension, and thus sounds are divided into classes; the slow vibrations being called *bass*, *low*, or *grave* notes, and the quick vibrations being termed *sharp*, *acute*, or *high* notes. In a long or heavy string, there is a greater mass of matter to be moved, and hence there is a slower motion; and in a string which is slack, the force of elasticity which pulls it from any deviation back to the straight line is so much the less, thus giving rise also to a low note. It is found that a string of half a given length, or of one-fourth of a given weight, or of quadruple tension, vibrates twice as fast as on any one of these accounts.

These facts are familiarly illustrated in the violin, in which instrument, whilst all the strings have the same length, they differ in thickness and quantity of matter, the acute notes being generated by thin strings and the grave ones by thick strings. Their pitch can also be varied by means of the pins to which they are attached at one end, these increasing or decreasing their tension according to circumstances.

MUSIC.

All continued uniform sounds result from a repetition of similar vibrations. Hence, in the series from grave to acute, there is, with respect to the number of beats in a given time, a relation similar to that existing between the numbers 1, 2, 3, 4, &c. It is evident that between two sounds, one of which has twenty beats in a given time, and the other only half that number in the same period, there will be a coincidence at every alternate vibration of that which beats quickest; and where the relations of the beats are as twenty to thirty, there is the same coincidence at every third vibration of the quicker, and so on. Sounds which have these simple relations to each other are remarkably agreeable to the ear, whilst those in which the coincident beats are either farther apart or less regular, are not so agreeable; nay, sometimes where the irregularity is great, they are found to be positively harsh to a musical ear. There is a remarkable fact connected with this part of the subject, which is, that the coincident or double pulses of any two concordant sounds generate a third sound, which is always heard with them, and is denominated their *grave harmonic*.

Relative to this fact, Dr Arnott observes, "If a long musical string be made to sound, and the number of its vibrations in a given time be ascertained, we find that half of it, used as a whole, will vibrate twice as fast; a fourth part, four times as fast; and so on, producing the sounds of tones most nearly related to each other. A fine illustration of this is afforded by the string of a violoncello, when made to vibrate by a bow moved very gently across it; near the bridge, there is then heard not only the sound or note belonging to the whole length of the string, but also more fully the subordinate notes belonging to its half, its third, its fourth, &c. beautifully mingling with the first sound, and forming with it a rich harmony. Often, in such a case, the subordinate sounds swell with such a force as to overpower for a time the fundamental note; and then, if the string be carefully examined, it will be found to be vibrating, not as a whole, but in two, three, or four distinct fractions, with points of rest between them, on which points little pieces of paper thrown will remain, while similar pieces are shaken off from every other part. The same harmonic sounds may be produced still more certainly, while drawing the bow across the string, by touching the string lightly with the finger at the points where we wish it to divide. The sounds thus belonging to a single cord or string, and produced by its spontaneous division into different numbers of equal parts, constitute, when heard together, or in succession, the simple music of nature herself. It is produced pleasingly, as just described, by the single string of a violoncello, but in the most perfect manner by the instrument called the Æolian harp."

It is well known that the strings of an Æolian harp are generally tuned in perfect unison with each other to the same pitch, except one, which serves as a bass, being thicker than the others, and vibrating one-half as fast. By the varied undulations of the breeze, these are all thrown into motion, and each generates a sound, or rather a series of such sounds as have been mentioned, corresponding to the force of the current of air which sweeps the strings. Thus, nature herself generates the simple major scale or chord, a scale which has arisen in all nations, however remotely situated, and into which the most untutored individual naturally falls in ascending from any given note, provided he possesses a musical ear. The relation between the chords is such, that any notes in the principal beat thrice, whilst the corresponding notes in the low chord beat twice; and the notes of the high chord beat thrice, whilst the corresponding notes of the principal beat twice; and in the complete scale, the principal chord begins five notes above the lower, and five notes above the higher. The diatonic major scale has eight notes, the first and the last of which are in unison, and called *octaves*, the upper note vibrating twice as fast as the lower one. However far the musical scale may be extended, it is only a repetition of the notes succeeding that from which we began; these, including that note, are eight in number, and are called, according to their relation to the initial or key-note, *second*, *third*, *fourth*, and so on.

KEY-NOTES, &c.

The human ear is capable of perceiving a note so low that it beats only thirty times in a minute, and the highest which it is capable of appreciating has thirty thousand beats in the same space of time. The intervals between the notes in any musical octave are not all alike; two of them are only half as large as the others; and whatever note we begin from, these invariably lie in the major scale between the third and fourth, and the seventh and eighth, and are called *semitones*. Did these semitones not exist in the octave, there would be no use for any signature (that is, a flat or sharp at the commencement of the stave); neither would there have been any necessity for fixing upon one note of the scale as a fundamental note, or what is vulgarly and most inappropriately called the natural note, that is C; for an instrumental performer could have chosen any one as such. To the vocalist all are alike, for his ear leads him to strike the half notes naturally, and without effort; it is only where additional semitones are introduced that he is as it were compelled to deviate from the natural path for a moment; but striking off upon a new bias, he changes the position of the semitones only with regard to the key-note from which he has departed; in the key-note into which he has modulated, they still retain the same relative position, and they are immediately taken by him with the most perfect ease. It will not be difficult to show the propriety of what is called sharpening and flattening the scale, in order to insure both melody and harmony in the execution of any piece of music. One note, C, has been fixed upon as the fundamental note upon which all the other key-notes are formed, not because it possessed any inherent quality or virtue more than other notes, but because, since it was necessary to fix upon one note as a fundamental one, it was found to be the most convenient, suiting the compass of voices and instruments best, and being in the middle of the scale. It is usually termed the natural key-note, and there is a prejudice which prevails not only amongst the uninitiated in musical science, but is even found to obtain countenance amongst those who should know better, that there is something mysterious connected with C; that it is the note most natural to the human voice, and is hence the one upon which the untutored ear and the wild savage will pitch his strain of triumph or love. Nothing can be more absurd. No note of the gamut is more natural than another. D, B, A, or any other note, might have been taken with equal propriety as far as that goes, but C was chosen for the reasons assigned. A tune in the major mode which has no signature, that is, without any sharp or flat attached to it, is upon the key of C. But it would be inconvenient to set every piece of music upon this key; hence, notes above or below it are fixed upon as key-notes, and they have all one or more sharps or flats placed between, or upon, certain lines at the beginning of each stave. The reason of this will appear obvious by a short explanation. In the key of C the semitones lie between the third and fourth, that is, technically, E and F, and the seventh and eighth, that is, B and C. Now, suppose we wish to set the tune upon a higher key than C, say D, it is evident, that, since the semitone lies between E and F in the fundamental key, if the key-note be D, it will lie between the second and third instead of the third and fourth; and in order to place it there, F must be sharpened, that is, raised half a tone. Accordingly, upon the F line, a sharp is placed in all tunes in the key of D where sharps are employed, for the purpose could be effected by flats equally well. In the fundamental key, the other semitone lies between B and C, the seventh and eighth; but in the key of D, the interval between B and C is evidently not the seventh and eighth, but the sixth and seventh, so that, in order to place it there, C must be sharpened, which will be found invariably the case in pieces of music having D as their key-note. By this means the semitones are placed in their proper relative position in the octave. Upon the same principle all the other key-notes are formed. The purpose can be effected by means of flats, but this does not alter in the slightest degree the rules laid down. In the minor mode, the semitones lie between the second and third, and sixth and seventh, in ascending, and the fifth and sixth in descending; and the signatures in this, as in the major mode, are so placed as that, in every key upon which a piece of music is set, they shall retain the same relative posi-

* Encyclopædia Britannica, vol. i., p. 111.

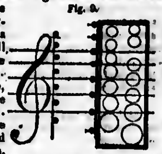
tion. The fundamental note in the minor mode is A. It is impossible in this place to enter farther upon the subject, but the above description will be sufficient to convey an idea of what is technically called transposition, and which is too often by empirical professors of the science enveloped in a cloud of mystery.

MUSICAL INSTRUMENTS.

With regard to musical instruments, and other parts of our subject, we shall avail ourselves of a portion of the article Acoustics, in the British Cyclopædia, written, we believe, by Professor Partington.

Glass vessels of different dimensions are capable of being arranged so as to form a regular musical scale: "The arrangement of the glasses, as originally suggested by Dr Arnott, is shown in fig. 9. The small, open circles represent the mouths of the glasses standing in a mahogany case, and the relation of the glasses to the written musical notes is shown by the common music lines and spaces which connect them.

Fig. 9.



The learner discovers immediately that one row of the glasses produces the notes written upon the lines, and the other row the notes between the lines, and he is mentally master of the instrument by simple inspection. This arrangement also renders the performance easy, for the notes most commonly sounded in succession are contiguous; and the relations of the notes forming a simple air are so obvious to the eye, that the theory of musical combination and accompaniment is learned at the same time. The set of glasses here represented has two octaves, and the player stands at the side of the case, with the notes ascending towards the right hand, as in the pianoforte.

The vibration of plates differs from those of rods in the same manner as the vibrations of membranes differ from those of chords, the vibrations of which cause the plate to bend in different directions, being combined with each other, and sometimes occasioning singular modifications. These vibrations may be traced through wonderful varieties by Professor Chladni's method of strewing dry sand on the plates, which, when they are caused to vibrate by the operation of a bow, is collected into such lines as indicate those parts which remain either perfectly or very nearly at rest during the vibrations. Dr Hooke had employed a similar method for showing the nature of the vibrations of a bell, and it has sometimes been usual in military mining to strew sand on a drum, and to judge, by the form in which it arranges itself, of the quarter from which the tremors produced by countermining proceed.

It usually happens that the vibration of a cord deviates from the plane of its first direction, and becomes a rotation or revolution which may be considered as composed of various vibrations in different planes, and which is often exceedingly complicated. We may observe this by a microscopic inspection of any luminous point on the surface of the chord; for instance, the reflection of a candle in the coil of a fine wire wound round it. The velocity of the motion is such, that the path of the luminous point is marked by a line of light, in the same manner as when a burning coal is whirled round; and the figures thus described are not only different at different parts of the same chord, but they often pass through an amusing variety of forms during the progress of the vibration; they also vary considerably according to the mode in which that vibration is excited.

A very useful instrument for ascertaining the effects of length and pressure, with reference to a vibrating string, is shown in fig. 10. The string is firmly attached at one extremity to the projecting arm, and passing over a bridge somewhat nearer to the centre, is strained by the weight and pulley at the opposite end. A second moveable bridge is seen near the pulley by which the length is regulated.

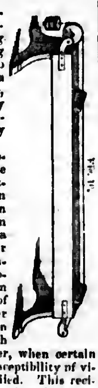


Fig. 10.

The resonances of sound, or reciprocated vibrations of columns of air, have been fully examined by Mr Wheatstone, and we cannot do better than give the result of his observations on this interesting part of acoustics. An elastic body may be made to assume a vibratory state in two ways; either immediately by any momentary impulse, which, altering the natural positions of its particles, allows them afterwards to return by a succession of isochronous oscillations to their former state; or, secondarily, by means of an immediately sounding body, which causes it to reciprocate to the latter, when certain conditions, on which depends its susceptibility of vibrating in such a manner, are fulfilled. This reciprocation to which, where the effect is referred to, the term *resonance* is applied, is effected by means of the undulations which are produced in the air, or in any fluid or solid medium, by the periodical pulses of the original vibrating body; these undulations being capable of putting in motion all bodies whose pulses are coincident with their own, and consequently with those of the primitive sounding body. Gallileo observed, that a heavy pendulum might be put in motion by the least breath of the mouth, provided the blasts be often repeated, and keep time exactly with the vibrations of the pendulum; and this remark affords a correct explanation of the phenomenon.

Some of the most obvious cases of resonance are—the vibrations of a string when another tuned in unison with it is made to vibrate; the resounding of the drinking-glass to the sound of the voice, or of a musical instrument; the reciprocated vibrations of a sounding-board, communicating immediately with a vibrating string or tuning-fork, &c. In the last-mentioned instance, though the string and the fork are the original vibrating bodies, the audible sound is dependent on the resonance of the sounding-board.

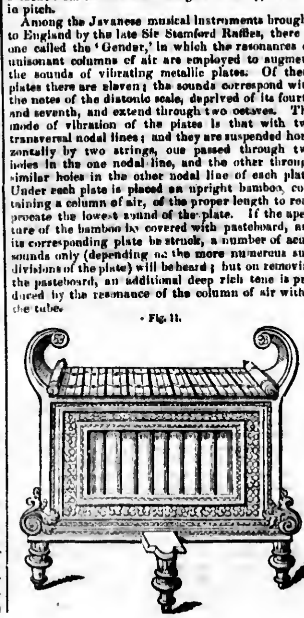
If one of the branches of a vibrating tuning-fork be brought near the embouchure of a flute, the lateral apertures of which are stopped so as to render it capable of producing the same sound as the fork, then the feeble and scarcely audible sound of the fork will be augmented by the rich resonance of the column of air within the flute. The sound will be found greatly to decrease by closing or opening another aperture; for the alteration of the length of the column of air in such case renders it no longer proper to reciprocate perfectly the sound of the fork. This experiment may be easily tried on a concert flute, with a C tuning-fork. To ensure success, it is necessary to remark, that when a flute is blo... ...n to with the mouth, the under lip partly covering the embouchure, renders the sound about a semitone flatter than the sound when the embouchure is entirely uncovered; and as the latter must be in unison to that of the tuning-fork, it is necessary, in most cases, to finger the flute for B when a C tuning-fork is employed.

A similar effect may be produced by substituting for the column of air in the flute, the alterable volume of air contained within the cavity of the mouth. Mr Wheatstone found the sounds of tuning-forks reciprocated most intensely by placing the tongue, &c. in the position for the nasal continuous sound of *ng* (in song), and then altering the aperture of the lips until the loudest sound is obtained.

A column of air may also reciprocate a sound originally produced by a wind instrument, as the following experiment will show. Place two concert flutes on a table, parallel to and at a short distance from each other; on the one which is nearer, sound C sharp (all the lateral apertures being open), and draw out the tube of the second flute, so that it shall be about a semitone flatter, to make it equivalent to the flattening of the first flute by the partial closing of the embouchure by the lip; a material difference will then be distinguished in the intensity of the tone, by alternately closing and opening the first hole of the more distant instrument, thereby rendering it incapable or capable of reciprocating the original sound. That this effect is occasioned solely by the transmission of the sonorous undulations, and not by any wind actually blown into the second flute, is evident from the difference being in intensity, and not in pitch.

Among the Javanese musical instruments brought to England by the late Sir Stamford Raffles, there is one called the 'Gender,' in which the resonances of unisonant columns of air are employed to augment the sounds of vibrating metallic plates. Of these plates there are eleven; the sounds correspond with the notes of the diatonic scale, deprived of its fourth and seventh, and extend through two octaves. The mode of vibration of the plates is that with two transversal nodal lines; and they are suspended horizontally by two strings, one passed through two holes in the one nodal line, and the other through similar holes in the other nodal line of each plate. Under each plate is placed an upright bamboo, containing a column of air, of the proper length to reciprocate the lowest sound of the plate. If the aperture of the bamboo be covered with pasteboard, and its corresponding plate be struck, a number of acute sounds only (depending on the more numerous subdivisions of the plate) will be heard; but on removing the pasteboard, an additional deep rich tone is produced by the resonance of the column of air within the tube.

Fig. 11.



The Gender from which the above drawing was taken is at present in the museum of the Honourable East India Company, and there is another specimen in the possession of Lady Raffles.

If a rod be firmly fixed at one end, and allowed to vibrate freely through its whole length, tones of a very peculiar kind are found to result. Thus, a rod only two feet in length will give a tone as deep as that of the bell employed in the church of St Paul; and the Parisian clockmakers have availed themselves of this fact, in the construction of their ornamental chimney clocks, which by this means cost less, and strike without the sharp and dissonant tinkle common to light bells.

A very pretty instrument, called a 'Kaleidophone,' has been contrived by Mr Wheatstone, of which the accompanying cut is a representation. It consists of four vibrating rods, on which variously formed bodies are placed, and very beautiful and vivid figures produced by merely drawing either of the rods out of the perpendicular, and then allowing them to vibrate freely. Quicksilvered glass beads reflect the light of a lamp or the sun-beams better probably than most other objects; but Mr Wheatstone showed the editor the letters on a common address card, and which, when attached to a bent rod, produced two most elegant compound figures. The white lines in the figure beneath show the paths of a series of these rods.

Fig. 12.

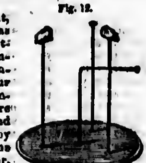


Fig. 13.

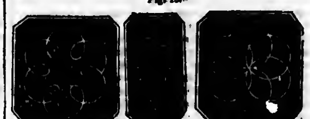
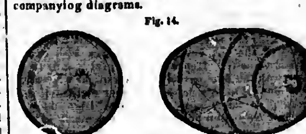


If a sound or wave be reflected from a curved surface, the new direction which it will assume may be determined either from the condition that the velocity with which the impulse is transmitted must remain unaltered, or from the law of reflection, which requires that the direction of the reflected pulse or wave be such as to form an angle with the surface, equal to that which the incident pulse before formed with it. Thus, if a sound or wave proceed from one focus of an ellipsis, and be reflected at its circumference, it will be directed from every part of the circumference towards the other focus; since the distance which every portion of the pulse has to pass over in the same time, in following this path, is the same, the sum of the lines drawn from the foci to any part of the curve being the same: and it may also be demonstrated that these lines form always equal angles with the curve on each side. The truth of this proposition may be easily shown by a simple experiment on a basin of water; the curvature of a circle differs so little from that of an ellipsis of small eccentricity, that if we let a drop fall into the basin near its centre, the little wave which is excited will be made to converge to a point at an equal distance on the other side of the centre. The effects of these reflections are perfectly illustrated in the accompanying diagrams.

Fig. 14.



An umbrella held in a proper position over the head may serve to collect the force of a distant sound by reflection, in the manner of a hearing-trumpet; but its substance is too slight to reflect any sound very perfectly, unless the sound fall on it in a very oblique direction. The whispering gallery of St Paul's produces an effect nearly similar by a continued repetition of reflections. Mr Charles's paradoxical exhibition of the Invisible Girl has also been said to depend on the reflection of sound; but the deception is really performed by conveying the sound through pipes ingeniously concealed, and opening opposite to the mouth of the trumpet from which it seems to proceed.

The speaking and hearing horns owe their operation to the reflection of sound. The reader has already seen how capable a continuous pipe is of transmitting the waves or pulses of the air. This is also, to a certain extent, accomplished by a trumpet-mouthed vessel, and a second apparatus may be employed to collect the pulses which have thus been transmitted.

Fig. 15.

The above figure shows at one view the joint effects of both forms of the trumpet."

WIND INSTRUMENTS.

Wind instruments produce their effect by the vibrations of a column of air confined at one end, and either open or shut at the other. The length of the sounding column determines the nature of the vibrations; but along with the fundamental tone, there are interior and subordinate vibrations. The whole column divides itself into regular portions equal to the half, the third, and so on, of the longitudinal extent, in the same manner as we showed was the case in stringed instruments. We may observe something similar to these vibrations in the contraction and expansion of a long and very elastic string, to one extremity of which a ball is attached. A spiral spring also shows, and perhaps more clearly, the repeated stretching and recoil. If suddenly struck at one end, it will exhibit not only a vibration throughout its whole extent, but likewise partial ones, which wind vermicularly along the chain of elastic rings. If the air be struck with great force, the subordinate vibrations sometimes predominate, and yield the clearest and loudest tones. This may be observed in the dying sounds of a bell, which rise one or two octaves, and expire in the acutest note. Upon the degree of force with which the instrument is blown, depends the performance of the bugle horn, whose compass is very small, consisting only of the simplest notes. In other wind instruments, the nature of several notes produced depends upon the length and size of the tube, or the positions of the holes in its sides. In the organ there is a pipe for each note, and wind is admitted from the bellows to the pipes by the action of keys similar to those of a piano-forte. The organ may be played also by a barrel made to turn slowly under the keys, and to lift them in passing, by means of pins projecting at certain determinate intervals from the surface of the barrel. In wind instruments which are furnished with reeds, the tone depends on the stiffness, weight, length, &c. of the vibrating plate or tongue of the reed, as well as on the dimensions of the tube or space with which it is connected.

A very singular effect is produced in the vibrations of a column of air, contained within a tube open at both ends, by means of hydrogen gas, used in the following manner. Professor Leslie thus describes the experiment:—"A phial, having a long narrow glass pipe fitted to its neck, being partly filled with dilute sulphuric acid, a few bits of zinc are dropped into the liquid. As the decomposition of the water embodied with the acid now proceeds, the hydrogen gas thus generated flows regularly from the aperture, and is capable of catching fire, and of burning for some considerable time with a small yet steady round flame. This very simple arrangement, frequently styled the philosophic lamp, is in reality of the same nature with the combination, on a large scale, of the gas lights. A glass tube being passed over the exit pipe, the burning speck at its point instantly shoots into an elongated flame, and creates a continued sharp and brilliant musical sound. This effect is not owing to any vibrations of the tube itself, for it is nowise altered by tying a handkerchief tightly round the glass, or even by substituting a cylinder of paper. The tremor excited in the column of air is therefore the sole cause of the incessant tone, which only varies by a change in the place of the flame, or a partial obstruction applied at the end of the tube. But still it is not easy to conceive how the mere burning of a jet of hydrogen gas within the cavity should produce such powerful vibrations. The exciting force must necessarily act by starts, and not uniformly. The length of the flame might seem to prove that the hydrogen gas is not consumed or converted into aqueous vapour as fast as it issues from the aperture. A jet of it catches instantaneous fire, but is immediately followed by another, the succession of the inflamed portions being so rapid as entirely to escape the keenness of sight. The column of air contained within the tube would thus be agitated by a series of incessant strokes or sudden expansions."

SPREAD OF SOUND.

That water is a vehicle of sound as well as the air is proved by various circumstances, particularly by the fact that a bell wrung under water can be heard; and if the head of the auditor be also under water, it will be still more distinctly heard. The sound which the sonorous body produces, however, is graver than that which it gives forth in the air. Indeed, the law is, the rarer the medium in which bodies sound, the sharper will be the tone. Solids convey sounds more perfectly than air, of which fact the following are instances:—A scratch of a pin at one end of a wooden log is heard by the ear applied to the log at the opposite extremity, although through the air it is not at all audible. If a cannon be discharged on ice, the report will be carried much farther by the ice than by the air around. Savages, it is well known, are in the habit of putting their ear to the ground, in order to discover the proximity of enemies, or of beasts of prey. The awful sound of the earthquake is merely the muttering of subterranean explosions, communicated from immense distances by the solid strata of the earth.

The property of solids to convey sounds much more perfectly than air, has been applied to useful purposes in medicine. Dr Laennec of Paris has invented what he calls a *stethoscope* or *chest inspector*, which is simply a wooden cylinder. One end of this instrument is applied to that part of the surface of the body opposite to the part which we wish to examine, and the ear rests upon the other end. By this means the actions going on in the chest, and the nature of the diseases there, can be detected by the difference of the sounds conveyed. The results of the use of this instrument have in many instances been important.

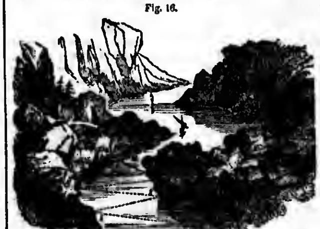
REFLECTION OF SOUND.

When a wave of water strikes a wall, it is thrown back with a degree of force proportioned to its mass, and the velocity with which it came into collision with the wall. It is in the same manner that the pulses or waves of sound are reflected or thrown back from flat surfaces, thus producing what is termed an *echo*. It is evident that the smoother the surface which reflects the sound, the more perfect will be the echo. An irregular surface, by throwing back the wave of sound at irregular intervals, will confound and distract it, that no distinct or audible echo will be reflected. On the contrary, a regular concave surface will reflect sound in such a manner that at a certain point the reflections from each part of the concave surface will be concentrated into a focus capable of producing a very powerful effect. The concentration of sound in this manner produces many remarkable effects both in nature and art. Some of these have been already noticed.

The velocity with which an echo returns to the spot where the sound originates, depends of course upon the distance of the reflecting surface; and since sound travels at the rate of about 1130 feet in a second, a rock situated at half that distance will return an echo in exactly one second. The number of syllables which we pronounce in a second will in such a case be repeated distinctly, while the end of a longer story would blend with the commencement of the echo. Where there is an echoing surface on the opposite side of a river, its breadth could be determined by ascertaining the time which transpires before an echo is returned. Dr Arnott observes, "There is a curious effect of echo which both illustrates the nature of the phenomenon, and proves that a tone or musical sound is merely a repetition of pulses following each other very quickly. Iron railings are generally formed of square bars, of which individual bars any side, therefore, is a plane surface, and may produce an echo. Now, a sound, such as the sharp blow of a hammer, occurring on one side, and near the end of such a railing, is echoed to a corresponding place on the other side by every bar in it; and as the echoes do not return all at once, but in regular succession, according to the increasing distance of the bars, the consequent regular succession of slight pulses, with uniform and small intervals, affects the ear, not as the echo of a single blow, but as a continued musical tone, the pitch of which depends on the distance of the bars from each other."

One of the most singular and distinctly marked illustrations of the reflection of sound forming a natural echo, occurs on the banks of the Rhine nearly Lurley. By referring to the accompanying picturesque illustration, the reader will readily understand how the reverberations of sound are produced.

Fig. 16.



P is considered as the phonic centre, the primary point of radiation for the sound, and the waves striking at the first series of numerals are reflected to twenty, and so on through the series of reflecting points.

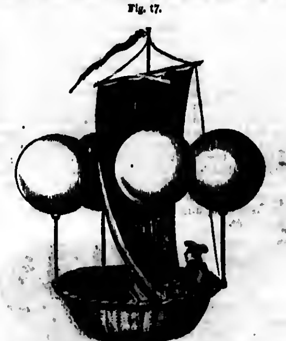
THE ANIMAL EAR.

Beautifully as the ear is adapted to the purposes of life, its mechanism is exceedingly simple. There is first externally a wide-mouthed tube or ear-trumpet, which collects the undulations of sound. It is differently formed in different animals, but always admirably adapted to their circumstances and habits. It is moveable in many animals, so that they can turn it in the direction in which the sound comes. In man, it is close to the head, and so constituted as to collect the sounds with great accuracy; in other animals it is more simple, but in general much larger, having the appearance of an oblong funnel; and this gives them a greater delicacy of hearing, which their situation and manner of life require. The sound concentrated at the bottom of the ear-tube falls upon a membrane, stretched there like the top of an ordinary drum, over the tympanum or drum of the ear, and causes it to vibrate. On the opposite side of this membrane, there is a small cavity hollowed out in bone, which is termed the barrel of the tympanum. Between this part of the ear and the external atmosphere there is a passage to the back part of the mouth, by which the air enters, and thus equipoises the pressure of the atmosphere on the other side of the membrane. Deafness ensues when this tube is obstructed. Across the cavity there is extended, though by no means in a straight line, a series of small bones, the exterior one of which is attached to the membrane we have just mentioned, the most internal of the set being firmly connected with another membrane, which, in conjunction with it, shuts up the entrance to a still more deepened cavity called the labyrinth of the ear. This complex inner apartment, over which the nerve of hearing is spread as a lining, is full of water; and, therefore, by the law of fluid pressure, when the force of the moving membrane of the drum, acting through the chain of bones, is made to compress the water, the pressure is instantly felt over the whole cavity, the same as in a hydrostatic press. The labyrinth consists of the vestibule, a hollow space, and three semicircular canals, imbedded in the hard bone, and a winding cavity called the cochlea, convoluted somewhat like a snail's shell, in which fibres, stretched across like harp strings, constitute the lyra. All the passages are lined by a membrane, on which the sentient extremity of the auditory nerve is expanded in different shapes; from these it is collected into one trunk, and goes on to join a particular part of the brain, and thus completes the communication between the external agent and the sensorium. Such is the mechanism of the ear. For a more detailed account of it, anatomical works must be consulted.

AERONAUTICS.

Aeronautics is the art of sailing in or navigating the air. In remote ages, the idea of rising in the atmosphere by a machine was entertained, but never realised until modern times, when gases lighter than air were discovered. Francis Lana, a distinguished Jesuit, in the year 1670, was the first who attempted to construct scientific apparatus for navigating the aërial ocean. The following cut represents it. He

Fig. 17.



proposed to raise his vessel by the aid of four balls exhausted of air. The inventor argued that the diminished weight of the balls would buoy up not only themselves, but the aëronaut and his vessel; but it is evident that, before balls capable of withstanding the external pressure of the air could be constructed, the materials employed being necessarily of a strong nature, they would turn out to be bulk for bulk heavier than the air. Thus the scheme was abortive. The discovery of inflammable air, or hydrogen gas, suggested to Dr Black, the distinguished chemist, the idea of filling a bladder with it; and leaving it to itself, he correctly concluded that it must ascend in the atmosphere. In 1782, Cavallo made some experiments, in which the fact was proved; and in the same year, the two brothers Montgolfier constructed a machine, and ascended in it the year following. The attention of philosophers being now drawn to the subject, several experiments were made with success. It was also found, that, if a fire be placed under the aperture of a very thin bag, and thus rarify the air within, the bag will ascend. Thus there were two species of balloons discovered. The process of filling balloons on the small scale for this species of aërial navigation, will readily be understood by a reference to the accompanying sketch, in which a simple condenser is employed. The common mode is to generate hydrogen gas in a bottle, by pouring dilute sulphuric acid on granulated zinc; but the hot and moist vapour from the acid speedily destroys the balloon. To prevent this, the experimenter has only to employ a second bottle containing water, and carry a bent pipe from the first bottle through a cork in the second; it dips beneath the surface, and is condensed, and the pure hydrogen ascends by the second pipe to the balloon.

Fig. 18.

It is unnecessary to enumerate all the ascents made by different individuals at different times subsequent to the successful one of Montgolfier in 1783. Associated with them are the names of Pilatre de Rozier, Charles, Robert, Lunardi, Blanchard, and others. The latter individual rendered an essential service to aëronauts by the invention of the parachute, which they can safely descend with in cases of emergency.

Fig. 19.

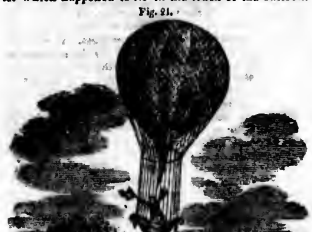
In the right-hand figure, M. Garnerin's apparatus is seen as it ascended from St George's Parade. A cylindrical box, about three feet in height, and two in diameter, was attached by a straight pole to a truck or disc at the top, and from this was suspended a large sheet of linen somewhat similar to an umbrella. The form it assumed on the descent of the aëronaut is shown in the next figure. When first cut from the balloon, it descended with amazing velocity, and those who witnessed its progress considered the destruction of the aëronaut as certain; but after a few seconds, the canvass opened, and the resistance was so great, that the apparatus diminished in its speed, till, on its arrival near the earth, it was not greater than would have resulted from leaping a height of two feet.

Amongst the unfortunate aëronauts we may place Major Money, who ascended from Norwich, under the full impression that the aërial current would take the balloon in the direction of Ipswich. Scarcely, however, had he attained an altitude of one mile, when a violent hurricane, operating in a new direction, drove the balloon towards Yarmouth. Several small row boats immediately put out from that port, and endeavoured to keep pace with the balloon, but without success, and Major Money first touched the sea about nine miles from land, and more than three from any means of assistance.

Fig. 20.

The above illustration shows the critical situation of Major Money, about ten minutes after he had parted with a portion of his clothes and instruments. He was fortunately picked up in an exhausted state by a cutter which happened to lie in the track of the balloon.

Fig. 21.



The preceding illustration exhibits a very picturesque view of the ascent of that veteran, Mr Green, from the Park, on the occasion of the coronation of his late majesty, George IV. The balloon itself, the form of which is similar to but infinitely more beautiful than a pear, is composed of strips of variegated silk, the harmony of which has a particularly pleasing effect on the eye. Over this is thrown an envelope of network, which passing down serves as a support to which the car is attached.

It must be confessed that aëronautic experiments are not of very great practical utility. However, several eminent philosophers have ascended in balloons, and ascertained various interesting scientific facts. MM. Biot and Gay Lussac some years since rose to a considerable elevation, and having provided themselves with a number of philosophical instruments, such as barometers, hyrometers, electrometers, &c., they were enabled to determine several points of importance. After they had risen to the height of about 6500 English feet, they began their experimental operations. The magnetic needle was attracted, as usual, by iron; but they found it impossible at this time to determine with accuracy its rate of oscillation. A voltaic pile, consisting of twenty pairs of plates, exhibited all its ordinary effects. By rejecting some more ballast, they had attained the altitude of 8940 feet, but afterwards settled to that of 8600 feet. At this great elevation the animals which they carried with them appeared to suffer from the rarity of the air. They let off a violet bee, which flew away very swiftly, making a humming noise. The thermometer had fallen to 56·4° by Fahrenheit; yet they felt no cold, but were, on the contrary, scorched by the sun's rays. Both of them had their pulses much accelerated; but notwithstanding this, they experienced no sort of uneasiness, nor any difficulty in breathing. What perplexed them the most was the difficulty of observing the oscillations of a delicately suspended magnetic needle. But they soon remarked, on looking attentively down upon the surface of the conglomerated clouds, that the balloon slowly revolved, first in one direction, and then returned the contrary way. Between these opposite motions there intervened short pauses of rest, which it was necessary for them to seize. Watching, therefore, the moments of quiescence, they set the needle to vibrate, but were unable to count more than five, or very rarely ten oscillations. A number of trials, made between the altitudes of 9500 and 13,000 feet, gave 7″ for the mean length of an oscillation, while at the surface of the earth it required 7 1-20th″ to perform each oscillation. A difference so very minute as the hundred and fortieth part could be imputed only to the imperfection of the experiment; and it was hence fairly concluded that the force of magnetic attraction had in no degree diminished at the greatest elevation which they could reach. The direction of this force, too, seemed, from concurring circumstances, to have continued the same.

At the height of 11,000 feet they liberated a green linnet, which flew away directly; but feeling itself abandoned in the midst of an unknown ocean, it soon returned, like the dove to the ark, and settled on the stays of the balloon. Then mustering fresh courage, it took a second flight, and dashed downwards to the earth, describing a tortuous yet almost perpendicular track. A pigeon which they let off under similar circumstances afforded a more curious spectacle. Placed on the edge of the car, it rested a while, then launching into the abyss, it fluttered irregularly, and seemed at first to try its wings on the thin element; till, after a few strokes, it gained more confidence, and, whirling in large circles or spirals, like the birds of prey, it precipitated itself towards the mass of extended clouds, where it disappeared.

It was difficult, in those lofty and rather humid regions, to make electrical observations. However, they let down from the car an insulated metallic wire of about 250 feet in length, and ascertained that the upper end indicated resinous or negative electricity. This experiment was several times repeated; and it seemed to corroborate fully the previous observations of Saussure and Volta relative to the increase of electricity met with in ascending the atmosphere. The diminution of temperature in the higher regions was found to be less than what is generally experienced at the same altitude on mountains.

The hygrometer, or rather hygroscope, of Saussure, advanced regularly towards dryness, in proportion to the altitude which they attained. At the elevation of 13,000 feet it had changed from 80.8° to 30°. "But still," says Professor Leslie, from whom the account of this ascent is principally taken, "the conclusion, that the air of the higher strata is drier than that of the lower, we are inclined to consider as fallacious. In fact, the indications of the hygroscope depend on the relative attraction for humidity possessed by the substance employed, and the medium in which it is immersed. But air has its disposition to retain moisture always augmented by rarefaction, and, consequently, such alteration alone must materially affect the hygroscope. The only accurate instrument for ascertaining the condition of the air with respect to dryness is founded on a property of evaporation." These are the principal experiments which the French aëronauts performed, and their ballast being exhausted, they descended. M. Gay-Lussac afterwards ascended alone. Scarcely had the observer reached the height of 3000 feet, when he observed spread below him, over the whole extent of the atmosphere, a thin vapour, which rendered the distant objects very indistinct. Having gained an altitude of 9950 feet, he set his needle to vibrate, and found it to perform twenty oscillations in 83″, though it had taken 84.33″ to make the same number at the surface of the earth. At the height of 12,680 feet he discovered the variation of the compass to be precisely the same as below; but with all the pains he could take, he was unable to determine with sufficient certainty the dip of the needle. M. Gay-Lussac continued to prosecute his other experiments with the same diligence, and with greater success. At the altitude of 14,480 feet he found that a key, held in the magnetic direction, repelled with its lower end, and attracted with its upper end, the north pole of the needle of a small compass. This observation was repeated, and with equal success, at the vast height of 20,150 feet; a clear proof that the magnetism of the earth exerts its influence at remote distances. He made not fewer than fifteen trials at different altitudes, with the oscillations of his finely suspended needle. It was generally allowed to vibrate twenty or thirty times. The mean result gives 4.22″ for each oscillation, while it was 4.210″ at the surface of the earth; an apparent difference so extremely small as to be fairly neglected.

The ascents performed by MM. Biot and Gay-Lussac are memorable for being the first ever undertaken solely for objects of science. It is impossible not to admire the intrepid coolness with which they conducted those experiments, operating, while they floated in the highest regions of the atmosphere, with the same composure and precision as if they had been quietly seated in their cabinets at Paris. Their observations on the force of terrestrial magnetism show most satisfactorily its deep source and wide extension. The identity of the constitution of the atmosphere to a vast altitude was likewise ascertained. The facts noted by Gay-Lussac, relative to the state of the thermometer at different heights, appear generally to confirm the law which theory assigns for the gradation of temperature in the atmosphere; but many interesting points were left untouched by this philosopher. It is to be regretted that he had not carried with him the cyanometer, which enabled Saussure to determine the colour of the sky on the summits of the Swiss mountains, and also that he was not provided with an hygrometer and a photometer of Leslie's construction. It would have been extremely interesting, at such a tremendous height, to have measured with accuracy the feeble light reflected from the azure canopy of heaven, and the intense force of the sun's direct rays, and hence to have determined what portion of them is absorbed in their passage through the lower and denser atmosphere.

Since that time, numerous ascents have been performed in different countries, generally by adventurers guided by no philosophical views, nor leading to any valuable results. It would therefore be superfluous to recount such repeated attempts.

Balloons have at different times been thought capable of useful application. It has been even proposed to employ their power of ascension as a mechanical force. This might be rendered sufficient, it was believed, to raise water from mines, or to transport obelisks, and place them on great elevations. We can easily imagine situations where a balloon could be used with advantage; such as to raise, without any scaffolding, a cross or a vane to the top of a high spire. But the power would then be purchased at a very disproportionate expense. It would require $4\frac{1}{2}$ pounds of iron, or 6 of zinc, with equal quantities of sulphuric acid, to yield hydrogen gas sufficient to raise up the weight of one pound.

But to a skilful and judicious application of balloons, we may yet look for a most essential improvement of the infant science of meteorology. Confined to the surface of this globe, we have no direct intimation of what passes in the lofty regions of the atmosphere. All the changes of weather, which appear so capricious and perplexing, proceed no doubt from the combination of a very few simple causes. Were the philosopher to penetrate beyond the seat of the clouds, examine the circumstances of their formation, and mark the prevailing currents, he would probably remove in part the veil that conceals those mighty operations. It would be quite practicable to reach an elevation of seven miles, where the air would be four times more attenuated than ordinary. A silk balloon, of forty feet diameter, if properly constructed, might be sufficient for that enormous ascent, since its weight would only be eighty pounds, while its buoyant force, though not more than a quarter filled with hydrogen gas, would amount to $533\frac{1}{3}$, leaving $453\frac{1}{3}$ pounds for the passenger and the ballast. The balloon could be safely charged, indeed, to the third part of its capacity, on account of the contraction which the gas would afterwards suffer from the intense cold of the upper regions; and this gives it an additional buoyancy of 177 8-9th pounds. The voyager would not, we presume, suffer any serious inconvenience from breathing the very thin air. The animal frame adapts itself with wonderful facility to external circumstances. Perhaps the quickened pulse and short respiration, which some travellers have experienced on the summits of lofty mountains, should be attributed chiefly to the suddenness of their transition, and the severity of the cold."

No. 42. PRICE 1½d.

PRESERVATION OF HEALTH.

ALL mankind will readily agree that the preservation of health is of the utmost importance to every person; for without that blessing there can be no enjoyment in life. The greatest riches, the highest rank, the most highly-gifted genius, cannot purchase an immunity from sickness, which, with all its train of miseries, enters alike the palace gate and the cottage door. The nobleman lounging in his drawing-room or park, the merchant busy in the pursuit of his daily occupations, the peasant labouring in the open fields, are in this respect placed on the same level; but, unhappily, the majority of men are apt to be insensible of the good health which they enjoy, and, by trifling with their constitutions, not unfrequently entail sufferings on themselves and distress upon their families. Indiscretions of this kind never fail to be afterwards deeply regretted; for the season of sickness in every household is one of great affliction. For this reason, every family should be in possession of a CODE OF HEALTH, the precepts of which should never be forgotten. Thus might parents be better enabled to secure the health of their children, and every individual learn to manage his constitution in such a manner as to enjoy permanent health. It is with this view that we now proceed to lay before our readers a body of information concerning the means of preserving health, which we trust will be found acceptable in every domestic circle.

AIR.

A constant accession of fresh and pure air is essential to the existence of human life, and upon this principle, that it is the means of purifying the blood, and rendering it fit to circulate through the body. Hence, if the supply of air be cut off—as in cases of hanging, drowning, smothering, &c.—the blood stagnates in the lungs, the heart does not receive a sufficient quantity of this fluid to stimulate it to action, and death ensues. In breathing, we perform two actions; first, the act of inspiration, whereby the air enters the lungs; second, the act of expiration, by which the air is again expelled from them. This being premised, it is necessary to remark, that the expired air differs from the air inspired, inasmuch as, while in the lungs, in the act of purifying the blood, it loses a portion of its stimulating, and acquires noxious properties. Accordingly, crowded apartments—such as nurseries, hospitals, and the rooms of large manufactories—should be well ventilated, otherwise the children or persons living in them will suffer materially, from constantly breathing a vitiated atmosphere. To prevent this, ventilators, or small movable wheels, made of sheet-iron or brass, should be fixed in some part of the windows, which will allow the heated air of the apartment to escape, and the external air to enter. In respect to bedrooms which have more than one bed, the doors should be furnished with similar ventilators; and during the summer months the windows should be kept partially open during the night and day. Furthermore, as Dr Darwin observes, the fireplace should not be stopped up at any season of the year by a chimney-board or bag of straw, as many rooms are made to shut up so close that this is the only aperture by which fresh air can be admitted. To this should be added, that the bed-curtains should never be drawn close round the beds, which confine the air spoiled by frequent respiration, and the perspirable matter, like a noxious atmosphere, over the sleeper. At the same time, none of the beds should be placed very near either to an open window or to an open chimney, as a current of air should always be avoided. In many manufactories, where deleterious gases arise during certain chemical operations, it is of most vital importance that the rooms should be so well ventilated as to permit their free exit. In Hencke's Journal we read, that in some of the hat manufactories in Petersburg, the workmen experienced fatal accidents and diseases from the inhalation of nitrous acid fumes, occasioned by their dissolving mercury in nitric acid during the process of their business. It is much to be feared that, even in our British manufactories, sufficient attention is not paid to the ventilation of the workrooms; and to this subject, therefore, we would earnestly call the attention of the masters or directors.

The air we breathe may prove injurious to the constitution in two ways: first, by its being loaded with poisonous matters, such as marsh miasm; and, secondly, by its surrounding us with a sudden vicissitude of temperature. In many districts in England, Germany, Italy, France, and North America, a marsh miasm arises from the soil, which gives rise to severe intermittent fever. During the time the wind blows from the Campagna di Roma over the city of Rome, the inhabitants of that city shut up their houses which are exposed to the current, and retire to another part of the city, in order to avoid inhaling the miasm by which the disease is produced. The nature of this miasm, which is of so subtile a nature as to defy all analysis, has been a matter of much speculation. By some it is presumed to be a gas which arises from the earth; by others it is supposed to be a diseased secretion of plants, which become so diseased from the effects of the standing water by which they are surrounded:—whichever theory be adopted—and neither admits at present of any satisfactory demonstration—it is certain that when such marshy soils are drained, the air of the district becomes purified, and intermittent fever disappears. This was the case in Edinburgh. Before the North Loch was drained for the purpose of laying out the present beautiful gardens in Prince's Street, intermittent fever was common in the town; but since that improvement has been made, the disease has almost entirely disappeared. For this reason, dwelling-houses in the neighbourhood of lakes, fens, and marshes, should be avoided; indeed, the most healthy situation to build a house is on a rising ground, upon a chalky soil, in an open and dry country, neither exposed to the severest degree of cold in winter, nor the highest degree of heat in summer. Trees, also, with heavy and thick foliage, ought not immediately to surround the windows of a house, because they interrupt the free current of air, have a tendency to make the rooms damp, and during the evening or night exhale odours that are often extremely injurious to health.

In large and populous cities the free ventilation and cleanliness of the public streets are imperatively required; otherwise, the most frightful and fatal diseases will be generated. There is indeed every reason to believe that the great plague of London, in the year 1665, was occasioned by the negligence which prevailed in these respects. By referring to the writers of that period, we find that London was then an extensive plain, from which effluvia of every kind were generated; dirt of all kinds was suffered to lie in the streets, the drains were choked up, and every description of excrementitious matter thrown into them; the floors even of the middle ranks were covered with straw and hay, beneath which, though occasionally renewed, grease, fragments of meat, and every kind of filth, were permitted to remain unmolested; the houses, too, were high and irregular, the streets narrow, and every obstacle that could prevent a free current of air was offered. Breathing such a polluted atmosphere, it is assuredly not surprising that the inhabitants of a city so infested should fall victims to the plague. At this very period, the city of Oxford, to which the court retired, having had its streets cleaned, and its drains and rivers cleared, was so healthy, that, says Dr Quincey, "the sickness (*i. e.* the plague), in 1665, never visited any person there, although the terms were there kept, and the court and both houses of Parliament did there reside." The public authorities of every town and village should bear these facts in recollection; and every householder, however humble may be his dwelling-place, should remember that free ventilation and cleanliness are the best safeguards against such fearful visitations. If any more recent fact were wanting in confirmation of this assurance, it would be found in the circumstance of the late epidemic cholera having been so manifestly checked in Edinburgh by the precautions adopted in that city, which consisted principally in clearing away every species of dirt out of the courts and alleys, and fumigating the houses of the poor.

Enough, however, has been now said concerning the morbific impregnations of the atmosphere; let us next attend to the transitions of its temperature, which so frequently give rise to severe and often fatal maladies. The powers of endurance in the human body are so considerable, that, provided the change be made by degrees, man can live either beneath the burning rays of a tropical sun, or in the icy regions which surround the north pole. The change, however, from the extreme of heat to the extreme of cold, must be gradual; for it is only by degrees that his system can accommodate itself to such opposite conditions. That which is true in respect to his transferring himself thus from the coldest to the hottest region of the globe, is also true in respect to his suddenly passing from an over-heated into an extremely cold apartment. Indeed, the air of crowded public meetings, and that which is met with in ball-rooms and theatres, is often of as high a temperature as in the equatorial regions; and the transition into the cold midnight air does not offer a less severe shock to the constitution than were the individual suddenly transported from the equator to the snowy shores of Baffin's Bay. By this imprudent conduct, many a young person in the bloom and beauty of life has been hurried to the tomb. But in vain does the medical philosopher raise a warning voice; society still demands the sacrifice; and the most cautious are continually tempted to transgress. Under these circumstances, it remains for us to explain the precautions which should be adopted to prevent the ill effects of such exposures. The condition of the body, on going out into the open air, requires attention; it should be as warm as possible, short of perspiration. It is a bad practice to linger about the halls and doors, under an idea that the body should be cool before venturing out. Many lives are annually lost by this ill-judged caution; for in this state the body is highly susceptible of the baleful influence of the night air. It is better to go forth with some degree of perspiration, than wait until we are chilled. The greater degree of animal heat we are in on going out, the less injury are we likely to sustain. To protect the system as much as possible from the air, the body, especially the throat and chest, should be protected by warm clothing; such as are made of woollen, cotton, &c. A large net or comforter should also be folded loosely round the face, which will receive a portion of heat from the breath at each expiration; and this being communicated to the current of air entering the mouth at each inspiration, will impart to it some degree of warmth before it enters the delicate structure of the lungs. Persons who have carriages in waiting should adopt the same precautions; for, before the steps of the carriage can be put up, and the door closed, a cold blast of air may enter, sufficient to produce that chill which is so carefully to be guarded against. Those who return on foot should proceed along at a brisk pace, in order to keep up the animal heat of the body with which they set out. As the transition from the heated apartment into the cold night air must have in some degree checked the perspiration, it is prudent, on arrival at home, to take a little of some stimulating liquid—wine and water, or spirits and water, whichever may be preferred; and if there be any disposition to shivering, or apprehension of cold having been taken, the feet, on going to bed, should be immersed in hot water, with a view to restore the perspiration of the skin. By these means the evil effects which are apt to arise from exposure to the night air, may perhaps be averted; but let not the invalid, nor young persons affected with delicate constitutions, rely on any such hope; for in their cases it will in all probability prove fallacious; and they will be left, when too late, to repent that they allowed themselves to be tempted, by the attractions of a transitory scene of pleasure, into an indiscretion by which they may bring upon themselves an illness which no medical skill may be able to check.

From the observations we have already made, it will appear obvious that young persons ought not to be accustomed to small and heated apartments; indeed, the more children are allowed to play in the open air during the day-time, provided the weather be not inclement, the better. Persons who live much in the open air, for the most part enjoy very vigorous constitutions. The old Romans, and many other nations of antiquity, were accustomed to live continually in the open air; but it is in this country the pernicious custom with many persons to live in apartments, the atmosphere of which is heated above the natural temperature of our climate; and when, therefore, they venture into the open air, they run the most imminent risk of taking cold. Besides this, there are many ladies who habituate themselves to living almost exclusively in the house: they fancy themselves so delicate that they apprehend the slightest breath of wind will wither their beauty and destroy their constitution; but the truth is, and this should ever be remembered, that there can be no grace, beauty, or dignity of the human frame, unless every limb and feature be lighted up with the expression of conscious health, which is a blessing the victims of such artificial habits cannot enjoy: their tasselled couch yields to them a less comfortable rest than the humblest cottage chair renders the hardy peasant, and their studied repast is less welcomed than the rudest fare of the cottage table.

DIET.

Instinct leads the inferior animals to select the food which is best adapted for their nourishment, but the majority of men are apt to transgress the dictates of nature, and by converting their necessary meals into feasts of luxury, impose duties on the digestive organs which they are not able to perform; hence arises a host of maladies which the most skilful physician is often unable to conquer. Let every person, therefore, who is anxious for the preservation of his health, attend strictly to his diet. The human body, and indeed the body of every animal, is constantly undergoing a certain waste, and requires a certain repair. The old particles even of the most solid textures—such as the bones—after a time become useless, and are ejected from the system, and new particles are deposited in their stead. These new particles are derived from the nutritious portion of the food which is eaten; and this renovation is the great object of digestion. It is evident, therefore, that such food should be chosen as will supply the requisite nutrition; and this nature has amply provided. The kind of food which every animal should eat, is in a great measure indicated by the structure of the body. Thus, carnivorous animals, or those destined like the lion to live on flesh, have a short and straight intestinal canal, in order to allow a quick passage for the food; herbivorous animals, or those destined to feed on different descriptions of herbs, have on the other hand this canal very long and complicated, for such food does not so readily part with its nutrition, and requires to be detained longer in the digestive canal. In the horse, the large intestines are of enormous size, and dilated into small sacs; in the ram, the intestinal tube, which is termed the alimentary canal, is twenty-seven times the length of the body. The shape of the teeth and jaws, also, bears obvious reference to the kind of food which animals are destined to live on. The teeth of carnivorous animals—such as the lion—are long, sharp, and pointed, and those of the lower shut within those of the upper jaw; the teeth of herbivorous animals are not thus calculated for seizing and lacerating prey, but present broad and flat surfaces; and the jaws, instead of being able only to move upwards and downwards, command a motion from side to side, so that they are able to give the vegetable food on which they live that more perfect comminution which it requires. The structure of the human body shows that man has been ordained to live both on animal and vegetable diet. His teeth and jaws associate him with the monkey tribe, his stomach with the lion, his intestines with the ourang-outang. He is truly, therefore, an omnivorous animal, and may adapt his diet to almost any peculiarity of habit, situation, or climate. The ancient Britons lived entirely on flesh and milk; and vegetables, which now grow in our kitchen gardens, were not in England cultivated until the time of Catharine of Arragon. The Romans, during the time of their campaigns, lived almost entirely on vegetables very simply dressed; and many Italians, even at the present day, support themselves almost entirely on bread, fruits, and the produce of the earth. In a savage state, some nations live almost entirely on fruits and roots, others on raw animal flesh of the coarsest description. Dogs are eaten in the South Sea Islands, horses in Tartary, and many African tribes are said to feed on dead lions and hippopotami. The Hindoo supports himself on rice and maize; the wandering Moor on gum seneca; the Greenlander eats the flesh of the whale; the Esquimaux that of the walrus; and the Kamschadales feed on coarse fish oil, made into a paste with sawdust. When pressed by hunger, men have been known to swallow large quantities of earth, and even devour with avidity the flesh of their fellow-creatures. This dreadful means of appeasing hunger is said to have been had recourse to on the raft of the French frigate Medusa, when wrecked on the coast of Africa; and also on a rock in the Mediterranean, where the Nautilus frigate was lost. Man, however, is not the only omnivorous animal: the swine, and many insects, as the ant, are also omnivorous. Among the inferior animals, eccentricities in the choice of food, and extravagances when urged by hunger, have been committed, as remarkable as those above narrated. In some tracts in the East, the horse is fed on fish; and Dr Tyson, in the Philosophical Transactions, states that he knew a horse that would stand at a tavern door and eat oysters, crunching the shells and swallowing them with their contents. On board of a ship, a lamb had been fed on flesh until it refused grass. In like manner, the hawk has been fed on bread; pigeons on meat; and sheep, when the earth has been covered with snow, have eaten the wool off each other's backs.

While it has been clearly demonstrated that man is naturally an omnivorous animal, it has been also ascertained that he cannot enjoy health if limited to one kind of food; the reason of which is, that the digestive organs require a certain degree of stimulus; and if the same substance be always presented to them, they become so accustomed to it that it no longer continues to be sufficiently stimulating. It appears by the bills of mortality in London, that, before the vegetables now used at table were cultivated in England, the scurvy raged to a prodigious extent; and probably, for the same reason, on board a ship, where, during a long voyage, men are confined to the same food, this disease is apt to appear. A certain variety of food is necessary, therefore, for the preservation of health. The errors, however, that are apt to be committed in respect to diet will be better understood by explaining the nature of the digestive process; and in so doing we shall explain the reason for laying down certain precautions which ought to be observed.

The food, animal or vegetable, is in the first place introduced into the mouth, where it undergoes what we may term the first stage of the digestive process. It is there masticated and mixed with the saliva. This, which many persons consider an act of little consequence, is in reality one of great importance. The saliva is a fluid similar in its properties to the gastric juice of the stomach; and if the food be not well broken down and softened with it, when transmitted into the stomach, it will not be properly digested. There is a case recorded, in one of the medical journals, of a gentleman, who, in consequence of a stricture in the gullet, required that his food should be introduced by an aperture made externally into that tube. In consequence, however, of its not being properly mixed with the saliva, he suffered considerably from indigestion. There is also a curious case recorded of a criminal, who, to anticipate the punishment of his crime, cut his throat with a razor while in prison. The parts retracted so as to prevent them being reunited; and the criminal, who survived the attempt at suicide, was fed with little inconvenience, his food being introduced into the gullet by means of a tube. In this case it was observed, that, immediately after every meal, there was a profuse discharge of saliva from the mouth, amounting to from five to six or eight ounces, and the quantity was always increased when the food was hot. A very intimate relation, therefore, exists between the stomach and the glands which secrete the saliva, sufficient to show how essential is its agency in the digestive process. Hence, minced meats, jellies, and substances that pass rapidly into the stomach, for want of being properly saturated with the saliva, are difficult to digest. The manner of eating, therefore, should be deliberate; and young persons should be prevented from bolting their food, or swallowing it without sufficient mastication. There is another reason for eating slowly; namely, that the action of the stomach is slow, and persons eating hurriedly are not apt to regard the time when their appetite is appeased. Accordingly, the stomach is inadvertently overloaded. The man of business who swallows his meals thus hastily, finds, on returning to his counting-house, an oppression at the pit of the stomach; a sure sign that he has eaten too much, or in an improper manner.

The food having been properly masticated, is, by the action of the tongue, thrown into the gullet, in passing along into which a fleshy curtain, which hangs at the back of the palate, is carried backwards and upwards, so as to close the passage into the nostrils. The windpipe is immediately before the gullet, the entrance into which is protected by a very curious contrivance. It is covered with a little lid, which, as the food passes over it, is shut down so completely as to prevent the entrance of any extraneous matter. Sometimes, however, substances have found their way into this passage; but, in general, where this does happen, the matter is quickly ejected by a violent expiration. The alimentary mass having entered the gullet, now descends into the stomach, not by its own gravity, but by its being urged along by the contractions and motions of the gullet itself. That it does not descend by its own gravity, is evident, for we may swallow in any position. Tumblers or mountebanks, for the amusement of ignorant people, often exhibit the feat of swallowing a glass of water or piece of bread while standing on their head. The anatomy of the gullet shows very clearly the manner in which these contractions and motions take place. It sometimes happens, in swallowing, that a piece of food or bone sticks in the passage; the best way to overcome which, is to swallow immediately a large piece of bread, after which a glass of water, in order that it may be propelled down into the stomach. This failing, a probang—that is, a piece of whalebone with a knot of Indian rubber at the end—may be fearlessly plunged down the throat, in order to displace it. The food, we are to presume, has now passed into the stomach, which may be considered as an expansion of the gullet, or that part of the alimentary canal. It is, in fact, a membranous pouch or bag, very similar in shape to a bagpipe, having two openings, the one by which the food enters, the other that by which it passes out. It is into the greater curvature of the bag that the gullet enters; it is at its lesser where it opens into that adjoining portion of the canal into which the half-digested mass is next propelled.

When food has been introduced, the two orifices close, and that which we may term the second stage in the process of digestion commences. The mass already saturated with saliva, and so broken down as to expose all its particles to the action of the gastric juice, is now submitted to the action of that fluid, which, during digestion, is freely secreted by the vessels of the stomach. This gastric juice in its healthy state is neither acid nor alkaline, but very similar in its properties to the saliva of the mouth. Its solvent power is, however, prodigious.

The food having thus entered the stomach, the secretion of this fluid becomes more copious, and acts from the circumference to the centre of the mass. The original food, by its action, is converted into a soft, grey, pultaceous mass, called chyme, which, by the muscular contraction of the stomach, is urged on into the adjoining part of the alimentary canal, which is called the duodenum. This is generally completed in the space of two or three hours; but the period will vary according to the nature and volume of the food taken, and the mastication and insalivation it has undergone. It is desirable, during this stage of digestion, that a person should remain at rest; indeed, exertion after taking a full meal may prove very injurious. An experiment on this subject was made some years ago by Professor Harwood worth relating. He caused a pointer, after a full meal, to be hunted, and another dog of the same kind, after a full meal, to lie down in his kennel; both were killed after an equal lapse of time, when it was found that, in the quiescent dog, the digestion of the food was far advanced, while in the hunted dog it had scarcely commenced.

The alimentary mass having been reduced into chyme, and propelled into the duodenum (which is so called on account of this intestine measuring twelve inches in length), there becomes intimately mixed and incorporated with the bile and pancreatic juices; also with a fluid secreted by the mucous follicles of the intestine itself. The bile is a greenish, bitter, and somewhat limpid fluid, secreted by the liver, which occupies a considerable space on the right side of the body, immediately under the ribs. From this organ the bile, after a portion of it has passed up into the adjacent gall-bladder, descends, through a small duct about the size of a goose-quill, into the duodenum. The chyme, when mixed with these fluids, undergoes a change in its appearance; it assumes a yellow colour and bitter taste, owing to the predominance of the bile in the mass; but its character varies according to the nature of the food that has been taken. Fatty matters, tendons, cartilages, white of eggs, &c., are not so readily converted into chyme as fibrous or fleshy, cheesy, and glutinous substances. Sir Astley Cooper made various experiments on the digestibility of different substances, by feeding dogs on different kinds of meat, and opening their bodies at the end of a certain time, whereby he ascertained how far in each case the digestive process had proceeded. He found that pork was the most rapidly digested; then followed mutton, then veal, and lastly beef, which seemed to him the least digestible of all. In some cases the pork and mutton had entirely disappeared, while the beef remained untouched. By other experiments he found that cheese and fish are also very digestible substances. The potato appeared to be less so, and boiled veal two-thirds more digestible than the same substance roasted. It is evident from these facts that much attention should be paid to the nature or digestibility of the food that is taken, and to this important subject we shall immediately recur. In the meantime, we may observe, that the chyme, having undergone the changes adverted to, is urged by the peristaltic motion of the intestines onwards through the alimentary canal. This curious motion of the intestines is caused by the contraction of the fibrous coat which enters into their structure, and one of the principal uses ascribed to the bile is that of stimulating them to this motion. If the peristaltic motion be diminished, owing to a deficiency of bile, then the progress of digestion is retarded, and the body becomes constipated. In such cases, calomel, the blue pill, and other medicines, are administered for the purpose of stimulating the liver to secrete the biliary fluid, that it may quicken by its stimulating properties the peristaltic action. But this is not the only use of the bile: it also assists in separating the nutritious from the non-nutritious portion of the alimentary mass, for the chyme now appears to be mixed with a fluid termed *chyle*, which is in reality the nutritious fluid eliminated from the food. The chyme thus mixed with chyle arrives into the small intestines, and there we notice a beautiful provision of nature, for on the walls of the intestines will be found a series of exquisitely delicate vessels ramifying in every direction. They may be compared to an inverted tree, the branches of which are spread out on the coats of the intestines, and are found leading to a parent trunk, which ascends in the abdomen along the side of the backbone, and opens into the right side of the heart. Here, then, we may trace—and the course is very simple—the chyle from the alimentary mass into the circulation. Thus it takes place: The mouths of these vessels having the mixed chyme and chyle above them, absorb or take up the chyle, leaving the rest of the mass to be ejected from the body; the chyle thus taken up by them is carried into little bodies or glands, where it is still farther elaborated, acquiring additional nutritious properties; after which, corresponding vessels emerging from these glands carry along the fluid to the parent trunk, called the thoracic duct, which pours it into that side of the heart to which the blood that has already circulated through the body returns. Here the chyle is intimately mixed with the blood, which fluid is now propelled into the lungs, where it undergoes, from being exposed to the action of the air we breathe, the changes necessary to render it again fit for circulation. Thus, then, do we trace the chyle into the circulation; but after it has entered the lungs, it cannot as a separate fluid be again detected. It is in this organ, therefore, that the process of digestion is completed; the blood has now acquired those nutritient properties from which it secretes the new particles of matter adapted to supply the waste of the different textures of the body. That the chyle which is eliminated from the food we eat does in reality supply the blood with its nutritious properties, is clearly proved; for in those cases where the chyliferous vessels have been obstructed by disease, persons have emaciated and died. It sometimes happens in children that those little bodies called glands—situated in the mesentery, which is a membrane connected with the bowels, in which we have stated that the chyle acquires additional nutritive qualities—become diseased; and in these cases the little patient often wastes very rapidly away, and dies. It may also be observed, that in old people these glands become frequently, as was shown by Cruickshank, obliterated, which may in like manner explain the reason of their becoming emaciated. In both cases, the chyle, not having undergone the necessary change in these glands, does not supply the blood with the nutritious elements necessary for renovating the system. Thus, then, from the preceding remarks, it will appear that the digestive process proceeds in the following manner:—The first stage is the mastication of the food in the mouth, and its proper saturation with saliva; the second is its conversion into chyme in the stomach; the third is the separation of the chyme from the chyle in the intestines; and the fourth is the transmission of the chyle into the blood, and its admixture with that fluid.

ANIMAL FOOD.

It has been already shown that mankind is destined to live on a mixed diet, that is, both on animal and vegetable food; the different kinds of which now claim attention. The animal food commonly used in this country consists of the flesh of quadrupeds, birds, fishes, and amphibious animals. Among the former may be included the flesh of oxen, sheep, pig, deer, hare, and rabbit; the history and nutritious qualities of each of which kinds of food we shall now proceed to consider.

FOOD DERIVED FROM QUADRUPEDS.

Beef and Veal.—The flesh of oxen is extremely nutritious, and easily digested by persons who are in good health; it is not, however, so easy of digestion as mutton, although, when digested, it is equally nutritive. Indeed, for strong and hard-working men it affords a most serviceable diet, but persons who are very plethoric, or of full habit, should partake of it sparingly. Although generally boiled, beef and also veal are rendered more digestible and nutritive by being roasted, in which case the jelly between the interstices of the meat escapes, whereas, when boiled, it remains there and becomes converted into a substance by no easy means very digestible. The flesh of all young animals is of a softer texture than that of old animals; this arises from the quantity of loose cellular texture and fatty matter, which in them is interposed between the fibres of the muscles; but as age advances, this is absorbed; and the fibres approaching each other more closely, the flesh is rendered denser and more compact. For this reason veal affords more jelly than beef, and, consequently, makes an excellent broth for persons affected with chest complaints, and who, in consequence of their cough, require soft and soothing liquids. The fluid, however, which remains after boiling beef, called beef-tea, is far more nutritive, and of great service in restoring strength to those who have been debilitated by sickness. This state of young meat is limited to a certain period of the growth of the animal; it is in veal when the calf is under two months old; for after that, the muscular fibre becomes more distinguishable, and the whole substance less tender. The stringy nature of young meat, and the quantity of gelatinous matter interposed, renders it generally difficult of digestion; hence veal, although tender and nourishing, is by no means easily digested. It requires, particularly in delicate persons, the addition of some stimulant, as the condiments which enter into the stuffing, or vegetable acid, as lemon juice or vinegar; besides which, the disposition of fat in the bodies of old and young animals renders the flesh of the latter more indigestible than that of the former. In old animals the fat is collected in masses or layers external to the muscles; in young, it is interspersed between the fibres of the muscles, whereby the meat is rendered throughout fatty and rich; and fat is known to be a substance scarcely soluble in the human stomach. It is not, therefore, to mere fastidiousness of appetite that children reject fat; it is the natural antipathy of the stomach against a substance it cannot digest; therefore, nothing is more absurd than for parents to force children to eat that which will injure the digestive organs.

Mutton and Lamb.—No meat is more digestible and nutritious than mutton, which, however, is a species of food not to be found good in many parts of the world. Britain is remarkably fortunate in respect of its breeds of sheep, especially the small black-faced kinds which are reared on the Welsh and Scottish pastures. The Spanish may appear to possess a larger and finer fibre, but neither the flesh for eating, nor the wool for manufacturing purposes, is found equal to that yielded by the British breeds. Much of the quality of mutton depends on its being reared on dry pasture-grounds; and its digestibility is greatly affected by its age. Under two years of age, mutton is certainly less digestible than when older; at the age of five it appears to attain its greatest perfection. With respect to lamb, it may be said that if the animal be allowed to live upon its mother's milk for six months, it will then afford a more nutritious and digestible aliment than lamb of the same age weaned at two months. For the reasons, however, above described, the flesh of the lamb is not so eligible a substance of diet as the flesh of the same animal at a more advanced age. It is also more digestible when roasted than when boiled, and its fat is said to be more indigestible than the fat of any other kind of animal.

Pork.—Sir A. Cooper has shown, by the experiments above detailed, that pork is more easily and rapidly digested than mutton, beef, or veal. It does not follow, however, that because a substance is very digestible, therefore it will be very nutritious, for undoubtedly pork affords less nutrition than beef or mutton. The flesh of the young suckling pig is in general esteemed a great delicacy; but it is very rich, and not adapted for persons in a delicate state of health. A moderate quantity of bacon is very digestible, and is the principal article of diet among the labourers in Herefordshire, and some other counties in England. A very indigestible preparation, called brawn, is made from this species of food; it consists chiefly in the fatty layer being so closely compressed, that much of the oily part escapes into the cellular texture, and unites with it so closely as to form a half-transparent substance. This few stomachs can easily digest. Formerly the flesh of the wild boar was considered a very great luxury. The wild race of these animals is, however, entirely extinct, although the tame boar is still occasionally used, and bears salting well. Salted and smoked hams are common in all families, being chiefly eaten as an adjunct, or stimulant, with other milder kinds of food, as with poultry; but the operation of salting and smoking certainly impairs the digestibility of the meat. It is true, as we shall presently show, that a certain proportion of salt, with the food, is essential to healthy digestion; but, in the process of salting, a chemical combination between the animal fibre and the salt takes place, by which the texture of the fibre is so changed as to be rendered much less nutritive and digestible. In the process of smoking, the heat of the chimney assists this combination; and, by drying the fatty matter between the interstices of the muscles, the meat is rendered much less soluble in the stomach. Accordingly, this kind of food is only advantageously used to stimulate the palate, and is not to be relied upon as affording nutrition to the body.

Deer.—Food derived from animals of the deer kind has been always in this country esteemed a luxury, probably on account of their being objects of the chase, and therefore well adapted to adorn the tables of the great. To this kind of food the term venison is applied. There are three species of deer thus employed in this country, viz. the stag, the fallow-deer, and the roebuck. The stag in its wild state is now extinct in England; therefore, when this beautiful animal is hunted, it is turned out of some gentleman's park, to be pursued and killed in the open country. The flesh of the stag is of a firmer texture than that of the fallow-deer, which is by far the most digestible and nutritious. The fallow-deer, although allied, are a species distinct from the stag; they are smaller and less robust, and their horns, instead of being round, are flattened or palmated. They do not afford so good a chase as the stag, but their flesh is more delicate. The roebuck is the smallest of the deer kind known in our climate, and their flesh is still more delicate than that of the fallow-deer; but owing to its abounding with more fat, it is often on this account less digestible.

Hare and Rabbit.—The hare and rabbit, though resembling each other, are different species of the same genus of animals, and both are yet subjects of the chase. The ancients considered the flesh of the hare to be a luxury, and Pliny in particular dwells on the circumstance of its muscles being free from any fat. It may be here observed, that the flesh of animals that have been hunted always possesses a peculiar tenderness; hence, the hare which has been run down by a long chase presents us with more delicate food than that which has been suddenly killed. The muscular fibre of the hunted hare having been long kept on the utmost stretch, undergoes, when death occurs, a corresponding degree of relaxation, so that the rigidity of its texture is thus effectually overcome. A lingering death has the same effect; and hence there was an old and very cruel law, that no bull beef should be exposed for sale, unless the animal had been previously baited. It is stated by Dr Paris that the action of vinegar, administered to an animal some hours before killing it, renders the flesh less tough; and therefore it is a common practice in the country to give a spoonful of this acid to poultry, when they are intended for the immediate service of the table. The flesh of the young hare or leveret is more digestible and nutritious than that of the older hare. Venison, hare, and other kinds of game, are in general kept a long time before they are eaten; they are preserved until they have become what is called *high*—that is, until the putrifactive process has commenced. Singular as it may appear, the effect of this process is to overcome the rigidity of the animal fibre, and thereby increase the tenderness of the meat. Even beef and mutton, unless kept some days—the number of which must be determined by the season of the year—will not eat tender. The flesh of the rabbit is extremely white and very dense; and unless the animal be killed very young, its flesh is by no means digestible.

Minor Parts of Animals.—It remains for us to speak of the different parts of the above animals which are occasionally served at table; as the brain, marrow, liver, lungs, &c. The brain of the calf and sheep is often served up in the form of sauce or brain-cakes; but in consequence of the quantity of fatty matter contained in the substance of the brain, these are apt to disagree with tender stomachs. The brains of the hare and rabbit are, however, very delicate eating. The marrow is a soft and very soluble substance, and may, in very small quantities, be eaten with impunity. It is, as we have elsewhere premised, the reservoir of nutrition for the bones; and little or none is found in the bones of cattle that have been overdriven, or suffered from privation of food. The tongues of different animals, particularly of the calf and sheep, when salted, form an excellent stimulating adjunct to the milder kind of meats, as to poultry; but the objection urged against salted hams here also applies; and hence, although stimulating to the palate, it is not a food easy of digestion. The roasted heart, particularly of the calf, is often brought to table; but in consequence of the density of the fibres of this organ, it is very slowly digestible. The liver of birds, particularly of the goose, was formerly esteemed a great luxury; and by confining these birds, and feeding them on a certain kind of food, particularly milk, this organ increased to a prodigious size, which considerably enhanced its value. The livers of animals afford very little nutriment; and the same may be said of the lungs, kidneys, and pancreas or sweet-bread, and spleen. Many persons are very fond of tripe, which is entirely composed of gelatin, and certainly not very digestible. It was considered so great a luxury by the Romans, that they often killed oxen for the sake of the tripe, not caring for the flesh of the animal. The gizzards of birds are, it is to be observed, exceedingly dense, and very indigestible. The feet of many animals, as of the calf, sheep, &c., afford vast quantities of jelly, in consequence of numerous ligaments and tendons which enter into the construction of this part of the body.

FOWL.

The birds which are used for purposes of diet may be divided into the domesticated, such as the hen, duck, goose, and pigeon; and the wild, such as the partridge, pheasant, woodcock, snipe, and blackcock. It may be laid down as an established principle, that white meats afford a less stimulating chyle than meats of a darker colour. The flesh of veal is less stimulating to the system than that of venison; that of chicken less stimulating than that of partridge or grouse. Although more easily digested, the flesh of birds is not so nutritious as that of quadrupeds. It affords, therefore, one excellent diet for persons who are disposed to be plethoric, or likely to be attacked by apoplexy. In consequence of its digestibility, also, it is well adapted for weak and irritable stomachs; and hence Dr Johnson, in his admirable work on the "Morbid Sensibility of the Stomach," recommends chicken as the least irritating and most easily digested aliment after farinaceous food; such as sago, arrowroot, tapioca, &c. The different parts of birds vary in their degrees of digestibility; thus, the wings of birds whose principal exercise is flying, and the legs of those that are accustomed principally to running, are, in consequence of the effect of the exercise in thickening and increasing the bulk of the muscular fibre, rendered less digestible than other parts of the body. The woodcock is obliged to fly much about, while the partridge runs more and flies less; hence, the wing of the woodcock is very tough, while that of the partridge is very tender; and, on the contrary, the leg of the woodcock is very tender, while that of the partridge is very tough. Hence the doggrel distich—

"If the partridge had but the woodcock's thigh,
He'd be the best bird that e'er doth fly."

The effect of advancing age in diminishing the digestibility of the flesh of all birds, is notorious. The common fowl is best about a year old, after which time its flesh becomes more and more indigestible. Of the domesticated birds, the flesh of the chicken is by far the most digestible; then follows that of the guinea-fowl, turkey, pigeon, pheasant, duck, and goose, which increase in indigestibility according to the order in which they are here arranged. Of wild birds, the woodpigeon, woodcock, and snipe, afford an aliment which is very delicate and easy of digestion. The flesh of the blackcock is said to be more easily digested than that of the partridge, and the flesh of the partridge is more digestible than that of the quail. Of the class of birds which may be designated sea-birds, it may be observed, that, in consequence of their living upon fish, their flesh is very tender and easy of digestion; but it often possesses a rank fishy taste, which to many stomachs proves insuperably offensive. This is the case with the solan goose, which, although esteemed by some persons as a luxury, is by many rejected as being altogether unpalatable.

Eggs, which should properly be considered in this place, are, in point of nutriment and digestibility, to be classed next to milk; but their qualities will greatly depend on the manner in which they have been cooked. When raw, they are not so easily digested as when lightly boiled, so as to coagulate slightly their albumen, or the white fluid which envelopes the yolk; but if boiled too long (beyond three minutes), the whole becomes converted into a hard mass, which is very indigestible. The qualities of the egg, the taste and colour of the yolk, and even the nourishment it affords, depends on the food given to the hen. The best eggs are those from hens fed with wheat; next to that, on rice, barley, and potatoes. How far the qualities of the eggs of different birds may differ from each other, does not appear to be well ascertained. "I am certain," observes Dr Cullen, "that, in many instances, the peculiar odour and taste of the flesh of the bird is in no degree communicated to their eggs; for example, in certain sea-fowl, whose flesh is of the rankest odour and taste, their eggs are as free from taste and smell as the eggs of our domestic fowl. Even in the latter we can observe some difference in the taste of the yolks, and in the density of the whites, which seems to depend on the food the bird lives on."

FISH AND AMPHIBIOUS ANIMALS.

Fish is more digestible, but less nutritive, than beef and mutton. It is evident from the texture of its muscular fibre, that the flesh of most fish is very tender, and therefore easily soluble in the stomach; but it affords the body little stimulus, and even the pulse is not strengthened after a repast on this kind of food. Hence, owing to its want of stimulating power, it requires the assistance of some condiment—as salt, pepper, or some stimulating sauce. The whiting is the most tender and delicate fish, and may be given to the weakest stomach; the haddock resembles it, but is of firmer texture. The sole and flounder, for tenderness and delicacy, rank next. Trout and salmon-trout then follow, and are more digestible than cod, the flesh of which has been not inaptly called the "beef of fish." The salmon, which attains its highest perfection, or comes into season, some time previous to its spawning, affords an aliment which is very nutritious, but by no means easily digested. To assist its digestion, it requires the addition of some stimulating sauce, or Cayenne pepper, or vinegar; the lobster sauce generally eaten with it loads the stomach, and contributes to impede the digestive process. The same may be said of turbot as of salmon; it is very nutritious, but not easily digested; and often the ill effects which arise from eating it are aggravated by the sauce taken with it. It may indeed be observed, that all fish that is of an oily nature is difficult to digest; and this is particularly the case with eels, and also with skate, which, when taken, should always be qualified with vinegar, or some other stimulant. Many persons are very fond of mackerel and herrings, both of which are excellent articles of diet, but the former is less digestible than the latter. The pike is also a delicate and excellent fish; but great care should be taken in eating it, lest any of the bones, which are small, sharp, and jagged, be swallowed.

Shell-fish are all comparatively indigestible, and should never be eaten without some accompanying stimulant, such as vinegar or pepper. The oyster is said to contain a considerable quantity of nutritious matter; but when cooked, in consequence of its albuminous matter being coagulated, it is rendered still more indigestible. The substance of the lobster and crab is very similar; and it is only perhaps in consequence of its more elegant appearance that the former is a greater favourite at our tables than the latter. The shrimp is the most delicate, and perhaps the most easily digested of any of the shell-fish above enumerated. The mussel is reported in many instances to have given rise to noxious effects; and certainly the food derived from this class of fish often gives rise to eruptions of the skin, and is peculiarly apt to disagree with the stomach.

From the amphibious tribe of animals, few are selected as articles of food; the most noted are the turtle and the frog. The flesh of the turtle, though by no means easy of digestion, is said to be very nutritious; but the process of cooking which it undergoes in this country renders it still more indigestible. The flesh of the frog, which is esteemed a luxury in France, was analysed by Geoffroy, who states that its qualities are very similar to the flesh of the turtle, but somewhat less gelatinous.

THE COOKERY OF ANIMAL FOOD.

The legitimate object of cookery is not to pander to the taste of the gourmand, by presenting him with a variety of "dishes tortured from their native state," but to render the food which nature has supplied digestible and nutritious. The fact has been ascertained, that meat, boiled, roasted, and even putrid, is more digestible than meat in a raw state; and hence, as Fordyce observes, in all countries, however savage, where fire can be procured, the inhabitants use heat for the preparation of their food. The changes which animal substances undergo during the process of cooking are either mechanical or chemical. Thus, by overcoming the rigidity of the muscular fibre, the meat is reduced to a certain texture, which renders it more easy of digestion; this may be said to be a mechanical change. Again, according to the experiments of Hatchett, by the process of boiling, animal substances are converted into gelatin; and this may be said to be a chemical change, for, according to this view, free gelatin does not exist in the bones, or in any other of the animal tissues, but is produced by the process of boiling, during which the material particles arrange themselves in a new position, and thereby give rise to a new substance. When authors speak of the gelatin of meat that is uncooked, they merely mean that animal substance which is most easily reducible into gelatin. Let us now, then, attend to the different processes of cooking, and the effect which they severally have in rendering animal substances more digestible and nutritious.

Roasting is of all others the best process of cooking, for by the application of dry heat in an open space, the fat between the interstices of the meat is dissolved and escapes, while the nutritious matter remains. Roasted beef, mutton, veal, poultry, &c., are far more digestible and nutritious than the same food boiled. At the same time that the fat escapes, and the watery part of the meat exhales, the meat becomes at first brown, then scorched, and requires to be frequently moistened with dripping or butter. The reason of this is, that the outer surface becomes at first condensed, and it is necessary to keep it moistened, in order that the heat may penetrate into the interior of the joint. When meat is exposed to a very intense fire, and this treatment neglected, the outer surface becomes condensed and scorched, while the inner parts still remain undone, or in a raw state.

Boiling is a less preferable operation, because it deprives the meat of those nutritious matters which are soluble in water. The solution of the gelatinous matter, and of a peculiar principle called *osmazone*, converts the liquid in which the meat is boiled into broth or soup, which contains the nutritious principles which the meat formerly possessed, and which now is reduced to a mass of dry hardened fibres. The osmazone is a very peculiar animal principle, which gives soup its characteristic taste and odour. Its odour, indeed, is very peculiar: it is that remarkably fragrant odour which rises with the steam from the kitchen windows of cook-shops and hotels. Both in the process of roasting and boiling, the heat ought never to be very intense, for it has been clearly ascertained that, in order to be well cooked, all kinds of food should be cooked very slowly. Count Rumford made many very curious and interesting experiments on this subject. He showed that a leg of mutton, boiled in water only just boiling, is more juicy, and much higher flavoured, than the same kind of meat cooked in water kept constantly on the boil. The fragrant steam which arises during the process of boiling or digesting meats, is in fact loaded with the nutritious part of the food, which is thus carried away and dissipated by the injudicious rapidity and intensity of the heat that is applied. It is also to be observed, that if meat be overboiled, it is rendered very indigestible. In this case, if it contain albumen, that substance is converted, like the white of an egg, into a hard indigestible mass, which may be observed, as is the case with overboiled beef, congealed between the interstices of the muscular fibre. So also the gelatinous matter with which young meat—such as veal—abounds, becomes converted, by being overboiled, into a substance by no means easy of digestion. When only a little water is applied, and the heat continued at a gentle temperature for a long time, the process is called that of *stewing*, which, for the reason just assigned, has the effect of rendering the meat very tender and sapid.

Baking differs from roasting, inasmuch as the meat, although exposed to a dry heat, is confined in an oven or limited space; the consequence of which is, that the exhalations being confined, the meat never fails to acquire a very disagreeable smell and taste. It is true that the retention of the juices thus occasioned may render the meat more tender, but the muscular fibre, as it were, soddens in fat which does not escape, and thereby such meat is rendered difficult of digestion.

Broiling is an operation which consists in subjecting the meat to the application of a naked fire, whereby, from the intensity of the heat, the surface of the meat becomes browned and hardened before the heat penetrates the entire mass. Hence it is a kind of cookery adapted only to meat cut into slices, and which may be eaten a little underdone. In this state the meat is particularly nutritive; hence this form of diet is considered the most eligible for persons who are desirous of strengthening themselves, whether for the recovery of health, or in the art of training.

Frying is a culinary operation, in which slices of meat cut are placed in a pan or vessel interposed between the meat and naked fire; but as the surface of the meat in contact with the bottom of the vessel would become suddenly heated, and thereby scorched, it is always found necessary to interpose some fluid matter. Fat or butter is generally had recourse to for this purpose, and, being of an oily nature, such matters, when exposed to a strong heat, soon become empyreumatic, and the meat so saturated is very liable to disagree with the stomach.

To the cooking of fish considerable attention should be paid, as upon this their digestibility mainly depends. The process best adapted to render them wholesome is that of boiling. Fried fish and stewed fish prove particularly injurious to weak stomachs. The same objections as those to salted meat apply to salted fish, which, however, may be eaten with a due admixture of potatoes and parsnips, but with no other vegetable.

VEGETABLES AND FRUITS.

The vegetable diet, which so well diversifies the nature of the food on which we subsist, is derived from the seeds, roots, stalks, leaves, blossoms, juices, and fruits of plants. The seeds of certain grasses, as of wheat, rye, barley, and oats, contain a quantity of starch or farina, which renders them particularly nutritious. Sago, which is prepared from the pith of an East Indian palm-tree; arrow-root, which is obtained from the root of an Indian plant called the *Maranta arundinacea*; tapioca, which is prepared from the root of another plant called the *Jatropha manihot*; and the common potato, owe their nutritious qualities to the presence also of this farina: wherefore they are called farinaceous aliments. The first process for converting farinaceous seeds into food is that of grinding them into powder; and the meal so produced, when separated from the husk of the seed or bran by sifting, presents us with the powder denominated flour. When this flour is mixed with water, it forms a paste or dough, which is by no means digestible. If, however, it be allowed to remain for some time, its component ingredients react upon each other, and that spontaneous change which is called *fermentation* commences; carbonic acid, acetic acid, and alcohol, are set free; and if the mass be now baked, it becomes light and porous, and pleasant to the taste. The old paste is called the *leaven*; and if mixed with the new-made paste, the fermentation commences more readily. Instead of this leaven, however, the ferment which collects on the surface of fermenting beer, and which is called *barm* or *yeast*, is used in this country. In consequence of the quantity of gluten in the seed of the wheat, the flour of the wheat makes by far the finest and best bread.

There are three kinds of bread made from the wheat which are commonly used in this country—white, wheaten, and household. In the first, all the bran is separated, and the bread is made of pure flour; in the second, only a part of the bran is separated—so that this wheaten bread is a mixture of flour and bran; in the third, none of the bran is separated—so that household bread consists of a mixture of the coarse bran with the flour; it is, in fact, composed of the whole substance of the grain. The distinctions here pointed out are of importance, in as much as the tendency of starch upon the bowels is astringent; that of bran laxative, owing, says Dr Paris, to its exerting a mechanical action on the intestines, and thus exciting them into action. Accordingly, the tendency of the bread made of the whitest flour is to produce costiveness; therefore, persons of this habit of body should prefer the wheaten, or even household bread. It is said by some persons that bread made of different kinds of grain is more wholesome than that made of only one sort; and certainly this is the case with what is commonly called brown bread, which is made of a mixture of wheat and rye flour: the former being of a more starchy nature, is apt to produce costiveness, the latter laxativeness; so that a due proportion of each furnishes a desirable compound.

Among the class of farinaceous aliments, the potato is held deservedly in high estimation. The plant is a native of Peru, and was first extensively cultivated by the Irish, whose peasantry still subsist almost exclusively on this article of diet. The digestibility and nutrition which the potato affords depend on the kind that is used, and the method of cooking which is adopted. The waxy kind of potato, as it is termed, is very indigestible; the mealy kind, however, if properly boiled, readily yields to the powers of the stomach, and affords a healthy nutriment. Count Rumford, in his zeal to promote the culinary art, insists at great length on the necessity of understanding the proper method of boiling potatoes, and on this subject cites the directions which were given by the Board of Agriculture in their report, from which we make the following extract:—"The potatoes should be as much as possible of the same size, and the large and small ones boiled separately. They must be washed clean, and, without paring or scraping, put in a pot with cold water, not sufficient to cover them, as they will produce themselves, before they boil, a considerable quantity of fluid. They do not admit of being put into a vessel of boiling water, like greens. If the potatoes are tolerably large, it will be necessary, as soon as they begin to boil, to throw in some cold water, and occasionally to repeat it till the potatoes are boiled to the heart (which will take from half an hour to an hour and a quarter, according to their size), otherwise they will crack and burst to places on the outside, while the insids will be nearly in a crude state, and, consequently, very unpalatable and unwholesome. During the boiling, throwing in a little salt occasionally is found a great improvement; and it is certain that the slower they are cooked, the better. When boiled, pour off the water, and evaporate the moisture by replacing the vessel in which the potatoes were boiled once more near the fire, which will make them remarkably dry and mealy." Such are the directions given by this report for preparing this very valuable article of diet, and attention to them, we have no doubt, will improve its digestibility, and the amount of nutrition it will yield. That the nutritious quality of the potato is increased by being properly cooked, there is no doubt. Hogs fatten on dressed potatoes more rapidly than when fed on potatoes in their raw state. The esculent roots of plants used as articles of food consist of the carrot, which is very nutritive and slightly laxative; the turnip, which ought to be well boiled, and separated from its watery parts by pressure; the parsnip, which is also very digestible and nutritious; and others that possess peculiar stimulating qualities, as the radish, onion, leek, shallot, &c., all which are useful in exciting the tone of the digestive organs, and correcting the tendency to flatulence. The esculent herbs of which the stalks and leaves are eaten consist of what are termed greens and salads, and include the cabbage tribe—asparagus, lettuce, water-cress, &c. The central and upper leaves of the cabbage are the tenderest part of this plant, which, for the purpose of cooking, should be plucked when very young. Cabbages, by their colour, are distinguished into two kinds—the white and the red, of which the latter is found to be of the sweetest and tenderest kind. The species, however, of this plant, called the cauliflower and broccoli, are to be preferred, as being most tender and easy of digestion. It is, however, to be remembered, that all the cabbage tribe is liable to produce flatulency; they should therefore even in health form only a small portion of our diet; and by those who suffer from indigestion they should be carefully avoided. This class of vegetables, it may be observed, possess a certain essential oil, which gives cabbage-water its peculiarly offensive smell; and to get rid of this noxious ingredient, this vegetable should be boiled in two successive waters. The asparagus is a very delicate vegetable, and one easily digested, even by weak stomachs; the lower part of the stalks, however, should never be eaten. The lettuce and water-cress are both agreeable articles of food; the former contains a narcotic principle, which some persons appear to be more affected by than others. It is stated that Galen, being subject in the decline of life to sleeplessness, cured himself by eating a lettuce every evening. The water-cress acts as an aromatic; it stimulates the stomach, corrects flatulency, and should therefore be always eaten with other raw vegetables.

Fruits, allowing the term its conventional meaning, are in this country rather esteemed as luxuries than as essential articles of diet. The ripening of fruit is a kind of fermentation by which the acids they contain are converted into saccharine matter; consequently, if eaten when in their unripe state, they will disagree even with the strongest stomach. The small-seeded fruits are more digestible than the larger stone-fruits. The strawberry, raspberry, gooseberry, &c., are more easily digested than cherries, plums, nectarines, &c. Care should be taken, however, not to swallow the skins of fruits, which are universally indigestible, and remain acting as irritants against the coats of the stomach and bowels. The skins, the seeds, the husks, and the fibres of fruits (says the celebrated Dr Armstrong), are all irritants; and again and again you may trace the rise of inflammation along the alimentary canal to the irritation of fruits, especially among children.

DRINK.

Having so fully explained the precautions which should be observed in taking solid food, it remains for us to consider those which should be observed in respect to the liquid portion of our diet. Ill health, misery, and all those misfortunes which await with unerring certainty indiscretion and vice, are perhaps more apt to be incurred by the abuse of liquid than of solid food; for the former is more immediately exhilirating than the latter; and when men meet together in society, anxious to please and be pleased, the wine, spirits and water, or whatever other cheer be afforded, stimulates their senses to forgetfulness of the ordinary cares of life, and surrounds them with so much social enjoyment, that, in the midst of their dreamy pleasure, they overstep the boundaries of prudence, and commit excesses which they themselves afterwards have cause to regret; for the higher and more felicitous the excitement, the deeper and more painful is the depression which succeeds. In the whole code of health there is no law more imperious than that uniform temperance should be observed under all circumstances and in all conditions of life, and the transgressor of this law will himself be universally the sufferer. It is to be observed, that the transgression may be made by drinking, even in small quantities, fluids which are of a strong or pernicious quality, or by drinking, in large quantities, fluids which, although much diluted, are still of a stimulating description. Accordingly, we should attend in particular to the quality and the quantity of the fluids we drink. Spirits of every description, taken in an undiluted state, are exceedingly pernicious; and those who indulge in the vicious habit of drinking brandy, whisky, hollands, and rum, in this state, invariably contract diseases which are beyond the cure of the physician. The immediate action of such fluids on the coats of the stomach must evidently destroy their healthy condition. The blood-vessels on the internal coat of this organ thereby become so excited, as to appear involved in one complete mass of inflammation, while at the same time the nerves experience a shock from the over-excitement, which is immediately transmitted to the rest of the system. The use of ardent spirits, under all circumstances, should be studiously restricted, and in no case should they be drunk in an undiluted state. With respect to the choice of spirits, it may be observed, that brandy acts more immediately as a tonic than whisky or hollands. It is less liable also to turn acid on the stomach, for which reason, for invalids or persons troubled with weak digestion, when diluted with water, it is preferable to wine. When pure, whisky diluted with water may be occasionally taken with impunity; but certainly it does not agree with persons in the south of England, as well as with those in the north, or in Scotland. The reason seems to be, that the air in these northern parts is drier than in the south; consequently the perspiration from the surface of the body more readily escapes. In the south, however, the air is more loaded with moisture, and consequently less favourable to the escape of the perspiration. For the same reason, in the Highlands of Scotland, and in ascending high mountains, being surrounded by a drier atmosphere, the traveller takes his whisky and water with more impunity than he would do under other circumstances. It is well known that hollands, which is a light spirit, acts as a diuretic, and in certain cases is preferable either to brandy or whisky. The common gin which is sold in London and other towns of England is often adulterated with the most pernicious ingredients. It is drunk in the shops—which are fitted up in London at an enormous expense to tempt the street passengers into them—in large quantities, and generally in a raw state, and deplorable are the effects thus induced. The diseases of the body, the demoralisation of the mind, engendered by gin-drinking in the metropolis, are indeed almost incredible; and all establishments in which this pernicious practice is encouraged, may most truly be described as temples set apart for the performance of human sacrifice.

The wines commonly used in this country are very numerous; some are called dry and light, such as Hock, Moselle, Burgundy, Claret; others dry and strong, such as Port, Sherry, Madeira; some, again, sparkling or effervescing; and others sweet, such as are home-made. It is a singular fact observed by dietetic writers, that the stomach is often outraged by a wine to which it is not accustomed; and it is equally true, that a mixture of different wines is a common source of indigestion. Of all the wines which are used, Claret is considered to be the most beneficial; on account of the small quantity of spirit as well as extractive matter which it contains, it is more salubrious than Port. Hock combines the effects of an acid with those of a spirit; but on account of its acid effects, we have seen it disagree with invalids. Burgundy contains a large quantity of spirit, and is more heating than any other kind of wine. Although the wines of Burgundy were prescribed in the time of Louis XIV. in affections of the chest, no physician of the present day would advise them to be used by any persons of an inflammatory habit. Port wine, it is well known, has a tonic and astringent effect; a glass or two daily to persons of weakly constitution may be taken with advantage. It is observable, however, and the fact is curious, that men accustomed to take Port wine freely after dinner, are apt, if they have recourse to an occasional excess of Claret, to be affected by gout; which arises from the transition from the Port to the Claret causing derangement of the digestive organs.

The malt liquors commonly drunk are ale, porter, and small beer, the qualities of which vary according to the mode in which they are manufactured. In ale there is certainly the narcotic principle of the hop; therefore it disposes to sleep. If the malt of which it is made be slenderly dried, it is of a pale colour; if it be roasted or high-dried, then it is of a brown colour. Porter is made from high-dried malt, and differs very considerably according to the proportion of the ingredients which enter into its composition. Malt liquors give a greater degree of fullness to the blood-vessels than any other species of drink; and thus, by imposing on the heart a greater quantity of blood to propel through the body, disturb the circulation, and often induce disease of the heart, and apoplexy.

While the abuse of spirits, wines, malt liquors, &c. gives rise to the most distressing maladies, their utility, under proper management, is nevertheless very considerable; under which circumstances they may unquestionably be considered as preservatives of health. It is evident, however, that water is the most natural, and, when pure, the most healthy, beverage that man can drink; but it is to be remembered that its qualities differ according to the source whence it is obtained. When collected in fields, at a distance from any town, rain-water is the purest natural water; but if collected in a town, in consequence of having fallen through a smoky atmosphere, or dripped from the roofs of houses, it is apt to become contaminated, and should in such cases never be used without being previously boiled and strained. It may be observed concerning the origin of rain-water—for it is always interesting to associate the facts and phenomena observable in nature—that from the surface of seas and lakes vapours are constantly rising into the higher regions of the atmosphere; they are thence wafted by the winds over distant countries, and being condensed by a cold current of air, fall in drops of rain. Accordingly, rain-water is produced by a natural distillation; and when it has fallen in this way to the earth, it descends or filters through the crevices of rocks, pores of soil, &c., and accumulates below its surface. These accumulations of water are termed *springs*. In thus descending, the water dissolves the soluble materials contained in the rocks or soil through which it passes, and hence spring-water is always impregnated with a quantity of saline materials. In particular, there is one salt—the sulphate of lime—which imparts a quality of hardness to the water, which renders it unfit for domestic or medicinal purposes. It is called, therefore, *hard* water; and it is well known that in it, soap, instead of dissolving, decomposes and curdles on its surface. Cooks, knowing from experience that this kind of water will not dissolve vegetable matters, never use it in processes of cookery; and the brewer also rejects it, knowing that it will not dissolve the extractive matter of his malt. The water not impregnated with this salt, and which, in contradistinction, is called *soft* water, is always preferred. It may be added, that hard water, when drunk often, gives rise to a sensation of uneasiness or heaviness in the stomach. As above stated, besides the quality, the quantity of the fluids we drink is a matter of importance; for if the stomach be overloaded with fluid, the digestion of its contents must be impeded, owing, in the first place, to the bulk of the fluid stimulating the organ to contract too rapidly, and thereby expelling the food before it has undergone the necessary changes; and in the second, to its diluting the gastric juice so much as to prevent its acting upon the food with its wonted solvent powers. It is for these reasons objectionable to drink immediately before taking any meal, but a little quantity of fluid taken during a meal will rather assist than impede digestion. Moderation in the quantity which we eat and drink is of serious importance in the preservation of health; and hence there was much wisdom in the reply of an Eastern dervis, who, being asked by a Mahometan of what service was his order, answered, "If you were more cautious and temperate in your meals, if you would learn to govern your passions and desires by a due attention to abstinence, you all might be sages, and have no occasion for dervises among you; but your *appetite* and *aliment* impair your understanding."

EXERCISE.

The whole constitution of man shows that he was destined for an active existence; and it is an invariable rule of nature that every mental and bodily faculty is liable to be increased in power, and preserved in soundness, by exercise, while inaction tends to weaken and disorder the same parts. He, therefore, who wishes that the powers of his body and mind should be improved, or even preserved in their existing state, will take care to keep them in moderate exertion; while he who is ignorant of or indifferent to the principles on which mental and bodily sanity depends, will act in the opposite manner, and encounter the hazards which attend this, as well as all other violations of the laws of nature.

The human body contains upwards of four hundred muscles, and it is a duty of every man to himself to keep these in moderate exercise. A muscle is a distinct piece of flesh, composed of innumerable small fibres or threads, each separated from, and at the same time loosely connected with, the others, by an almost invisible sheath of cellular membrane. The use of the muscles is to produce motion, and to enable us to operate upon the objects around us. We desire, say, to put one foot before the other, or to move away a particular substance: the mind, which in the first place has formed the design of doing so, sends its command to the proper muscles by means of a distinct set of nervous fibres, communicating between the brain and these muscles; another set of nervous fibres conveys back to the mind intelligence of the muscular power necessary for the operation. The necessary communication having been thus established, the operation is produced by an union of muscular power and mental energy or will, the latter being generally by far the more powerful of the two forces, though useless without the other. While a muscle is in operation, it is contracted; afterwards it relaxes into its usual state.

Exercise operates favourably upon the human frame by promoting the circulation of the blood, and increasing the power and healthiness of the muscles. In a series of exertions, the breathing becomes rapid, and the arterialisation takes place more quickly; the muscles, moreover, by jostling the neighbouring blood-vessels, which they do when in a state of exertion, stir and propel their contents. The effect upon the muscles takes place through increased vascularity and the accretion of new substance. The quantity and flow of blood through the part are increased by the exertion, a greater degree of animal heat is evolved in the part, and a secretion of coagulable lymph takes place, which, becoming organised, produces new fibre.

Exercise, however, produces little or no good, if it be not prompted by a liberal portion of nervous energy. A walk taken without a motive to animate the mind is of hardly any service: in that case, says Dr A. Combe, "the muscles are obliged to work without that full nervous impulse which nature has decreed to be essential to their healthy and energetic action." When we walk, however, with an object at the end of our journey, the nervous impulse is in full and harmonious operation with the muscles. Sports which we enjoy with one or more companions are generally the best, as the society tends to awaken the mind to nervous energy; and where a contention for victory, or for some stake sufficient to excite the mind, is superadded, the advantage must be still greater. It is also of great importance that we should have a curiosity after objects: thus, a taste for scenery, or for geological and botanical pursuits, may enliven a walk, and enable us to keep up a proportion between the muscular and the nervous energy. One rule, however, must be observed—that *the will and the muscle must be directed to the same end, and at the same time.* Dr Combe, from whose admirable treatise these observations are chiefly taken, does not deny that walking for health may be attended with the desired effect: for the object may there be sufficient to keep up the proper mental stimulus.

Exercise is usually considered as of two kinds—active and passive. The active consists in walking, running, leaping, riding, fencing, rowing, skating, swimming, dancing, and various exercises, such as the poles, ropes, &c., prescribed in gymnastic institutions. The passive consists in carriage-riding, sailing, frictions, swinging, &c. In walking, the weight of the body rests on one foot while the other is advanced; it is then thrown upon the advanced foot while the other is brought forward, and so on in succession. In this mode of progression, the pace may, at the pleasure of the individual, be increased or diminished. Those who are accustomed to sedentary habits should not on a sudden betake themselves to quick and violent walking; for thereby, in proportion as the breathing becomes hurried, the action of the heart is accelerated sometimes to a painful and injurious degree. "In my own person," says Dr Johnson, "I had some years ago a very severe and alarming instance of the bad effects of too great muscular action, occasioned by a habit of walking very fast. After a day and night of unusual fatigue and rapid pedestrian exertion, together with considerable mental anxiety, I was suddenly seized with an intermission of the pulse at irregular periods. During each intermission I felt the heart give a kind of struggle, as it were, and strike with great violence against the ribs, accompanied by a peculiar and most distressing sensation in the cardiac region which I cannot describe." These symptoms became aggravated, and lasted for eight weeks, "during which time," he continues, "I used horse-exercise, and kept, when at home, in a horizontal position. At length the heart gradually lost its morbid irritability; and at the end of fourteen or fifteen weeks I could walk as well as ever." The affect of this kind of exercise, viz. walking, on the body, is very well described by Dr A. Combe, who, speaking generally, says, "walking agrees well with every body; but as it exercises chiefly the lower limbs and the muscles of the loins, and affords little scope for the display of the arms and muscles of the chest, it is insufficient of itself to constitute adequate exercise: and hence the advantage of combining with it movements performed by the upper half of the body, as in rowing a boat, fencing, shuttlecock, and many other useful sports." The exertion of walking may be carried to a great perfection; thus, Captain Barclay walked on one occasion 180 miles without resting, and on another 1000 miles in 1000 successive hours: but such feats are always performed at the risk of health and life, and ought not to be encouraged. "In summer," says Dr Combe very truly, "walking excursions to the Highlands of Scotland are common among the youth of our cities; and when proportioned in extent to the constitution and previous habits of the individual, nothing can be more advantageous and delightful. But not a season passes in which health is not sacrificed and life lost by young men imprudently exceeding their natural powers, and undertaking journies for which they are totally unfitted. It is no unusual thing for youths, still weak from rapid growth, and perhaps accustomed to the desk, to set out in high spirits at the rate of twenty-five and thirty miles a-day, and to come out so much worn and debilitated that they never recover. Young soldiers, whose growth is scarcely finished, are well known to die in great numbers when exposed to long and heavy marches, particularly when food is at the same time scanty." Many such unhappy cases are on record; therefore, due attention should be paid to the constitutional strength and previous habits of the individual before heavy pedestrian excursions are undertaken.

Running is an exercise which is intermediate between walking and leaping; it consists, in fact, of a series of leaps performed in progression from one foot to another, and the degree of its rapidity bears a constant proportion to the length of the individual and successive leaps. During this exercise the individual is obliged to take long inspirations, and make slow expirations; the air-cells of the lungs are hereby distended, and the action of the heart being at the same time increased, and the circulation through the lungs much accelerated, a sense of oppression is felt on the chest, which is often exceedingly painful: then, when the violent action is discontinued, the heart palpitates with intermitting strokes in the endeavour to recover its natural equilibrium of motion. Although this and other gymnastic exercises, such as leaping, wrestling, throwing heavy weights, &c., may, when judiciously had recourse to, invigorate the body—a fact proved by the athletic exercises which were prescribed to the Greek and Roman youths—yet, in consequence of the evils and accidents which may be so occasioned, young persons ought not to be permitted to engage in such exercises, except under the care of some judicious professor of gymnastics.

Fencing is of all active exercises that which is the most preferable, inasmuch as it throws open the chest, and at the same time calls into action the muscles both of the upper and lower extremities. Add to this that it improves very much the carriage of the body; in consequence of which, its acquisition, independent of its occasional utility in countries where the sword is the principal weapon of assault and defence, is justly esteemed an accomplishment which is a necessary branch of polite education. The salutary effects of the other exercises which are taught in gymnastic institutions, such as exercise with the ropes, poles, pullies, &c. in increasing the strength of the body, will be seen by consulting Mr Roland's excellent Treatise on Gymnastics, where will be found a table showing the amount of the increasing growth and strength of the body in a given time, during the employment of these exercises.

Dancing is an exhilarating and healthful exercise, and seems to be almost the only active exercise which the despotic laws of fashion permit young ladies to enjoy. The only evils which are attendant on this species of exercise arise from the indiscretion of the parties themselves, who are apt to overheat themselves, and in this state expose themselves to a chilling blast of air; in gay assemblies, too, while the body is thus overheated, ices and iced liquids are not unfrequently taken, from which we have occasionally seen the most fatal effects ensue.

Riding, which we have classed among the active exercises, may, if taken gently and with moderation, be ranked among the passive exercises, and is extremely beneficial to many invalids. In many nervous affections, hypochondriasis, melancholy, nervous palpitations of the heart, and also in chronic affections of the lungs, it has been justly extolled. In nervous affections it operates beneficially by engaging the mind in the management of the animal, or the variety of surrounding scenery, at the same time that it calls into gentle action the muscles of the body. In affections of the lungs, the succussions of the body during horse-exercise have the effect of equalising the circulation, and dissipating the congestion, or undue accumulation of blood, which may occur in the membranes lining that organ. At the same time, the gentleness of the motion does not hurry the breathing, which in such cases is to be carefully guarded against.

The amount of exercise which should be taken must vary according to the habits, strength, and general health of the individual. It was an aphorism of Boerhaave, that every person should take at least two hours' exercise in the day, and this may be regarded as a good general rule. Again, the time of taking exercise has been a subject of some dispute. The truth is, that active exertion should not be taken when the stomach is full, as after a full meal, nor when the stomach is empty, as after a long abstinence. The medium should be observed; and for this purpose a walk or ride, some two or three hours after breakfast, will be found most agreeable and salutary.

CLOTHING.

Montaigne has, in one of his amusing essays, very gravely argued, that man was not destined to wear clothes; but the early history of all nations that ever attained to any thing like civilisation, and more especially the structure of the body itself, prove the contrary position. It is true that certain tribes of savages may have been found running naked in the forests; but it is certainly not thence to be inferred that nature intended all mankind should go about in the same exposed condition. On the contrary, the rudest people in the darkest ages had recourse to some species of clothing; they made themselves garments of the leaves of trees, or they covered their bodies with the skins of animals. The necessity, however, of adopting some form of dress will appear manifest, when we consider the construction of the body. It is well known that an equal distribution of blood through the system is essential to the enjoyment of health. The heart, therefore, has been provided as a fountain for the circulation of this vital fluid, which it propels through the internal organs, and over the whole surface of the body. It has been ascertained that the surface of the body extends to fourteen and a half or fifteen square feet, every part of which is crowded with blood-vessels, which appear to ramify in all directions. Hence it is manifest, that if, unprotected by clothing, this highly vascular surface be exposed to sudden transitions from heat to cold—such as must attend the ordinary vicissitudes of weather—the blood will be driven from the surface to the centre, and thereby occasion distressing and fatal maladies. The great object, then, of clothing, independent of its contributing to cleanliness and comfort, is to preserve the body at the same temperature, so that the circulation at the surface may not be interrupted; which physiological fact being recollected, we shall more clearly understand the principles by which we should be guided in the management of dress.

The first consideration obviously respects the quantity and quality of clothing that should be worn, which to a certain extent must be modified by the nature of the climate and the season of the year. Furs, woollens, flannels, &c., are necessary as we proceed northwards; linen and cotton as we advance into the warmer southern regions. It is necessary, however, to observe, that it is not so much the quantity as the quality of the clothing which contributes to our warmth; therefore a superabundance in the quantity of apparel worn is in no case necessary. The great rule which should be observed is, to preserve as uniform a system of dress as possible throughout the year, and thereby those sudden vicissitudes of temperature, the injurious effects of which we have already explained, will not be experienced. If it be necessary to observe this rule throughout the year, it is still more necessary that it should be observed during a single day; for among many persons a custom prevails of wearing a heavy dress in the morning and a light dress in the evening. Young ladies are very apt to clothe themselves in the morning with very warm habiliments; dressed in which, while the sun is above the horison attaining its meridian of heat, they go out into the open air, and enjoy a brisk walk; they then, when the heat of the day is about to decline, and the system is relaxed from exertion, put on a different character of habiliments altogether, and in the chill of the evening are found dressed in the lightest summer apparel. If the dictates of fashion be so imperious as to render a change of dress necessary for effect, care should be taken to compensate for the lightness of the upper evening dress by some additional under garments, otherwise the body will certainly be exposed to the chance of taking cold. For the same reason, as the seasons of the year succeed each other, the greatest caution should be observed in adopting a change of dress. We have known many persons suffer severely from inconsiderately and at once laying aside their winter and assuming their summer apparel; such changes so suddenly adopted in such a climate as this must always be attended with danger. In particular, delicate persons should be very cautious how they lay aside *any* article of apparel to which they have been accustomed.

As the clothing which is worn ought not to be excessive, neither ought it to be deficient, in quantity—an error which some parents commit, under the idea, that, in habituating their children to little clothing, they are inuring them to a strong and hardy constitution. This is an error; for, so far as clothing is concerned, it ought never to be so deficient as to expose any part of the body to an abiding sense of cold. There is no doubt that the effects of habit are considerable. The child of the cottager is seen running about in good health, exposing its little body half naked to the inclemencies of the weather; but it should be recollected, that, generally speaking, the constitution of every child corresponds in a certain degree with the constitution of its parents; so that, in respect to its clothing, food, &c., it will require in a great measure to be treated according to the habits which prevail in the sphere of life in which it is born. As the quantity of clothing ought not on any account to be inconsiderately changed, neither ought its quality; because, as we have already premised, the quality or kind of apparel worn has even a more important influence in maintaining the equal temperature of the body. Flannel, we all know, is warmer than linen; not because it imparts of itself any heat, but because it prevents the escape of the heat of the body. It is what is called a *bad conductor* of heat; for this reason, that it is of a loose texture, and the air between its interstices interrupts the heat being transmitted through it. Furs, woollen, &c., for the same reason, afford good winter clothing; and therefore we should be cautious how we lay aside apparel of this description for linen, which very readily permits the heat of the body to escape. Count Rumford, in one of his essays, states that he is convinced of the utility of flannel shirts in all seasons; that he has worn them in all climates, in the warmest apartments, and during the most fatiguing exercise, without the least difficulty; that he was relieved by the use of flannel from a pain in his breast, which he had been frequently subjected to, and never since knew an hour's illness; and that nothing exceeds the agreeable sensations of this dress, when we are once accustomed to it. "I have been informed," observes Dr Willich, "by the manufacturers in the different foundries in Birmingham, as well as at the ironworks of Colebrook Dale and Ketley, that in the most intense heat they wear no other than flannel shirts, without which it would be impossible to prevent continual colds, and the most fatal diseases." We would earnestly recommend all persons, particularly those who are liable to any affections of the chest, to wear flannel waistcoats or shirts next the skin, in this country, both during winter and summer. Its effect, as a preservative of health, cannot be too highly appreciated.

It is worthy of remark, that among all nations, however rude, a distinction is made between the male and the female form of dress, to individualise as much as possible the different character and habits of the two sexes. As civilisation has advanced, the desire of displaying the human form to the best advantage has suggested an infinite variety of fashions in clothing, many of which have been extremely absurd, and eminently calculated to injure health. The ideas of what constitute grace and beauty fluctuate every season, and are oftentimes ludicrously contradictory; indeed, the decrees of fashion respecting dress are so capricious as to set all reasoning at defiance; therefore, without attempting to argue with the fickle goddess herself, we shall merely caution her votaries against adopting such habits as may be prejudicial to their health. Whatever form of dress may be selected, no part of the body should be subjected to restraint or compression. If the neck be surrounded by a tight collar, handkerchief, or cravat, the veins which return the blood from the head will be compressed, and apoplexy may consequently be induced. No part of the dress, therefore, either of male or female, should very tightly surround the neck; a precaution which should be more especially attended to by those who appear predisposed to a determination of blood to the head. For this reason, when any person is observed to fall down as in a fit, the bystanders should immediately loosen the cravat or handkerchief, or the strings of the bonnet, or whatever else may act as a ligature on the windpipe and neighbouring vessels. The next principle to be observed is that of allowing the chest free motion. Every time we take an inspiration, the ribs are raised, and during every expiration they are depressed; no impediment, therefore, ought to prevent this important series of alternate actions. It was not long ago usual for ladies to wear stays as tightly laced as possible, and even now the anxiety to display a small waist tempts many a young woman to lace her stays to a degree equally unfavourable to health, and to the gracefulness of her own appearance. A more injurious custom than this cannot be adopted. It is evident that the compression of the stays round the chest will prevent the ribs being raised during inspiration, and thereby impede both the action of the lungs and heart. At the same time, being girded tightest round the centre of the waist, the stays approaching towards the hip, will have the effect of pressing the liver out of its natural position, and prevent that action of the digestive organs which is necessary for the disposal of food. Besides these effects, which give rise to many distressing and lingering diseases, the organs thus compressed will be forced to exercise a pressure on the larger blood-vessels contained within the chest and abdomen, whereby the circulation of the blood may become seriously impeded. We have often seen ladies faint from this cause; and not long ago a case was recorded in the London journals of a young woman who died suddenly after taking her dinner, and no other reason was assigned for her death, by the medical men who examined her body, than that of excessive tight lacing, the consequences of which were, that the stomach, when distended by food, could not turn upon its own axis; the surrounding vessels, by its muscular efforts, were forcibly compressed, and the action of the heart fatally interrupted. After a full meal, even men who wear their waistcoat or waistband of the trousers very tight, find a difficulty of breathing, owing to the circumstance of the distended stomach being forced by the unyielding girdle to press up against the diaphragm, or muscle which divides the contents of the chest from that of the abdomen. Another evil incident to the practice of wearing tight-laced stays is that of curvature of the spine, which is thus occasioned: By the compression of the stays, the motion of the intermediate parts of the spine is greatly circumscribed, and the action of the muscles attached to the trunk impeded; and the necessary circulation of the blood through their substance being interrupted, their power and size diminish, so that the vertebral column loses its natural support, and readily inclines to one side. It is perfectly evident that nature has so constructed the human body that it is able, if left to its own powers, to support itself; and accordingly, the finest women in the world, the Circassians, renowned in the annals of beauty, never wear any stays. When Lady Montague was travelling in the East, on the occasion of her undressing for the bath, the Turkish ladies who were present, on discovering she wore stays, could not restrain their curiosity and amazement. "What!" said one of them, "do all the women in your country *wall* themselves in after this fashion?" After all, it should be considered that the natural proportions of the human body can alone present us with a display of real symmetry; for a preternaturally small waist is as much out of nature, and as far from being really beautiful, as a compressed and crippled Chinese foot; the only difference, indeed, is in favour of the latter, for the ladies of China, in compressing their feet into as small a compass as possible, run no risk of injuring any of the vital organs. If, notwithstanding all the warnings and injunctions of medical men, this part of the dress be still held to be indispensable, it ought to be made of as soft and pliable materials as possible; the principle to be observed being that of allowing every muscle of the human body its full play, by which alone the muscular vigour of the system can be maintained.

Besides the evils which may arise from the effects of tight lacing, a considerable degree of mischief may be occasioned by the shoulder-straps of the stays being unequal in length, and pressing more on one shoulder than on the other. So, also, when the frocks of children are made too low, by slipping off the shoulders they induce a twitching, particularly of the right shoulder, to recover the falling strap, which calls into action the muscles of the right side of the body more frequently than those of the left, whereby a curvature of the spine to that side may be occasioned. Narrow sleeves in gowns and coats, tight bracelets, or wristbands in shirts, should be also avoided; for, by compressing the blood-vessels, such will occasion swelling of the veins at the back of the hand, rigidity, and weakness of the arms; and it is not improbable that to this cause may be attributed the thin and ill-formed arms that may so often be observed. To this evil women are more liable than men, because their arms are less muscular, and the veins therefore more readily compressed. Hence, the fashion of tying the sleeves of ladies' gowns close to the elbow, deserves censure; because the circulation and free motion of the arm are thereby apt to be obstructed. In like manner, tight and unyielding garters may be productive of much mischief; for, on the same principle, by interrupting the circulation of the blood, they will occasion enlarged or varicose veins, swelling or dropsy of the legs and thighs, and even aneurism. "Many years ago," observes Dr Willich, "when, in compliance with early habits and prejudices, I was accustomed to the use of garters, I could not walk or ride half a dozen miles without fatigue, which inconvenience I found immediately removed on abandoning these improper ligaments." It would be much better for the stockings to be tied by a tape to the waistband, than to be retained in their place by tight garters; but if this article of dress must still be retained, the most elastic, as those made of caoutchouc, or Indian rubber, should be used, which should be flat and broad, and tied above rather than below the knee, because there will be there less chance of compressing the blood-vessels, which lie more superficially below than above the joint. There is no part of the body the temperature of which should be more carefully preserved than that of the feet; wherefore, persons accustomed to worsted stockings should not inconsiderately exchange them for silk, which, on the occasion of evening parties, is often thoughtlessly done, and gives rise to all the evils incident to taking cold. Indeed, no article of dress should be either exchanged suddenly or laid aside for one of lighter texture; because any part of the body accustomed to a certain protection of clothing becomes chilled if it be taken away.

This is particularly illustrated by the cravat worn by men; for while delicate young women with impunity expose their necks without any covering to the open air, the strongest man, by laying aside his neckcloth and exposing his neck, will run the risk of catching a sore throat. It is related by Percy, that a regiment of infantry, travelling in very stormy and hot weather, were for their greater ease permitted by the colonel to take off their cravats; having done which, they entered a mountain-pass exposed to the north-east wind. The next day ninety men were obliged to be sent to the hospital, the greater part of whom were affected with violent inflammation of the throat; and during the following days as many as three hundred of their comrades became not less indisposed. So, also, those who are accustomed to wear a bonnet or hat in the open air, ought never to go out with the head uncovered; in very hot weather, by so doing, they will expose themselves to a *coup de soleil*, or sun-stroke; in damp or chilly weather, to severe cold. In this, also, may be recognised the effects of habit: thus, when the Asiatics expose themselves to the rays of the sun, they protect their head by wearing a turban; but the negroes in the West Indies, though exposed to the rays of a tropical sun, will on no account wear a hat or any other covering on the head.

Impressed with the conviction that where there is the slightest restraint there can be no ease nor freedom of motion, our ideas concerning grace and beauty become naturally associated with that form or style of dress which suggests the most perfect sense of ease and freedom. Hence, Hogarth has shown that beauty consists of lines flowing in easy curves; wherefore, those parts of dress composed of such curves are always the most agreeable. Hence, a sash descending from one shoulder to the opposite hip, or a Grecian veil thrown back, and winding carelessly down behind, suggesting the feeling of perfect freedom, are always beautiful. But whatever may be the rules suggested in respect to dress for the preservation of health, or whatever may be the arrangement of its style most consonant with the real principles of art, the imperious dominion Fashion will overrule; for it unfortunately happens in this country that every person, no matter whether it be becoming to them or not, indiscriminately adopts whatever style of dress may be introduced. "Not only," says Goldsmith, "ladies of every shape and complexion, but of every age too, are possessed of this unaccountable fashion of dressing in the same manner. They seem to have no other standard for grace but the run of the town; so that gardens, ballrooms, playhouses, &c., are filled with ladies in *uniform*; and their whole appearance shows as little variety or taste as if their clothes were bespoke by the colonel of a marching regiment, or fancied by the same artist who dresses the three battalions of the guards."

BATHING.

It is to be regretted that the practice of bathing, as a means of promoting cleanliness, and as a preservative of health, is not by us so highly appreciated as it was by the ancients, the remains of whose baths are to this day considered to rank among the most splendid ruins of antiquity. Already it has been observed, that the human body is constantly undergoing a certain decay and renovation; the old particles that have become useless are ejected out of the system, and new ones deposited in their stead. It is now, then, to be observed, that the vessels of the skin are constantly engaged in separating the effete watery particles of the blood, which are thrown off in the shape of insensible or sensible perspiration. The quantity of perspiration which the whole body yields daily, is estimated at from two to four pounds; the latter is the maximum, and the quantity generally perspired in tropical climates. Accordingly, it will appear evident that ablution is necessary, first, to wash away the perspirable matter, which will otherwise dry upon the skin; second, to stimulate the vessels of the skin to perform their healthy functions, otherwise they will become languid, and the fluid they should separate from the blood will be thrown back upon the system, and destroy that balance between secretion and excretion which is necessary for the renovation and health of the animal economy. Besides this, the perspiration thus secreted by the vessels of the skin is of the most eminent service in equalising the heat of the animal body; for by the superabundant heat to which it may be subjected being carried off by the process of perspiration, the temperature of the body in the hottest climates and in the warmest weather is maintained at its usual standard. If, then, the perspiration be checked, or the vessels of the skin cease to perform their functions, the system will become heated, and a feverish state be induced. It is further to be observed, that the skin, being continuous with the membrane lining the lungs and alimentary canal, so intimate a connection is established between it and these organs, that the functions of the one can seldom or never be disturbed without the functions of the other sympathising with the disturbance. If the body, when its surface is bedewed with perspiration, be exposed to a current of air, or the contact of water much below its temperature, the vessels near its surface will immediately contract, and the blood rush from them into the vessels of the internal organs; and hence arises inflammation of the lungs, bowels, &c. consequent upon what is commonly termed "catching cold."

These preliminary physiological considerations will enable us to understand the principles upon which the practice of bathing should be adopted, and the precautions which ought to be observed. All our sensations of cold and heat are, it is to be remembered, only relative; whatever is below the temperature of the body gives it the impression of cold—whatever is above its temperature gives it the impression of heat. Water at a temperature of 60 degrees excites neither a sensation of heat nor cold; at a temperature of from 32 to 65 degrees, it constitutes what is called a *cold* bath; from 65 to 85 degrees, a *tepid* bath; from 85 to 97, a *warm* bath; and from 97 as high as it can be borne above that degree, a *hot* bath; besides which forms of the bath there is also the vapour bath, in which the body is exposed to the steam of water. The best form of taking the cold bath, where it can be commanded, is that of sea-bathing; and the difference between this and fresh-water bathing consists in this, that sea-water holds in solution a greater quantity of saline matter, and has a more stimulating effect, therefore, on the vessels of the skin. For this reason, as the evaporation of the sea-water from the surface of the body which has been immersed in it is slower than that of fresh water under the same circumstances, persons are less likely to take cold from bathing in salt than from bathing in fresh water. The best season of the year for sea-bathing is after midsummer, because the earth, having during the summer months imbibed the heat of the solar rays, then imparts to the surrounding waters a genial warmth. The average temperature of the sea on the coasts of this country during the autumn months, has been stated by Dr J. Hunter to be about 63 degrees, although he has observed it occasionally to rise higher. Taking, therefore, the heat of the body at 90 degrees, it would appear that in sea-bathing at this season it plunges itself into a medium possessing a temperature of rather less than 30 degrees below its own heat. The effect of this sudden transition is to constrict the vessels of the skin, whereby the blood is driven into the larger and deeper blood-vessels, the elasticity of whose coats enables them to accommodate themselves to this change in the balance of circulation. Soon after this, however, *reaction* succeeds; that is, the heart and arteries overcome the additional burthen imposed on them, and propel the blood again into the superficial or capillary blood-vessels, and this rush of blood to the surface gives rise to that genial glow which is experienced after bathing. When the body first plunges into the sea, the difference of temperature excites a sudden impression on the nervous system, and the pressure of the surrounding fluid on the abdomen and chest excites a certain degree of breathlessness, which sensations combined constitute what is called a *shock*. The state of the body at the time of bathing is a matter of considerable importance. The general rule is, not to go into the water when the body is overheated, nor yet when it is reduced below its natural temperature. Many persons, after taking a brisk walk down to the sea-side, lounge about until they feel cool, when they imagine that they may bathe with impunity. This is an error. In such a state the vital energies are enfeebled and depressed, and after the cold immersion the system has not sufficient strength left to establish the reaction above explained. After such imprudence, the individual on leaving the water feels himself chilled. In fact, the blood does not return with its wonted stimulus to the surface of the body.

In consequence of the blood being driven, on immersion into cold water, from the surface to the internal organs, it is obvious, that, if an individual immerse himself in water up to the neck, leaving the head alone unbathed, there will be danger of the blood being driven to the brain, in which case throbbing of the temples, dizziness, and symptoms of apoplexy, not unfrequently ensue. Dr Cullen, in his lectures, used to relate the case of a lady, who after bathing was always affected with violent headache, drowsiness, and other symptoms approaching to apoplexy, although in other respects the use of the cold bath was of material service to her general health. On inquiry, he found that she carefully abstained from wetting her head. Next time she tried the bath, the doctor advised her to submerge her head as well as the rest of her body, which directions were followed, and from that time she continued to bathe not only with impunity, but with advantage. The use of the bathing-cap, commonly used by ladies to protect their hair from the effects of the sea-water, is for the same reason objectionable. Many persons accustomed thus to cover the head during bathing, are liable afterwards to severe headaches. These are occasioned by the determination of blood to the head, and will in general be completely averted by allowing the cold water to come in immediate contact with the head. In the reasons now assigned, the sooner any person in bathing plunges the head into the water, the better; although, perhaps, the custom of plunging in head foremost is objectionable, because it may determine a sudden rush of blood to the brain. It is also to be observed, that it is better to remain during a short time immersed in the water, than to take repeated plunges; in illustration of which fact, Dr Currie relates an interesting narrative of the effects of a shipwreck on some mariners who were cast away on a sand-bank that lies at the mouth of the river Mersey. They remained twenty-three hours clinging to the wreck, in the month of December. The part of the wreck to which they adhered lying in a sloping direction, those of the crew who were placed on the higher part of it were generally out of the sea, but frequently overwhelmed by the surge, and exposed to a piercing wind, while the others were almost constantly immersed in the water. In the former situation were placed the two masters, stout men in the prime of life, and accustomed to hardships. They both died during the night, while the remainder of the crew, among whom was a negro, were all preserved except one, and ultimately recovered. It is not necessary to remain longer in the water than two or three minutes, and during this time the body should be kept in constant motion. For the delicate, bathing-dresses are certainly useful. They protect the body to a certain extent from the danger of taking cold, but should be made of so open a texture as to admit the water in every direction. Immediately after bathing, the moisture should be wiped off the body; but rubbing the surface of the body perfectly dry is less necessary than resuming the clothes usually worn as speedily as possible. The sooner in particular that the chest is covered, the better. After bathing, it is desirable to take a moderate degree of exercise; but care should be taken not to prolong the walk or ride so as to produce fatigue or lassitude. If a sense of coldness or shivering occur, a slight stimulant should be taken—a little spirits or wine and water—with the view of establishing reaction. If this fail, the individual should be placed in a warm bed, and frictions, and bottles or bladders of hot water, applied to the surface of the body.

Cold-bathing is by no means a safe practice in all cases; indeed, no invalid should have recourse to it unless under professional advice. It has been shown that when the body is plunged into cold water, the blood leaves its surface, and rushes to the vessels of the internal organs. Accordingly, it is evident that if the lungs be delicate, or if any structural disease be lurking in that organ, it will not be able to sustain the accumulation of blood which may under such circumstances be driven to it. So, also, if the heart be diseased, it may be completely overcome by the shock of the blood thrown back upon it, and death immediately ensue. In like manner, persons who appear predisposed to apoplexy should be cautious how they indulge in cold-bathing. However, albeit that in such cases cold-bathing may be inadmissible, there is no doubt that, in early life in particular, it tends to invigorate very considerably the system. All young children in good health should be bathed every morning in cold water, and even those persons who are not very robust will derive considerable advantage from sponging themselves daily with cold vinegar and water, or with salt water.

For invalids, or persons of a weakly constitution, the tepid or the warm bath will be found by far the safest and most salutary form of bathing; and the period of immersion should vary, according to circumstances, from fifteen minutes to half an hour, during which time the water should never be allowed to become in the slightest degree chilled. The effect of immersion in cold water is, as we have explained, to produce a reaction in the circulation, by which the extreme vessels at the surface of the body having become constricted and partially emptied, are again dilated and filled by the return of the blood from the heart and arteries. The effect of warm-bathing, however, assumes a different character; for, in this case, by the application of the external warmth, the extreme vessels are relaxed, and more readily admit the blood which the enfeebled action of the heart and arteries could scarcely propel into them. Thus, the whole cutaneous system becomes filled with blood, while the interior organs are relieved, and the heart finding less difficulty in emptying its contents, becomes, as it were, encouraged to assume a fuller and stronger series of contractions. Hence, in persons of a weakly habit of body, the effect of the tepid or warm bath is to strengthen instead of to weaken the constitution—a fact attested by many high medical authorities, and recently by Dr Andrew Combe, who states that, in his own instance in particular, he is conscious of having derived much advantage from its regular employment, especially in the colder months of the year, during which he uniformly found himself most effectually strengthened against the impression of cold by repeating it at shorter intervals than usual. When the body is in a state of exhaustion from excessive fatigue, there is nothing which (on the principle just explained, of its facilitating the circulation of the blood to the extremities) is so refreshing and invigorating as a warm bath; and hence Homer describes Ulysses, among others, as refreshing himself with a warm bath, on his return home after all his fatigues and dangers.

The hot bath and the vapour bath are used rather as restoratives than as preservatives of health. Their effect is to soften the textures, increase the sensibility of the nervous system, promote absorption, restore the tone of the mucous membranes, and in many chronic diseases, especially in rheumatism, gout, scrofula, and cutaneous eruptions, they are found to be extremely beneficial.

SLEEP.

When the noise, bustle, and wonted occupations of the day have terminated, the stimulus of light is withdrawn, and nature invites all animals to repose. To the weary it brings rest; to the distressed temporary relief, and is the "wide blessing" which ministers to the comfort of all mankind. After having been engaged in daily occupations for fourteen or sixteen hours, a general feeling of fatigue and weakness is induced; the motions of the body become difficult, the senses confused, the power of volition or *will* suspended, and the rest of the mental faculties becoming more and more confused, sink into a state of unconsciousness. The sense of sight first ceases to act by the closing of the eyelids; then the senses of taste and smell become dormant; and then those of hearing and touch. The muscles, also, dispose themselves with a certain reference to ease of position, those of the limbs having ceased to act before those that support the head, and those that support the head before those of the trunk. In proportion as these phenomena proceed, the respiration becomes slower and more deep, the circulation diminishes, the blood proceeds in great quantity towards the head, and all the functions of the internal organs become retarded. In this state, shut out, as it were, from the external world, the mind still retains its wonted activity, deprived, however, of the faculties of judgment and recollection; in consequence of which, it does not perceive the monstrous incongruities of the imagery which sweeps before it, and takes no cognisance whatever of the time which elapses; wherefore, a dream, the pageantry of which has lasted during the whole night, will often appear, on our being awakened, to have occurred within a few minutes; and a complete dream, embracing a variety of successive incidents, which appear to be spread over a vast extent of time, will often pass through the mind in a few seconds.

It may be laid down as an axiom, that, the more uninterrupted sleep is, the more refreshing and salutary will be its effects; for, during this period, the body undoubtedly acquires an accession of nervous energy, which restlessness, however induced, must disturb; and therefore the state of the body before going to sleep, the kind of bed, the manner of clothing, require especial attention. As the functions of the body are performed more slowly during our sleeping than our waking hours, it is evident that a full meal or supper, taken immediately before going to bed, will impose a load on the stomach which it will be unable to digest, and, from the very great sympathy existing between the stomach and brain, will occasion frightful dreams. When these occur in their most aggravated form, the sleeper lies upon his back, and the heart pressing down while pulsating on the lungs, gives rise to a sense of intolerable oppression on the chest, which seems to bear down upon the whole body, so that in this painful state not a muscle will obey the impulse of the will, and every effort to move appears to be altogether unavailing. This constitutes *incubus* or *nightmare*; and it may be observed, that, as acidity on the stomach or indigestion gives rise to such dreams, so all dreams of this disturbed character are indications of indigestion; for which reason the great physiologist Haller considered dreaming to be a symptom of disease. It is certain that the dreams of healthy persons are the lightest, and most evanescent.

The kind of bed on which we repose requires attention. Some are advocates for soft, others for hard beds; hence some accustom themselves to feather-beds, others to mattresses. The only difference between a soft and a hard bed is this—that the weight of the body in a soft bed presses on a larger surface than on a hard bed, and thereby a greater degree of comfort is enjoyed. Parents on this subject err in fancying that a hard bed contributes to harden the constitution of their children; for which reason they lay them down on mattresses, or beds with boarded bottoms. This is a popular prejudice. The beds for young children cannot be too soft, provided the child does not sink into the bed in such a manner as that the surrounding parts of the bed bend over and cover the body. The too great hardness of beds, says Dr Darwin, frequently proves injurious to the shape of infants, by occasioning them to rest on too few parts at a time; it also occasions their sleep to be uneasy and unrefreshing. The universal analogy derived from other animals evinces the truth of this doctrine, both in respect to the softness and due degree of warmth of their beds. Birds line the nests of their young with feathers; the eider duck and the rabbit pluck the down from their own breasts to increase the softness of the beds of their tender offspring, and brood over them with their wings, or clasp them to their bosoms for the sake of warmth. For this reason, it is better that weak children should sleep with a bedfellow than alone; for, in this case, if any part of the body becomes cold, the child instinctively places that part in contact with the warmer body of his companion. So, also, it is better for a new-born infant to sleep with its mother in winter, or with its nurse, than in a solitary crib by the bedside. When in bed, the head should be always higher than the feet, and those accustomed to palpitation of the heart should lie with their heads very high. The clothes, which should never consist of more than a chemise or shirt, should be made of cotton or linen, and in such a manner as not to impose the slightest restraint on any part of the body. Sleeping with flannel drawers on, a flannel waistcoat, or petticoat, or with woollen stockings on, is decidedly an uncleanly and unhealthy habit. It is also highly improper to sleep in a bed overloaded with clothes; the body is thereby heated, and feverishness and restlessness induced. Many persons find themselves uncomfortable and restless during the night from this cause; and after throwing off a blanket or two, according to the number used, feel relieved and disposed to sleep. Accordingly, persons who complain of sleeplessness should look to the quantity of their bed-clothing; for the unnecessary addition of a single blanket may be the sole cause of the annoyance. It is also imprudent to lie with the head entirely within the bed-clothes; for, in this case, the same air which has been already breathed, must be again and again inhaled. For the same reason, the curtains should not be drawn closely round the bed. Washing the face and hands, and brushing the teeth before going to bed, will be found to contribute materially to comfort. The window-shutters ought never to be entirely closed, nor yet quite open, but so put together as to permit the full light of day to make only a sort of *glooming* or dawny light, which will not irritate the sight. In summer the windows should be a little raised; and indeed every bedroom should be kept well ventilated. Whatever be the time chosen for sleep, it is evident that no person can with impunity convert day into night. Eight o'clock for children, and ten for adults, may be recommended as good hours for retiring to rest. It is well known that children require more sleep than adults, tall people than short; and more sleep is requisite in winter than in summer. The average duration of sleep which may be recommended for adults is *eight* hours; but much depends upon habit, and many persons require only six. It is scarcely necessary to observe, that, on rising in the morning, the strictest attention should be paid to washing the body. The bedroom windows should then be immediately thrown open; and the clothes of the bed turned down, in order that the exhalations of the body during sleep may be dissipated. Instead of this, if the bed be made immediately after we have risen, these exhalations are again folded up with the clothes—a practice which is not consonant either with cleanliness or health. The bed-clothes, therefore, should be turned down, and the windows allowed to remain open some time before the bed is made.

We have now explained the principal rules which should be attended to for the preservation of health, and shall conclude by observing, that every individual has his health and happiness more immediately under his own control than is generally supposed, and is in some measure responsible for it to himself, society, and his Creator.*

* In writing the present number of the Popular Information, the author, among other works referred to and quoted, has been indebted to several excellent works, the titles of which are subjoined, that they may be consulted by those who wish to pursue farther a subject of such vast importance and extent as that of the means of preserving health:—Willich's Lectures on Diet and Regimen—James Johnston's British Hygiene—Dr Paris on Diet—Londe Nouveaux Elemens d'Hygiene—Darwin on Female Education—Ward on Distortions of the Spine, Chest, &c.—Moffet on the preparation of Foods—Thackrah on Diet—Tissot on the Disorders of People of Fashion—Sir John Sinclair's Code of Health—Dr Andrew Combe's Principles of Physiology—Henderson on Wines—Walker's Manly Exercises.

No. 43. PRICE $1\frac{1}{2}d$.

OPTICS.

THE term Optics is derived from a Greek word which signifies *seeing*, and applies to that branch of natural philosophy which treats of the phenomena of light and vision. As to the nature of that attenuated substance by whose instrumentality objects become visible, philosophers differ in opinion; there are two theories by which the phenomena of vision are accounted for. The first is, that light is a material substance, consisting of very minute particles, which are thrown off from luminous bodies in all directions and with immense velocity; the second, which is denominated the undulatory theory, is, that an exceedingly thin and elastic medium, called ether, fills all space and penetrates all material bodies. The particles of this ether are like air, of which we formerly treated, susceptible of being thrown into a state of vibration, so that waves are propagated in all directions; and when these undulations reach the retina of the eye, they excite the sensation of light. By this hypothesis, therefore, light is, like sound, rather a state of matter than matter itself. But independent of all speculations as to the abstract nature of light, it possesses certain general properties, which have been discovered by experiment and observation; and to these it is our purpose to devote this paper.

All visible bodies may be divided into two classes, self-luminous and non-luminous. Under the first head are comprised all those bodies which possess in themselves the property of exciting the sensation of light or vision, such as the heavenly luminaries, terrestrial flames of all kinds, phosphorescent bodies, and those substances which shine by being heated or by friction. Under the second class we recognise such bodies as have not the power of throwing off particles of light, or exciting undulations of themselves, but which possess the property of reflecting the light which is cast upon them by self-luminous bodies. A non-luminous body may receive light from another non-luminous body, and throw it upon a third so as to illuminate it; but, in every case, the light which renders objects visible must proceed from some self-luminous body. When a candle is placed in a darkened room, it renders objects visible by discharging particles of light upon them, which they throw back or reflect in directions which we shall afterwards describe.

Light proceeds from every visible point of an illuminated body, and in all directions in which the point is visible. A piece of paper held before a candle, or in the sun, will be found illuminated over the whole of its surface, no part being left destitute of light. This will be found to be the case in whatever position the paper is held, provided the rays of light are allowed to fall upon it.

All bodies throw off light of the same colour as themselves. Although the light of the sun is white, it is not simple, but compounded of seven different rays, as we shall see hereafter. This white substance falling upon objects of different colours, is decomposed by them—the green bodies reflect green light, the red ones red light, the yellow ones yellow light, and so on; thus giving rise to that beautiful variety of tints which the face of creation exhibits. In whatever situation we place ourselves, if the light thrown back by bodies is not obstructed, they are shown to be only of that colour which they reflect.

Light consists of separate parts or atoms, called *rays*, which are independent of each other. These are projected from the luminous body in straight lines, which is proved when the sun darts his beams through a cloud of smoke or dust. There the progress of light in straight lines may be distinctly seen. It is also proved by the fact that we cannot perceive objects through a bent tube; and it may be inferred from the form of the shadows of bodies. If light be admitted into a dark room by a small hole in the shutter, it illuminates a spot in the room exactly opposite the shutter. If a small portion of the admitted light be stopped, or if the whole of it except a very minute portion be arrested in its straightforward course, that which is allowed to pass is not in the slightest degree affected by its separation from the main column of light, proving that the rays are independent of each other. The smallest portion which we either stop or allow to pass is called a *ray of light*.

Light travels with extraordinary velocity. Astronomers have proved, by observing the eclipses of Jupiter's satellites when that planet is nearest and when it is farthest from the earth, that light moves from the sun to the earth in seven and a half minutes. It proceeds through a space equal to the circumference of our globe in the eighth part of a second—a flight which the swiftest winged bird could not perform in less than three weeks.

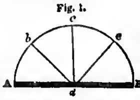
Of the light which falls upon a body, part is thrown back or reflected, and part is absorbed by the body or is transmitted through it. Those bodies, such as glass and water, which allow light to pass through them, are called transparent or pellucid bodies, and sometimes mediums. Bodies, such as a plate of silver, brass, &c., which throw back the light in great quantities, are called reflectors. Light is reflected according to certain fixed laws, the consideration of which forms a branch of the subject called *Catoptrics*. Light is also transmitted according to certain immutable laws, and this part of optics is denominated *Dioptrics*.

CATOPTRICS.

The term Catoptrics is derived from two Greek words, one of which signifies *from* or *against*, and the other to *see*, and denotes that branch of the science which treats of the reflection of light from plane or spherical surfaces, and the phenomena of the formation of images.

A *speculum* or *mirror* is any instrument of a regular form employed for the purpose of reflecting light, or forming images of objects. Mirrors usually consist of metal or glass, having a highly polished surface. Those which are constructed of glass are coated upon the back with quicksilver, for the purpose of reflecting more light; were this not the case, so little light would be thrown back, on account of glass transmitting it to a considerable extent, that a very indistinct image would be formed. The word speculum is generally confined to metallic mirrors, and they are either plane, concave, or convex. The plane ones are perfectly flat like a looking-glass; and a common watchglass conveys a very good idea of the other two species of mirrors. Coat the hollow surface with mercury, and place it before a candle, it forms a convex mirror; coat it upon the other side and employ it as before, it becomes a concave mirror. In the course of this paper, when mirrors are mentioned, those made of polished metal are meant.

Fig. 1.



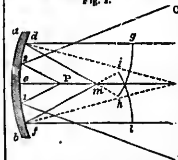
If a plane mirror A B be placed exactly in a horizontal position, and if a ray of light c darting downwards in an exactly perpendicular direction, and striking it at d, the ray will be thrown back in the exact path which it traversed in its descent, without any deviation. If, however, it descends in an oblique manner, as is shown at e, a point midway between the perpendicular c and the horizontal A B, it will not return, as in the former instance, to the place whence it came, but will be reflected from the mirror at an angle exactly equal to that at which it descended upon it. The ray $e\,d$ is called the *incident ray*, and the ray $d\,b$ is termed the reflected ray. The figure $e\,d\,c$ is called the *angle of incidence*, and $d\,b\,c$ the *angle of reflection*; and they are both, as we have observed, exactly equal to each other. This being the fact, we have afforded us a method of universal application, by which, when once the angle of incidence, or that at which the ray falls upon a body, is found, that of reflection is easily obtained. This holds true whatever shape the mirror may be of, plane, concave, or convex, and whatever number of rays may fall upon it.

Parallel rays, when reflected from plane surfaces, retain their parallelism after reflection. When *diverging* or *converging* rays fall upon a plane mirror, they retain their degree of divergency or convergency after they have been reflected. This fact is so obvious, that any farther illustration of it by diagrams is unnecessary.

REFLECTION OF RAYS FROM CONCAVE AND CONVEX MIRRORS.

When parallel rays fall upon a convex mirror, they will be made to converge or meet at a certain point called a focus. Thus, in the annexed figure, the parallel rays $g\,c\,l$ falling upon the concave mirror $a\,b$, are thrown back from its surface in angles of reflection equal to the angle of incidence, and meet at a common point m, which in the present instance is at exactly half the distance of the surface of the mirror from c, the centre of its concavity.

Fig. 2.



Thus, let c be the centre of concavity of the mirror $a\,b$, and let the parallel rays fall upon it at the points $d\,e\,f$. Draw the lines $c\,i\,d$, $c\,m\,e$, $c\,h\,f$, from the centre c to these points, these lines will be perpendicular to the face of the mirror, because they proceed like so many radii from its centre. Make the angle $c\,d\,h$ equal to the angle $d\,g\,c$, and draw the line $d\,m\,h$, which will be the direction of the ray g after it is reflected from the points of the mirror; so that the angle of incidence $g\,d\,i$ is equal to the angle of reflection $h\,d\,i$, the rays making equal angles with the perpendicular $c\,i\,d$ on its opposite sides. Draw also the perpendicular $c\,h\,f$ to the point f, where the ray $l\,f$ touches the mirror; and having made the angle $c\,f\,i$ equal to the angle $c\,f\,l$, draw the line $f\,m\,i$, which will be the course of the ray $f\,l$ after it is reflected by the mirror. The ray $c\,m\,e$ passes through the centre of concavity of the mirror, and falls upon it at e, the perpendicular to it, and is therefore reflected back from it in the same line $e\,m\,c$. All these reflected rays meet in the point m; and in that point the image of the body which emits the parallel rays $g\,c\,l$ will be formed, which point is distant from the mirror equal to half the radius $e\,m\,c$ of its concavity.

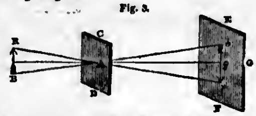
In all kinds of mirrors, of whatever substance they may be formed, the focal point is exactly equal to one-half of the radius of the mirror's concavity. The *focus* or *fire-place*, where the rays meet at a point, is so called on account of these collected rays possessing the power of burning any combustible body placed there. This property, however, of inflaming a body which the rays of light possess, is to be attributed to the presence of heat, which follows the same laws as light with regard to reflection. By means of reflecting mirrors, it is easy to produce an intense degree of heat. With respect to the reflection of diverging rays, or those rays which, proceeding from one point, such as c, and striking the concave mirror at $d\,e\,f$, &c. they will be reflected to a point nearer that of the mirror's concavity than they were concentrated to in the case of parallel rays. Thus, in the case of the reflection of diverging rays, the focal distance $c\,m$ of the mirror is greater than its distance from the parallel rays. On the other hand, converging rays falling on a concave surface, converge more, that is, they will meet at a point farther from the centre of the cavity of the mirror, than that to which the parallel rays $g\,c\,l$ were converged. Thus, let N and O be two converging rays which are severally projected upon a concave mirror at 1 and 2, their angles of incidence are evidently larger than those of the parallel rays; hence their angles of reflection will be greater. They therefore necessarily converge after their reflection, and meet at a point F, which is, as we have said, farther from the centre of concavity of the mirror than in any of the former instances.

If the reflecting mirror *a b* be reversed, and the convex side of it presented to the rays *g e l*, phenomena of a different kind will occur, but resulting from or depending upon the same laws. Instead of the rays being reflected inwards, and meeting at a focal point before the mirror, they will diverge as if they came from a point from behind the mirror, which is called their *virtual* focus, and which is similar to the distance *e m* in the former diagram. It is called a virtual focus, not because the rays meet there, but because the rays which pass from the surface of the mirror, if continued backwards, would all meet there, and seem to have diverged from that point. In reference to the reflection of diverging rays from convex mirrors, the virtual focal distance behind the reflecting surface will be less than for parallel rays, and with respect to converging rays it will be greater.

FORMATION OF IMAGES BY MIRRORS.

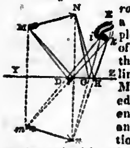
The image of an object is a likeness of it, formed generally by mirrors and lenses upon various grounds, and reflected accurately in shape and colour upon the eye which is fitted to perceive it. Images can also be formed upon a piece of paper, by placing a small hole between the object and the paper, and excluding all extraneous light. This will be best understood by the following diagram:—

Fig. 3.



Let C D be a window-shutter having a small aperture A, and E F a piece of paper placed in a dark chamber. Then, if an illuminated object, R G B, is placed on the outside of the shutter, we shall observe an inverted image of this object painted on the paper at *r g b*. In order to understand how this takes place, let us suppose the object R G B to have three distinct colours—*red* at R, *green* at G, and *blue* at B; then it is plain that the *red* light from R will pass in straight lines through the aperture A, and fall upon the paper E F at *r*. In like manner, the *green* from G, and the *blue* light from B, will severally fall upon the paper at *g* and *b*, and an inverted image *r g b* of the object R G B will be painted upon it. Every coloured point in the object R G B having a coloured point corresponding to it, and opposite to it on the paper E F, the image *b g r* will be an accurate picture of the object R G B, provided the aperture A is very small. If it be increased in size, indistinctness in the image will ensue; for, with a large aperture, two adjacent points of the object will throw their light on the same point of the paper, and thus create confusion in the picture. It is perfectly clear, that if the paper E F be moved to a farther distance from the hole A, the size of the image will be increased; and if it be brought nearer to it, it will be diminished. The law is, that when A *g* is equal to A G, the image will be equal to the object; when the distance between the two is less, the image will likewise be less; and when it is greater, it will be greater. As the aperture A is small, and admits only a small number of rays, and as to enlarge it would render the image indistinct, only a faint picture is formed. This is remedied, however, by means of mirrors and lenses.

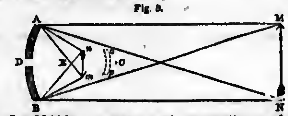
Fig. 4.



Images formed by Plane Mirrors.—Let Y Z be the surface of a plane mirror, M N any object placed in front of it, and E the eye of an observer placed at *i k*. Of the rays which shoot in a rectilinear direction from the points M N of the object, and are reflected from the mirror, those which enter the eye are few in number, and must be reflected from portions D F and G H of the mirror, so situated with reference to the eye and the object that the angles of incidence of the rays which fall on these portions must be equal to the angles of reflection of those which enter the eye between *i* and *k*. For instance, the ray M D is reflected in the direction D *i*, and the ray M F in the direction F *k*. In the same manner, the rays N G and N H will be reflected severally in the directions G *i* and H *k*. If the rays *i* D and *k* F be continued backwards, they will meet at a point M, whence they will appear to have come to the eye. For the same reason, the rays G *i* and H *k*, if continued in the same manner, will seem to meet at the point *n* as their focus, and *m n* will be the virtual image of the object M N. It is called virtual, because it is not formed by the actual union of rays in a focus, and cannot be received upon paper. The virtual image *m n* is supposed to be as far behind the mirror as the object M N is before it; consequently, if we join *m n*, it will be of the same dimensions as M N, and have the same position behind the mirror as the object has before it. If we join the points M *m* and N *n*, the lines M *m* and N *n* will be perpendicular to the mirror Y Z, and consequently parallel. In every position of the eye, the image is seen in the same spot and of the same size at equal distances from the eye. If the object M N is an individual surveying himself in the mirror, he will see his perfect image as if at *m n*; and thus we have an explanation of the principles and properties of the *looking-glass*.

Reflection of Images by Concave Mirrors.—If we bend the plane mirror Y Z in the last cut into a figure forming the segment of a circle, we will form a concave and a convex mirror.

Fig. 5.



Let M N be an object placed at some distance from a concave mirror A B, whose centre is C, and whose principal focus is E. The rays from M fall diverging upon the mirror, and are reflected to a focus at *m* (a little without the principal focus), where they form an image of the extremity M. In the same way, a representation of the extremity N will be painted at *n*, so that a complete but inverted image of N M will thus be formed; and it is evident that it will be very bright, though small, because a great number of rays are concentrated, and concur in forming each point of the image. The size of the image thus formed corresponds to the distance of the object from the mirror. If the latter be large, and the former very bright, a series of beautiful experiments may be made by varying the distance of the object, and observing the variations in the size and place of the image. As the object recedes from the mirror, the picture approaches E, and gradually decreases in size. It coincides with E when M and N are infinitely distant. If we consider *m n* as a small object, a magnified representation of it will be formed at M N, which, when viewed by a convex lens, such as will be afterwards described, constitutes a *reflecting microscope*. If we place a small concave mirror *o p* behind it, so as to enlarge the image, and reflect them through an opening D in the large mirror A B, then this second image may be magnified still more by means of a lens, in which case it constitutes a Gregorian reflecting telescope, so called from the inventor James Gregory. If instead of a concave we employ a convex mirror *o p*, and place it between E and *n m*, so as to reflect the rays which would otherwise have met at *n m*, then an enlarged image would in this case also be painted at D, where it can be magnified as in the former instance. This combination constitutes the Cassegrainian *reflecting telescope*, so called from its inventor M. Cassegrain.

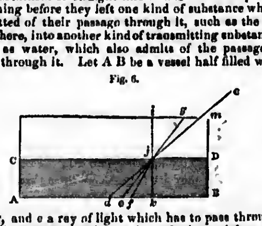
An image formed by a concave mirror is always highly magnified when the object is near the focus, but as it passes that point and approaches the mirror, the image gradually decreases in size, and becomes equal to the object when the latter touches the mirror. Indeed, when the image is placed between the principal focus and the mirror, the image is a virtual one formed behind the mirror. In convex mirrors, on the other hand, the image is always a virtual one formed behind the mirror. To perceive the truth of this, we have only to suppose the large mirror A B turned round, and *m n* placed at the back of it, or facing the concavity as at present, in which situation it will form the virtual image of the object M N at the virtual foci. In every position of the eye before the mirror, the image will be seen in the same spot *m n*, and it is always *erect*, and less than the object. The size of the image is to the size of the object as the distance of the image from the centre of the mirror is to the distance of the object. In approaching the mirror, the image and object approach to equality; and when they touch it, they are both of the same size.

DIOPTRICS.

Dioptrics is a term compounded of two Greek words, one of which signifies *through* and the other *to see*, and denotes that branch of optics which treats of the transmission of the rays of light through transparent bodies, the phenomena attendant thereupon, and the laws by which they are produced.

There is one general truth which the reader must bear in recollection: it is, that the rays of light, in passing from one medium into another, are bent from the rectilinear or straight-line course which they were pursuing before they left one kind of substance which admitted of their passage through it, such as the atmosphere, into another kind of transmitting substance, such as water, which also admits of the passage of light through it. Let A B be a vessel half filled with

Fig. 6.



water, and *c* a ray of light which has to pass through it. The direction of the ray is perfectly straight until it enters the water at *j*, when, instead of proceeding in a straight line to *d*, it is bent from its course and compelled to strike the bottom of the vessel at *e*. If oil instead of water had been used, the ray would have been still more bent, and have reached the bottom at *f*. A great variety of substances possess this power of bending the course of a ray of light, and it is called *refraction*, a term derived from a Latin word signifying *breaking back*, because, as in the above instance, the ray of light *c* is broken or refracted at *j*. The power by which bodies produce this effect is called their *refractive power*, and bodies that produce it in different degrees are said to possess different refractive powers.

Let the vessel A B be now emptied, and let a bright object, such as a sixpence, be cemented to the bottom of it at *d*. If the observer places himself a few feet from the vessel, he will find a position where he will see the sixpence through the hole. If water be now poured into the vessel up to C D, the observer will no longer see the sixpence; but if another sixpence be placed at *d*, and moved towards *e*, it will become visible when it reaches *e*. Now, as the ray from the sixpence at *e* reaches the eye, it must come out of the water at a point *j*, in the surface, found by drawing a straight line *j c* through the eye and the hole; and, consequently, *e j* must be the direction of the ray, which makes the sixpence visible, before its refraction at *j*. But if this ray move onward without being refracted at *j*, its path would have been *e g*; whereas, in consequence of the refraction, its path is *j c*. Hence it follows, that when a ray of light passing through any dense medium, such as water, &c., in a direction oblique or slanting to its surface, quits the medium at any point, and enters a rarer medium, such as air, it is refracted from the line perpendicular to the surface at the point where it quits it.

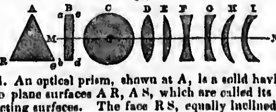
The degree of bending or refraction of light in traversing a transparent surface is ascertained by comparing the obliquity of its approach to the surface with the obliquity of its course after its departure. The angle which it forms with the perpendicular line *i k* determines the amount of refraction. The angle *i j c* is called *the angle of incidence*, and the angle *k j e*, which the ray *c* bent at *j* makes with the same perpendicular, is called the *angle of refraction*. When the ray comes out of the water, and is refracted in the manner described, these terms are just reversed. The line *i m* is called the sine of the angle of incidence, and the other line *e k* is called the sine of the angle of refraction. In every case these sines have a constant ratio to each other, and the number which expresses this ratio is called the *index of refraction*. The line *i m* which measures the obliquity before refraction, is invariably longer than *e k*, measuring it after refraction, by nearly one-third of the latter; and the refractive power of water is therefore signified by the index $1\frac{1}{3}$ nearly, or 1.336. In the same manner the greater refractive power of common glass has the index $1\frac{1}{2}$, that of the diamond the index $2\frac{1}{2}$, and so on. As we have observed, whatever relation holds between the obliquity of a ray and the refraction in any one case, the same holds for all cases. If, for instance, where the obliquity, as measured by its sine, is 40, and the refraction is 20, then, in the same substance, an obliquity of 10 will occasion a refraction of 5, and an obliquity of 4 will occasion a refraction of 2, and so on, the sines of incidence and refraction having always a fixed and invariable relation to each other. There is one fact to be observed, that a ray descending perpendicularly into any medium, or quitting it perpendicularly, suffers no refraction; it is only when it descends or rises in an oblique direction that this takes place.

With regard to the refractive power of transparent substances or media, the general rule, with certain limitations, is, that it is in proportion to the densities of the bodies. It increases, for instance, from the most perfect vacuum which can be formed, through air, fresh water, salt water, glass, and so on. But those substances which contain the most inflammable matter, have the greatest refractive power. It was from the great refractive powers of the diamond and water, that Newton, with admirable sagacity, predicted that they contained inflammable principles. This fact future discoveries in chemistry verified. Tables of the refractive powers of substances most interesting in optics will be found in Brewster's Optics. From these it would appear that substances which contain fluoric acid (See CHEMISTRY) have the least refractive power, as inflammable ones have the greatest. With regard to the cause of refraction, no good explanation has been given, but it may facilitate our conception of the phenomena, to consider it as depending upon the attractive power which the medium or body possesses over the light which passes through it.

REFRACTION OF LIGHT BY PRISMS AND LENSES.

The following figure represents the shape of the various optical instruments, where the effect is produced by refraction. They are most commonly made of glass. Sir David Brewster thus describes them:—

Fig. 7.



1. An optical prism, shown at A, is a solid having two plane surfaces A R, A S, which are called its refracting surfaces. The face R S, equally inclined to A R and A S, is called the base of the prism.

2. A plane glass, shown at B, is a plate of glass with two plane surfaces, *a b*, *c d*, parallel to each other.

3. A spherical lens, shown at C, is a sphere, all the points in its surface being equally distant from the centre O.

4. A double convex lens, shewn at D, is a solid formed by two convex spherical surfaces, having their centres on opposite sides of the lens. When the radii of its two surfaces are equal, it is said to be equally convex; and when the radii are unequal, it is said to be an unequally convex lens.

5. A plano-convex lens, shown at E, is a lens having one of its surfaces convex and the other plane.

6. A double concave lens, shown at F, is a solid bounded by two concave spherical surfaces, and may be equally or unequally concave.

7. A plano-concave lens, represented at G, is a lens, one of whose surfaces is concave and the other plane.

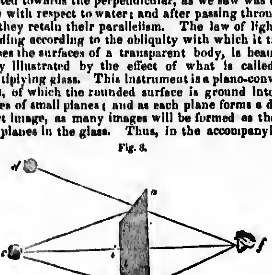
8. A meniscus, shown at H, is a lens, one of whose surfaces is convex and the other concave, and in which the surfaces meet if continued. As the convexity exceeds the concavity, it may be regarded as a convex lens. (It is called a meniscus, because it resembles the crescent moon.)

9. A concavo-convex lens, shown at I, is a lens, one of whose surfaces is concave and the other convex, and in which the two surfaces will not meet, though continued. As the concavity exceeds the convexity, it may be regarded as a concave lens.

In all these lenses, a line M N passing through the centres of their curved surfaces is called the axis. The figures represent only the sections of the lenses, as if they were cut by a plane passing through their axis; but the reader will understand that the convex surface of a lens is like the outside of a watchglass, and the concave surface like the inside.

As the peculiar manner in which these variously shaped crystals refract the rays of light must necessarily be represented when we show the manner in which, by virtue of their property, they form images of sizes different from the real object, only the general principle may be noticed. When a ray of light strikes the prism A R S on the surface A S, and perpendicular to it, it does not pass through the glass in a direct line, but is bent from its course in the same manner as was the case in the passage of light through water. The property of lenses having a convex surface, such as E, is to collect the rays of light into a focus—those having a concave surface, to disperse the rays. For instance, a parallel ray of light entering the double concave lens F is attracted in going through it upwards towards the thick end of the glass; and when it passes into the atmosphere, it is still more bent to the perpendicular, and is thus more widely dispersed. When parallel rays fall upon a double convex lens, such as D, the rays are refracted towards the axis, and meet at a focal point, which in a lens of this form is situated nearly at the centre of the sphere, of which the surface of the glass constitutes a portion. It is therefore at the distance of the radius of the sphere. In every case the focal distance depends not only upon the refractive power of the substance of which the lens is made, but upon the shape of the instrument. Parallel rays falling upon a plane glass, such as B, lying horizontally, are refracted towards the perpendicular, as we saw was the case with respect to water; and after passing through it, they retain their parallelism. The law of light's bending according to the obliquity with which it traverses the surfaces of a transparent body, is beautifully illustrated by the effect of what is called a multiplying glass. This instrument is a plano-convex lens, of which the rounded surface is ground into a series of small planes; and as each plane forms a distinct image, as many images will be formed as there are planes in the glass. Thus, in the accompanying

Fig. 8.

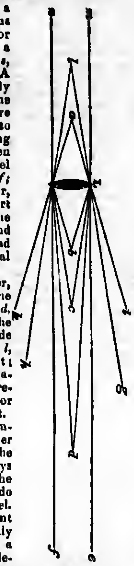


figure, $a\,b$ represents the plane side of the glass, and $i\,c$ a ray of light passing to the eye at f, upon which a distinct image is formed. The rays d and e striking upon oblique surfaces of the glass will be so bent as to reach the eye as if they had come in the direction $d\,f$ and $e\,f$, and in these directions two other distinct images will be seen. The refraction which light suffers in passing through a prism will be described when we come to notice the decomposition of light.

FORMATION OF IMAGES BY LENSES.

The principle upon which images are formed by light passing through small apertures, and by reflection from mirrors, we have already explained. Images are formed by lenses in the same manner as they are formed by mirrors. The image formed by a convex lens is inverted in position relatively to the object, as was the case in fig. 5. Its magnitude, in like manner, is to that of the object as its distance from the lens is to the distance of the object from the lens. By this means images of any size can be formed; small ones by removing the object from the lens, and large ones by bringing the object near the lens. These effects can also be varied by employing lenses of different focal lengths or distances.

In order to explain the power of lenses in magnifying objects, and bringing them near us, let us suppose an object placed at one hundred feet distance from the eye of a spectator. Let us place a convex glass of twenty-five feet focal distance half way between the object and the eye; then, as has been previously observed, an inverted image of the object, and of the same size, will be formed fifty feet behind the lens. If this picture is looked at six or eight inches behind it, it will be very distinctly seen, and nearly as well as if the object itself had been brought to within six or eight inches of the eye of the spectator. What is meant by the terms focal distance and conjugate foci, will be best understood by a diagram and explanation, fig. 9, which we quote from Dr Arnott:—



Rays falling from a on a comparatively flat or weak lens at L, might meet only at d, or even farther off; while, with a stronger or more convex lens, they might meet at c or at b. A lens weaker still might only destroy the divergence of the rays, without being able to give them any convergence, or to bend them enough to bring them to a point at all, and then they would proceed all parallel to each other, as seen at e and f; and if the lens were yet weaker, it might only destroy a part of the divergence, causing the rays from a to go to g and h, and after passing through, instead of to, i and k, in their original direction.

In an analogous manner, light coming to the lens in the contrary direction from b c d, &c., might, according to the strength of the lens, be all made to come to a focus at a or at l, or in some more distant point; or the rays might become parallel, as m and n, and therefore never come to a focus, or they might remain divergent.

It may be observed in the annexed figure, that the farther an object is from the lens, the less divergent are the rays darting from it towards the lens, or the more nearly do they approach to being parallel. If the distance of the radiant point be very great, they really are so nearly parallel that a very nice test is required to detect the non-accordance. Rays, for instance, coming to the earth from the sun, do not diverge the millionth of an inch in a thousand miles. Hence, when we wish to make experiments with parallel rays, we take those of the sun.

Any two points so situated on the opposite sides of a lens, as that when either becomes the radiant point of light, the other is the focus of such light, are called *conjugate foci*. An object and its image formed by a lens, must always be in *conjugate foci*; and when the one is nearer the lens, the other will be in a certain proportion more distant.

What is called the principal focus of a lens, and by the distance of which from the glass we compare or classify lenses among themselves, is the point at which the sun's rays are made to meet; and thus, by holding the glass in the sun, and noting at what distance behind it the little luminous spot or image of the sun is formed, we can at once ascertain the focus of a glass, as at a for the rays e and f.

It is remarkable that the bending power of the common glass should be such that the focus of a double lens of glass is just where the centre of the sphere would be, of which the surface of the lens is a portion. This gives us another fact with which to associate the recollection that the focus is near, as the convexity of the lens is greater; that is to say, as the surface is a portion of a smaller sphere. And such being the law, it may be proved, by calculation as well as by fact, that if a candle be held from a lens at twice the principal focal distance—suppose at c for a lens with the focus at a—the image of the candle will be formed at l, just as far on the other side. Thus, then, by trying with a lens until the image of a candle is formed at the same distance from it as the object is, we have a second mode of ascertaining the focal distance of a lens. Other kinds of glass, and other substances, refract with different powers; but the facts now stated should be retained in the memory as standards of comparison.

To revert to the case of the object placed at 100 feet distance, if, instead of a lens of 25 feet focal length, a lens of a shorter focus is made use of, and situated with respect to the eye and the object that its conjugate foci are at the distance of 20 and 80 feet from the lens—that is, the object is 20 feet before the lens, and its image 80 feet behind it—then the size of the image will be four times that of the object. If the eye, therefore, looks at this magnified image 6 inches behind it, it will be seen with great distinctness. In this case the image is magnified 4 times directly by the lens, and 200 times by being brought 200 times nearer the eye; so that its apparent magnitude is 800 times larger than before. At distances less than the preceding, the rule for finding the magnifying power of a lens, when the eye views the image which it forms at six inches distance, is, according to Sir David Brewster, as follows:—"From the distance beween the image and object in feet subtract the focal distance of the lens in feet, and divide the remainder by the same focal distance. By this quotient divide twice the distance of the object in feet, and the new quotient will be the magnifying power, or the number of times that the apparent magnitude of the object is increased. When the focal length of the lens is quite inconsiderable, compared with the distance of the object as it is in most cases, the rule becomes this:—Divide the focal length of the lens by the distance at which the eye looks at the image; or, as the eye will generally look at it at the distance of six inches, in order to see it most distinctly, divide the focal length by six inches, or, what is the same thing, double the focal length in feet, and the result will be the magnifying power."

TELESCOPE, MICROSCOPE, &c.

The word telescope is a compound Greek term, signifying *to see far*, and upon the above principle, the instrument in its simpler form is constructed. It consists of a lens whose focal length exceeds six inches, placed at one end of a tube which must always be six inches longer than the focal length of the lens. This is termed the object-glass; and here the light reflected by the objects in front is collected and formed into images near the other end of the tube, where they are inspected by another lens called the eye-glass. This lens is fixed in a smaller tube which slides backwards and forwards so as to admit of the focal distance being adjusted to different eyes, &c. In telescopes with only two lenses, such as those used for astronomical purposes, the image is inverted—a circumstance of no importance in viewing the heavenly bodies. To produce an upright image, another lens is introduced, so as to invert it a second time. There are various kinds of telescopes named after the makers, or the purposes to which they are applied; but as they are all constructed upon the above principles, it is unnecessary to describe them individually.

Microscope is a term compounded of two Greek words, signifying *to see what is small*, and denotes that instrument employed to examine minute objects. Those microscopes of greatest power, and termed compound, approach to the telescope in their form. The difference lies in this, that whilst in the telescope the object-glass forms the image of a distant object just as much smaller than itself as the distance of the image from the glass is less, in the microscope, conversely, a small object placed near the focus of the object-glass produces a more distant image, as much larger than itself as the image is more distant. In both cases an appropriate eye-glass is employed. The object-glass of a microscope is in general very small, that of a telescope large. An object-glass of a microscope having one-eighth of an inch of focal distance, and so placed as that the image of the object is formed at six inches, the image will be of a diameter forty-eight times as great as the object; and when viewed through an eye-glass of half an inch focus, it will appear magnified twelve times more, or will appear 30,000 times larger than the object. A single or one-lens microscope magnifies chiefly by allowing the eye to see the object nearer than it could do without the glass.

A *Camera Obscura* or *Dark Chamber* is formed by placing a convex lens, such as that represented in fig. 9, in an aperture made in the window-shutter of a darkened room. A glass of proper size and focal distance is chosen, and a screen or the wall of the chamber is properly prepared to receive the light, and by this means there is painted on it an accurate picture of all the objects seen from the window, every thing bearing an exact resemblance to the reality. Nothing can surpass the beautiful effects produced by this delightful instrument.

The *Camera Lucida* is an instrument now frequently used in drawing landscapes, delineating objects of natural history, and copying and reducing drawings. The best form of the instrument consists of a piece of thick parallel glass, at one end of which there is a metallic mirror having a highly polished face. The rays from the object are made first to pass through the glass, when they are reflected back upon one of its sides by the mirror, and from the glass they are again reflected to the eye.

The Magic Lantern.—When a small object is placed close to a lens, and the image reflected upon the wall of a dark chamber, at say one hundred times farther from the lens than the object is, there will be a greatly magnified representation of the object. It will only be seen, however, under ordinary illumination; and it is therefore necessary to have a very strong light, concentrated by a suitable mirror or glass, and directed upon the object. When artificial light is employed, as of a lamp, the instrument then becomes a magic lantern. It consists of an argand burner placed in a dark lantern, on one side of which is a concave mirror, the vertex being opposite to the centre of the flame, which is placed in its focus. In the opposite side of the lantern is fixed a tube containing a hemispherical illuminating lens, and also another convex lens at the external orifice of the tube. Between these two lenses there is a slit in the tube, through which sliders are introduced containing pictures, each painted and highly coloured with transparent varnishes. The light of the lamp, increased by the reflection of the mirror falling upon the hemispherical lens placed at the inner orifice of the tube, is by this lens concentrated upon the picture in the slider; and this picture being in one of the conjugate foci of the lens at the outer orifice of the tube, an enlarged image of it is painted on a white cloth or other screen made to receive it. The phantasmagoria is just a magic lantern in which the images are received on a transparent screen fixed in view of the spectator. The magic lantern mounted upon wheels is made to approach or recede from the screen at pleasure; and the consequence is, that the images upon the screen can be made to expand to a gigantic size, or contract into an invisible object, or a luminous point.

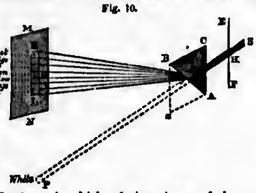
With regard to the aberration of lenses and mirrors, we can only refer the reader to larger works upon optics, such as that of Sir David Brewster in Lardner's Cyclopædia.

PHYSICAL OPTICS

Light is not a simple but a compound substance, and the phenomena exhibited by its decomposition and recomposition, as well as its other physical properties, are treated of under this head.

The white light of the sun, and that of any other luminous body, consists of seven different kinds of light, viz. red, orange, yellow, green, blue, indigo, and violet. There are two processes by which this compound substance may be decomposed, namely, by absorption and by refraction; the last method was that employed by Newton, who discovered the composition of white light in the following manner:—In the window-shutter E F of a darkened room, make a small

Fig. 10.



hole H, through which admit a beam of the sun's light S H, which, when nothing is interposed, will proceed in a straight line to P, and form a luminous white spot. If we now interpose a prism B A C, whose refracting angle is B A C, so that the beam of light may fall on its surface C A, and emerge at the same angle from its second surface B A in the direction g G, and if we receive the refracted beam on the opposite wall, or on a white screen M N, "we should expect," says Sir David Brewster, "from the principles already laid down, that the white beam which previously fell upon P would suffer only a change in its direction, and fall somewhere upon M N, forming there a round white spot exactly similar to that at P. But this is not the case. Instead of a white spot, there will be formed upon the screen M N an oblong image K L of the sun, containing seven colours, viz., red, orange, yellow, green, blue, indigo, and violet, the whole beam of light diverging from its emergence out of the prism at g, and being bounded by the lines g K g L. This lengthened image of the sun is called the solar spectrum, or the prismatic spectrum. If the aperture H is small, and the distance g G considerable, the colours of the spectrum will be very bright. The lowest portion of it at L is a brilliant red. This red shades off by imperceptible gradations into orange, the orange into yellow, the yellow into green, the green into blue, the blue into a pure indigo, and the indigo into a violet. No lines are seen across the spectrum thus produced; and it is extremely difficult for the sharpest eye to point out the boundary of the different colours. Sir Isaac Newton, however, by many trials, found the lengths of the colours to be as follow, in the kind of glass of which his prism was made. We have added the results obtained by Fraunhofer with flint glass:—

	Newton.	Fraunhofer.
Red . . .	45	56
Orange . . .	27	27
Yellow . . .	40	27
Green . . .	60	46
Blue . . .	60	48
Indigo . . .	48	47
Violet . . .	80	109
Total length	360	360

These colours are not equally brilliant. At the lower end L of the spectrum, the red is comparatively faint, but grows brighter as it approaches the orange. The light increases gradually to the middle of the yellow, where it is brightest; and from this it gradually declines to the upper or violet end K of the spectrum, where it is extremely faint.

From the phenomena which we have now described, Sir Isaac Newton concluded that the beam of white light S is compounded of light of seven different colours, and that for each of these different kinds of light, the glass of which his prism was made had different indices of refraction; the index of refraction for the red light being the least, and that of the violet the greatest.

If the prism be made of crown glass, for example, the indices of refraction for the different coloured rays will be as follow:—

	Index of Refraction.		Index of Refraction.
Red	1.5258	Blue	1.5360
Orange	1.5268	Indigo	1.5417
Yellow	1.5296	Violet	1.5466
Green	1.5330		

If we now draw the prism B A C on a great scale, and determine the progress of the refracted rays, supposed to be incident upon the same point of the first surface C A, by using for each ray the index of refraction in the preceding table, we shall find them to diverge as in the preceding figure, and to form the different colours in the order of those in the spectrum."

By means of a second prism placed behind a hole in the screen M N opposite the centre of each coloured space, Sir Isaac Newton refracted the light a second time. In this case it was not drawn out into an oblong image as before, and was not refracted into any other colour than that which formerly belonged to each particular ray. Hence this great philosopher concluded that the light of each particular colour possessed the same index of refraction; and he termed such light homogeneous or simple, white light being regarded as heterogeneous or compound. This doctrine is called the different refrangibility of the rays of light. The different colours as they exist in the spectrum are called primary colours, any combinations or mixtures of them being considered as secondary.

By various experiments, Sir Isaac proved that all the colours, when again combined, formed or recomposed white light. Indeed, the doctrine may be illustrated by mixing together in proper proportions seven colours as like those of the spectrum as can possibly be got. By their union, a greyish white is formed, for powders of the exact tint as those of the spectrum cannot be obtained. It may also be proved in this manner:—Let a circle of paper be divided into sections of the same size, and coloured like the spaces in the spectrum, and placed upon a humming top, which is made to revolve rapidly; the effect of all the colours when combined is to produce a greyish white. But the clearest proof is afforded by the following experiment:—Let a second prism B A a, represented by the dotted lines in fig. 10, be placed upon the first prism, in the manner shown in the cut, then the refraction suffered by the light in passing through A B C will be counteracted by the second prism B A a, and a single beam of white light g P will be formed, and fall in a bright spot at P.

The decomposition of light by absorption has been particularly investigated by the acute genius of Sir D. Brewster. It is a fact well known, that if a beam of white light be transmitted through a coloured prism, the latter absorbs a portion of the former. By looking at the spectrum K L, fig. 10, through the prism B A C, a prism of blue glass being interposed between the eye and the spectrum, Sir David found that the blue glass had absorbed the red light, which, when mixed with the yellow light, constituted orange; and had absorbed also the blue light, which, when mixed with the yellow, constituted the part of the green space next to the yellow. Thus, by absorption, green light was decomposed into yellow and blue, and orange light into yellow and red. Sir David Brewster analysed the spectrum with great care, and the conclusions which he arrived at were, that the solar spectrum consists of three spectra of equal lengths, viz. a red spectrum, a yellow spectrum, and a blue spectrum. The primary red spectrum has its maximum of intensity about the middle of the red space in the solar spectrum, the primary yellow spectrum has its maximum in the middle of the yellow space, and the primary blue spectrum has its maximum between the blue and the indigo space. The two minima of each of the three primary spectra coincide at the two extremities of the solar spectrum. Thus, then, it is concluded, that certain proportions of red, yellow, and blue, form white, and that these exist at every point of the solar spectrum, constituting its three primary colours.

DISPERSION OF LIGHT.

In fig. 10 we have considered the prismatic spectrum K L as produced by a prism of glass having a given refracting angle B C A. The green space G in the middle is called the mean ray of the spectrum; the index of refraction which belongs to it is called the mean refractive power of the prism; and the angle which the green ray forms with the line S P, the mean refraction of the prism. If the angle of the prism B A C be increased, the refraction will also be increased. The mean ray g G will be refracted to a greater distance from P; and the extreme rays will likewise be refracted to a greater distance in the same proportion, the length K L bearing always the same proportion to G P, whatever be the angle of the prism. It is a fact which was singularly overlooked by the great Newton, that prisms made of different substances produced spectra whose lengths are different when the mean refraction is the same. Flint glass, for instance, produces a spectrum which extends beyond K and L, and longer than that produced by the prism B C A, which is supposed to be of crown glass. Hence flint glass is said to have a greater dispersive power than crown glass.

In order to render this property of transparent bodies as intelligible as possible, let us suppose that in the crown glass prism B A C, the index of refraction for the extreme violet ray g K is 1·5466, and that for the extreme red ray g L 1·5258; then the difference of these two indices, or ·0208, would be a measure of the dispersive power of crown glass, if it and all other bodies had the same mean refraction; but as this is far from being the case, the dispersive power must be measured by the relation between ·0208 and the mean refraction, or 1·5330, or to the excess of this above unity, viz. ·5330, to which the mean refraction is always proportional. For the purpose of making this clearer, let it be required to compare the dispersive powers of diamond and crown glass. The index of refraction of diamond for the extreme violet ray is 2·467, and for the extreme red, 2·411, and the difference of these is 0·056, nearly nine times greater than 0·208, the same difference for crown glass; but then the difference between the sines of incidence and refraction, or the excess of the index of refraction above unity, or 1·439, is also about three times greater than the same difference in crown glass, viz. 0·533; and, consequently, the dispersive power of diamond is very little greater than that of crown glass. The two dispersive powers are as follow:—

$$\text{Crown glass} \quad . \quad . \quad . \quad . \quad \frac{\cdot 0208}{\cdot 5330} = 0\cdot0390$$

$$\text{Diamond} \quad . \quad . \quad . \quad . \quad . \quad \frac{\cdot 056}{1\cdot 439} = 0\cdot0388$$

When spectra of different lengths are examined by two bodies having very different dispersive powers, such as oil of cassia and sulphuric acid, there is a remarkable difference between them. It is found that in the former the red, orange, and yellow spaces, are less than in the latter; whilst the blue, indigo, and violet spaces, are greater; the least refrangible rays being as it were contracted in the former and expanded in the latter, whilst the most refrangible rays are expanded in the one and contracted in the other.

ACHROMATIC TELESCOPES.

By the application of the principles above explained, the refracting telescope has been greatly improved. It is evident, by an examination of fig. 10, that refraction cannot be effected without colour being produced—no two lenses of the same glass can be found to form an image perfectly free from colour. But by the different dispersive powers of different bodies, such as crown and flint glass, lenses formed of two such substances can be so adjusted as to produce an achromatic telescope, or one without colour. Let a convex lens, such as D, fig. 7, be formed of crown glass, and a concave one, such as F, be formed of flint glass, and both fitting neatly into each other, the ray falling upon the convex lens would have been refracted in the same manner as in the prism A B C, fig. 10, and separated into various colours. But as they have to pass through the concave lens, they are by it refracted to a certain focal point, where they again blend and form a white light. It is found, however, that the images of all luminous objects, when seen through such a lens, are bordered on one side with a purple fringe, and on the other with a green fringe. The difficulty, however, was surmounted by Dr Blair, who discovered, that, if muriate of antimony were enclosed between two convex lenses of crown glass, light would be refracted in parallel rays to a single focus, without any trace of secondary colour being observable. Other substances have also been employed, and telescopes are now formed so as completely to answer all philosophical purposes.

PHYSICAL PROPERTIES OF THE SPECTRUM.

Heating Power.—It was discovered by Sir William Herschel that the heating power of the spectrum gradually increased from the violet to the red extremity, and even beyond it. Hence he concluded that there are invisible rays in the light of the sun which had the power of producing heat, and which had a less degree of refrangibility than red light. Sir Henry Englefield confirmed his results, and obtained the following measures:—

	Temperature.		Temperature.
Blue .	56°	Red .	72°
Green .	58	Beyond red	79
Yellow .	62		

The place of maximum heat has recently been found to vary with the substance of which the prism is formed. Thus, in water, alcohol, and oil of turpentine, it is in the yellow; in crown glass, in the middle of the red; and in flint glass, beyond the red. In other substances it is intermediate between these two points.

Illuminating Power.—M. Fraunhofer, a celebrated philosopher of Munich, discovered, by means of a photometer, or measurer of the intensity of light, that the most luminous rays of the spectrum are not situated in the middle, but nearer the red than the violet end, in the proportion of 1 to 4 nearly, and that the mean ray is almost in the middle of the blue space. The same philosopher also discovered that the spectrum is covered with dark and coloured lines parallel to one another, and perpendicular to the length of the spectrum. They have always the same position in the coloured spaces in which they are found, their proportional distances varying with the nature of the prism by which they are produced. Their number, however, their order, and their intensity, remain invariable, provided light of the sun or moon be employed. One of the most important practical results of the discovery of these fixed lines, is, that they enable philosophers to take the most accurate measures of the refractive and dispersive powers of bodies; and by measuring the distances of the lines, their discoverer computed a table of the indices of refraction of different substances.

The spectrum exercises a chemical influence on certain bodies. The effect, for instance, produced on muriate of silver, varies with the nature of the coloured space where it is placed, and other substances are similarly affected. The solar rays possess also a magnetising power. If the violet rays be collected in the focus of a convex lens, and this focus carried from the middle of one-half of a small needle to the extremities of that half without touching the other, it will acquire perfect polarity. The indigo, blue, and green rays, produce this effect, but the others do not. Exposure to the sun's rays, under peculiar circumstances, can be also made to produce similar results on certain bodies.

INFLEXION OR DIFFRACTION OF LIGHT; COLOURS OF THIN AND THICK PLATES, FIBRES, GROOVED SURFACES, &c.

It is impossible within our circumscribed limits to enter into a full description of these various optical phenomena; and a few sentences explanatory of them in the simplest manner is all that we can venture upon.

If an aperture 1-40th of an inch diameter be made in the window-shutter of a dark room, or if a convex lens of a short focus be put in this hole, a beam of divergent light will be obtained. Bodies of any kind, if placed in this light, and their shadows accurately examined, will be found on each side of the shadow to have fringes of coloured light, the colours, reckoning from the shadow, being as follow:—First fringe, violet, indigo, pale blue, green, yellow, red; second fringe, blue, yellow, red; third fringe, pale blue, pale yellow, pale red. The shadow itself is divided by parallel fringes, which vary in number and breadth according to the distance from the body at which the shadow is examined. These phenomena depending upon light being in some way or other bent, this branch of optics is called the inflexion or diffraction of light.

When light is either reflected from transparent bodies, or transmitted through portions of them which possess parallel surfaces, it is always white. If, however, bodies of extreme thinness be employed, such as soap bubbles, beautiful colours are exhibited. This must have been observed by every one. In order to investigate a thin plate of air, Sir Isaac Newton took a double convex lens, to one of the sides of which he pressed the plane side of a plano-convex lens. When the rings are observed through the upper lens, so as to see those formed by the light reflected from the plate of air between the lenses, seven rings will be seen, or rather seven circular spectra or orders of colours. In the three first, the colours were very distinct; but towards the seventh they became gradually less and less, until they nearly disappeared altogether. Upon examining the light transmitted through the lenses, that is, by looking through the double convex lens, another system of circular coloured rings different from those seen by reflection were observed.

Sir Isaac first discovered and examined the colours produced by glass mirrors or thick transparent plates. Having admitted a sunbeam one-third of an inch in diameter through a hole in his window-shutter, he threw it in the direction of its axis on a glass mirror a quarter of an inch thick, concave in front, and convex and quicksilvered behind, the radius of the curvature of both its sides being equal to its distance behind the aperture. A sheet of paper having been placed on the window-shutter, with a hole in it to allow the ray to pass through, the hole was observed to be surrounded with several coloured rings. These rings had the same colours as those seen when light is transmitted through thin plates, as above noticed; and their diameters were reciprocally as the square roots of the thickness of the mirror. Sir David Brewster has investigated this subject with his usual skill and success. For an account of his discoveries we must refer the reader to his work on Optics, and his numerous papers in the Edinburgh Journal of Science.

If we look at the light of the sun or a candle through a plate of glass upon which we have breathed, or which is covered with very fine dust, it will be observed to be surrounded with a corona or ring of colours, resembling a halo. Minute fibres, such as those of silk or wool, produce the same effect, the rings in the first instance increasing with the size of the particles, and in the second with the diameter of the fibres which produce them. By employing the seed of the lycopodium, or by placing a drop of blood diluted with water between two pieces of glass, the coloured rings will be finely seen. Round the luminous body there is perceived a light area, terminating in a reddish dark margin; this is succeeded by a ring of bluish green, and then by a red ring, these two last colours succeeding each other several times, when the particles are of a uniform diameter. If surfaces of glass or metal be polished, and then crossed by small parallel grooves very near each other, an interesting class of colours will be exhibited. Mother-of-pearl, it is well known, possesses this singular property, and to the same cause, viz. the presence of minute grooves in its surface, it must be attributed. Sir David Brewster succeeded in transferring this quality of mother-of-pearl to other substances, by simply pressing its surface to theirs, whilst they were softened enough to receive an impression. By examining these surfaces with a microscope, Sir David discovered, in almost every specimen, "a grooved structure, like the delicate texture of the skin at the top of an infant's finger, or like the section of the annual growths of wood, as seen upon a dressed plank of fir. These may sometimes be seen by the naked eye, but they are often so minute that three thousand of them are contained in an inch."

The principle of thus producing colour by grooved surfaces, and of the communicability of these colours by pressure to various substances, has been happily applied to the arts by John Barton, Esq. With the point of a diamond, extremely minute grooves are cut in steel with the most perfect parallelism, and nothing can surpass the brilliant display of colours which are thus produced. Mr Barton conceived the idea of forming buttons for gentlemen's dress, and articles of female ornament covered with grooves, beautifully arranged in patterns, and shining in the light of candles or lamps with all the brilliant tints of the prism. To these the appropriate name of *Iris* ornaments was given. A variety of substances can be made to exhibit the same appearances.

To account for these phenomena, Newton supposed that the particles of light possessed the property at different points of their path, of fits or dispositions to be reflected from or transmitted by transparent bodies. How these fits are to be accounted for, Sir Isaac did not explain; and his theory has been to a great extent superseded by a new one, called the doctrine of interference, which may be thus explained:—Suppose two pencils of light radiate from two points very close to each other, and that they fall upon the same spot of a piece of paper held parallel to the line joining the points, so that the spot is directly opposite the point which bisects the distance between the two radiant points. In this case they may be said to interfere with one another, because they would cross each other at that spot if the paper were removed, and would diverge from one another. The spot will therefore be illuminated with the sum of their lights; and in this case the lengths of the paths of the two pencils of light are exactly the same. Now, it has been found that when there is a certain minute difference between the lengths of the paths of the two pencils of light, the spot upon the paper where the two lights interfere is still a bright spot. If we call this difference in the length of their path d, bright spots will be formed by the interference of the two pencils when the difference in the lengths of the paths is d, $2d$, $3d$, $4d$, &c. But it is a remarkable fact, and one which has been clearly demonstrated, that if the two pencils interfere at intermediate points, or when the difference in the lengths of the paths of the two pencils is $\frac{1}{2}d$, $1\frac{1}{2}d$, $2\frac{1}{2}d$, $3\frac{1}{2}d$, &c., instead of increasing each other's intensity of illuminating power, they actually neutralise it, and a dark spot is produced. This curious property is analogous to that of the beating of musical sounds, which depending upon vibrations of the air, it is conjectured that the phenomena above explained may go to support the undulatory theory which has made so great a progress in modern times. But as nothing clearly demonstrative of it has been yet advanced, it is not here that speculations as to its probability can be indulged in.

DOUBLE REFRACTION OF LIGHT.

In the foregoing part of this paper we have considered a single ray of light reflected or transmitted through the substance of a transparent body, as leaving it in the same way in which it came into contact with it, namely, in a single pencil or ray. But there are a great many bodies which have the power of breaking the pencil of light incident upon their surfaces into two separate parts or pencils more or less inclined to one another, according to the nature and state of the body, and according to the direction of the incident pencil. This is called double refraction, and the bodies which produce it are called doubly refracting bodies or crystals. They are very numerous, and include all salts and crystallised minerals not having the primitive forms of the cube, the regular octohedron, and the rhomboidal dodecahedron. The following is principally an abridgement of an article upon this subject in the British Cyclopædia:—

Of all known bodies, the Iceland spar, or rhomboidal carbonate of lime, shows the fact with the greatest certainty; and as it is a mineral easily procured, it has been generally used in experiments upon this subject. Its crystals are of a rhomboidal form, having six acute solid angles, and two obtuse. These last, x and x, fig.

Fig. 11.

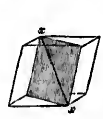


Fig. 12.

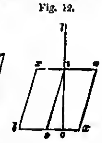
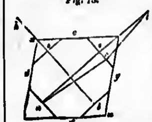


11, are formed by the junction of three equal plane angles, and equally inclined to each other. The line $x\,x$ joining these two angles, is therefore similarly situated with respect to the three planes forming each angle, and is called the axis of the crystal. A plane, perpendicular to the natural surface of the crystal, and coinciding with this line, is called its principal section, which term is also applied to any plane parallel to it. Let a small hole be pierced through any opaque plate, be applied to the lower surface of the crystal, and directed to a sheet of white paper. Let $x\,a$, $x\,b$, fig. 12, be the principal section of the crystal, and i a pencil falling on its surface. In this case it will be found that two images are formed. One part of the light will proceed in the ordinary direction (let us suppose perpendicularly), and is therefore called the ordinary ray, while the other portion of the light deviates considerably from this direction, and is called the extraordinary ray: $i\,o$ will represent the ordinary, and $i\,e$ the extraordinary ray.

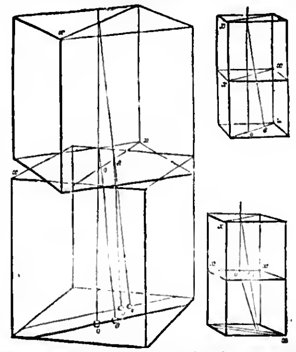
Fig. 13.



Let the crystal be cut by two planes $c\,g$ and $d\,f$ in the accompanying diagram, parallel to the axis, and two other planes, $e\,d$ and $f\,g$, perpendicular to the axis, to allow an object to be seen through it in the direction $c\,d$ or $o\,g$; it will be found that the two images will be farther separated, viewed in the direction $c\,d$, which is perpendicular to the axis, while in the direction of the axis there will be only one image. The inference from these experiments is, that there exists some peculiar force acting on the light passing through the crystal, producing a separation of the rays, and that this force emanates from the axis itself. As this produces a deviation of the second image towards or from the axis of the crystal, it is considered positive or negative, or, by Biot, attractive or repulsive.

The two rays into which a pencil of light is divided in passing through a crystal of Iceland spar, are always of the same intensity, and always in the plane of the principal section. But the two emerging rays are not merely diminished in intensity by the division of the light between them, but have undergone a most important modification; for if the rays be made to pass through another crystal, placed similarly to the first, there will be no subdivision of the light; the two images will be merely separated to a greater distance from the increased thickness through which the light passes. If now the two crystals are so placed that the principal sections are at right angles to each other, there will still be only two images; but the ray ordinarily refracted in the first will become extraordinary in the second, and the extraordinary ordinary. At all intermediate positions of the two crystals, however, there will be a subdivision of each ray, consequently four images: these four images will be of equal intensity when the principal sections of the two crystals are at an angle of 45° to each other; at all other angles one or other of the images diminish in intensity as the principal sections approach to a perpendicular or parallelism; not by the coalescence of the two images, but by the gradual diminution of the intensity of one and the augmentation of that of the other. In the subjoined diagrams, we have supposed the rhomboids reduced to the form of cubes in all three; the axis is denoted by $x\,x$, and the direction of the rays by the lines passing through the figure, and the letters e and o the extraordinary and ordinary rays. It is thus

Fig. 14.



seen that each emerging ray is only subject to a further division in particular positions of the second crystal, whereas natural light is always divided into two portions of equal intensity. Each ray has suffered a physical change; it is not acted on by the force of the second crystal, as natural light would be, but requires that the force be applied in a particular direction relatively to the modification it has received from the first crystal. The effect here produced has been termed

THE POLARISATION OF LIGHT.

Polarisation is also produced when light is reflected from the surfaces of bodies. Malus, a celebrated French philosopher, made the curious discovery, that a beam of light reflected from glass at an angle of 56°, or from water at an angle of 52° 45', possessed the very same properties as one of the rays formed by a rhomb of calcareous spar through which he had been looking at the light of the setting sun, as reflected from the windows of the Luxembourg palace in Paris. By a series of experiments, the important fact was established, that light reflected from all other transparent or opaque bodies, excepting metals, became polarised, the plane of polarisation being coincident with, or parallel to, the plane of reflection. This is more or less completely the case according to the angle formed with the surface. This angle varies for different substances; and Sir David Brewster discovered a law connecting the angle with the index of refraction of the given body, viz. "that the tangent of the angle of polarisation, measured from the perpendicular, is equal to the index of refraction," when complete polarisation, or the greatest the body is capable of, is produced.

To make the nature of polarisation as plain as possible, and to show the difference between common and polarised light, let us suppose a ray of light falls upon an unsilvered mirror plate, making an angle with it of 35° 25', then the ray will be reflected in a right line, so that the angle of reflection will be equal to the angle of incidence, according to the law laid down at the commencement of this paper. If we now receive this reflected ray on another similar plane of glass, it will in general suffer a second general reflection. But this reflection will entirely vanish, or, instead of being reflected, will be transmitted through the mirror, if the plane of incidence on the second mirror is perpendicular to the plane of incidence on the first mirror—that is, if it form an angle of 35° 25' with the ray reflected from the first plane of glass. Now, common or natural light—that is, light which had not been interfered with or experimented upon at all—would have been equally reflected in every position. It is to be observed, that a total transmission or obscuration will not take place if the angle of reflection of either mirror be greater or less than the angle of polarisation. It has been ascertained that the direction of polarity in the reflected light is to the plane of reflection similar to the polarity of the ordinary ray in Iceland spar to its principal section, or an identity of the modification produced in the reflected ray, and the modification produced by the action of the crystal on the ray ordinarily reflected; for if the ray reflected from water or glass at the polarising angle be received on a crystal of Iceland spar, the principal section of which coincides with the plane of reflection, the ray entering the crystal will proceed through it in the same direction that the ordinary ray emerging from another crystal would have proceeded. But if the principal section of the crystal be placed perpendicular to the plane of reflection, the ray will be reflected extraordinarily; but in both positions there will be no bifurcation of the ray. If the principal section of the crystal be any otherwise situated as to the plane of reflection, there will be two rays, but of equal intensity, when the angle contained between these two planes is 45°. If, again, the ordinary ray emerging from a crystal be made to fall at the proper angle on the surface of water, or any other reflecting surface capable of polarising light completely, it will be reflected when the principal section and plane of reflection coincide, but entirely transmitted when the planes are perpendicular to each other. But if the extraordinary ray fall on the surface, the reflection will take place when the planes are at right angles, and a total transmission will result when the planes coincide.

We are therefore justified in assuming that the physical change the light has suffered is the same in the two cases; that whether an ordinary ray be examined by subsequent reflection, or the reflected ray by a doubly refracting crystal, the inference is, that the polarity of each is in the same direction: the one in the plane of the principal section, and the other in the plane of reflection.

Light is not only reflected from the first surface of transparent bodies, but another portion is reflected

Fig. 15.

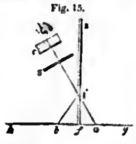


Fig. 16

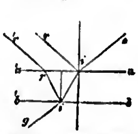


from the second surface. We will suppose these two surfaces parallel, and it will not be difficult to see that if the light be completely polarised by reflection from the first surface *a'*, fig. 16, the portion reflected from the second surface *b'* will also be completely polarised, and in the same plane.

Let *e i* be the incident ray, and *i r* the reflected polar ray, *i i* the refracted ray, partially reflected and refracted to *r'* and *i g*, the remaining refracted light will be perpendicular to *i r'*, the reflected ray, a condition producing complete polarisation.

From various experiments it has been proved that the quantity of light reflected even from the two surfaces of a transparent body is small in proportion to the incident light, and it is now convenient to inquire into the condition of the refracted portion under circumstances in which polarisation of the reflected light is produced. If the ray *i g* be examined by a rhomboid, it will be found divided into two rays, but not of equal intensity; for the ordinary or extraordinary ray will be found the most intense, as the section of the crystal is parallel or perpendicular to the plane of refraction. This condition of light is called partial polarisation, and is the same as the state of reflected light when the incidence is not such as to produce complete polarisation.

M. Arago gives the following experiments: let us suppose a plate of glass, *e f*, fig. 15, in the diagram, placed perpendicularly on a sheet of fine white paper *h g*, the eye will see at the same time the reflected ray and the refracted ray; interpose an opaque plate perforated with a small hole *s*; let the eye be furnished with a doubly refracting crystal *e*. If by a black screen, placed between *b* and *i*, we stop the ray *b i*, which would have been transmitted by the glass plate, the hole in the plate *s* is illumined by the reflected light alone; and if the principal section of the crystal coincide with the plane of reflection, we see two images of the pole, of which the ordinary is the most brilliant. If the screen be now so placed as to intercept the reflected ray, there will be still two images, but now the extraordinary ray will be the most brilliant.

Now, if the screen be entirely removed, allowing both reflected and refracted light to reach the crystal, the intensity of the two images is found by actual experiment to be exactly equal. It is hence to be inferred that the plane which contains the poles of light polarised by transmission is perpendicular to the plane which contains poles of light polarised by reflection, and that the quantity of polarised light contained in the ray transmitted by a transparent plate is exactly equal to the quantity of polarised light contained in the ray reflected from its surface, whatever the angle of incidence may be. M. Arago observes, that a body which, at its angle of complete polarisation, would reflect half the incident light from its surface, would also completely polarise the transmitted ray, and that when there is no transmission of light, there is no polarisation; and which seems proved experimentally, as no trace of partial polarisation is discoverable in the light reflected from the interior of a glass prism, when the reflection is total.

As transparent substances reflect but a small portion of the incident rays, the quantity of polarised light in the transmitted ray is small in proportion to the light which has not undergone that modification. Sir D. Brewster considers the transmitted ray as consisting of one portion completely polarised in a plane at right angles to the plane of incidence, and another portion of light "which has suffered a physical change more or less approaching to complete polarisation." Light, having passed through a pile of plates, is at last polarised in a plane perpendicular to the plane of polarisation of the reflected light. This effect requires the agency of twenty-four plates at an incidence of 61°; "consequently," says this learned philosopher, "twelve plates will not polarise the whole pencil at that angle. Let us now suppose that the quantity not polarised amounts to twenty out of 100; then if these twenty were absolutely unpolarised, and in the same state as direct light, they would require to pass through twenty-four plates in order to be completely polarised. But experiments prove that they require to pass through only twelve other plates to be completely polarised; it therefore follows that the twenty rays have been half polarised by the first twelve plates, and the polarisation completed by the other twelve."

This reasoning appears good; but as Malus, Biot, and Arago, have adopted a somewhat different theory in their illustration of the subject, and as their view of the question admits of a ready explanation, we shall adopt it.

Let *a b c d* be supposed to represent the successive plates through which the incident ray 1000 is to pass, and at a given angle fifty out of the 100 be completely polarised by reflection, and a similar quantity of rays by refraction; the light emerging from the first lamina will consist of 900 in the state of direct light, and fifty of light polarised in a plane perpendicular to the plane of incidence. We have already seen that light polarised in one plane will not be reflected in a plane perpendicular to its plane of polarisation, and consequently the portion fifty of transmitted light will escape reflection from the lamina *b*, and therefore the light reflected from *b*, which we have supposed one-twentieth of the incident light, must be taken from the 900 of direct light. In this manner we may suppose the quantity of direct light constantly diminished, and the polarised light increased, by each succeeding transmission. According to this view, *complete* polarisation could never be produced, but the quantity of direct light, after a few transmissions, would be absolutely imperceptible.

It cannot be necessary to explain the result of submitting the ray emerging from a succession of plates to another pile of plates, to a doubly-refractive crystal, or to a reflection from a polarising surface. It is in all respects similar in its polarisation relatively to the plane of incidence on the first surface, to the extraordinary ray transmitted by a crystal relatively to its principal section. We will, however, mention one consequence of the foregoing laws; that polarised light falling on the first surface of a pile of plates will be *partially* reflected when the plane of incidence coincides with the plane of polarisation; and, a further portion being also reflected at each successive plate, an eye placed at the back of the plates will receive no sensible quantity of light. If, on the contrary, the plane of polarisation be perpendicular to the plane of incidence, the whole light will be transmitted. It therefore follows that an apparatus may be constructed of the most transparent plates of glass, in two piles or bundles, forming a system perfectly transparent in one position of the piles, yet perfectly opaque in another. This effect is to be produced only by a great number of plates of glass, if the incidence be near the perpendicular, yet some substances possess this property of polarising transmitted light, whatever the incidence. A thin plate of tourmaline, cut parallel to the axis of the crystal, completely polarises the light at any incidence in a plane perpendicular to the axis, and a second plate will transmit or stop all the rays, as the axis of the two plates are parallel or perpendicular to each other.

Sir D. Brewster found that a plate of agate, having surfaces perpendicular to its lamina, about one-fifteenth of an inch in thickness, completely polarised the transmitted light.

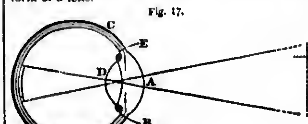
Among the most interesting phenomena connected with this branch of optics, are the colours produced by the action of crystallised bodies on polarised light. When thin plates of glass, selenite, mica, agate, quartz, crystal, tourmaline, and other substances, are exposed to a beam of polarised light, colours the most brilliant that can be conceived are exhibited. An attentive examination of them has led to a theory both of polarisation and double refraction, indeed one explanatory of optical phenomena in general. The experiments of Dr Young, by which two lights were made to produce darkness, and the law of interference, have been already mentioned. This was an important fact, and all that seemed awanting was a hypothesis of some mode in which light might be conceived to be propagated through an elastic medium, supposed to convey it in such a way as not to be contradictory to any of the facts, nor to the general laws of dynamics. Dr Young also supplied this. He conceived the idea, that the mode of propagation of a luminous impulse through the ether to be different from that of a sonorous one through the air. In the latter, the particles of the air advance and recede; in the former, those of the ether must be supposed to tremble laterally.

Fresnel, a French philosopher, made this the groundwork of his reasoning, and erected upon it a theory of polarisation and double refraction, "so happy in its adaptation to facts," says Sir John Herschel, "and in the coincidence with experience of results deduced from it by the most intricate analysis, that it is difficult to conceive it unfounded." It is impossible in this place to enter into details respecting the beautiful but artificial superstructure which the French philosopher has reared. His speculations are in support of the undulatory or Huygenian theory of light, one which certainly can be made to explain the phenomena to which the hypothesis of Newton cannot apply.

ON THE EYE AND VISION.

In applying optics to the explanation of natural phenomena, the structure of the eye, and the manner in which it performs vision, require particular notice. This masterpiece of divine mechanism is of a spherical form, with a slight projection in front. The eyeball consists of membranous coats, which have received the names of the sclerotic coat, the choroid coat, the cornea, and the retina; and these coats enclose three humours—the aqueous humour, the vitreous humour, and the crystalline humour; the last of which has the form of a lens.

Fig. 17.



The above figure represents an eye, supposed to be cut through the middle, from above downwards. C is the outer or sclerotic coat, known popularly, where most exposed in front, as the white of the eye. It is a strong and tough membrane, and to it are attached all the muscles which give motion to the eye. A is the clear and transparent coat called the cornea, joined to the edge of the round opening of the sclerotic: it is more bulging than the sclerotic, to which it is firmly united, and acts as a powerful lens for refracting the pencils of entering light. At B, and similarly all round the edge of the cornea, is attached the window-curtain or iris, shown here edgeways, immersed in the aqueous humour, and hanging inwards from above and below towards its central opening or pupil, through which the rays of light are passing to the lens. The iris has in its structure two sets of fibres, the circular and the radiating, which cross and act in opposition to each other. When the circular fibres contract, the pupil is lessened; when the radiating ones contract, it is enlarged; and the changes happen according to the intensity of light and the state of sensibility of the retina. The two parts into which the iris divides the eye are called the anterior and posterior chambers, the former containing the aqueous, and the latter the crystalline and vitreous humours, the last of which fills a considerable portion of the eye-ball. Behind the pupil is the crystalline lens D, a more solid substance than either the aqueous or the vitreous humours. It is suspended in a transparent bag or capsule by the ciliary process E, which is attached to every part of the margin or circumference of the capsule. This lens, as will be observed, is more convex behind than before, and it increases in density from its circumference to its centre, possessing likewise the doubly refracting structure. The three lines forming here the boundary of the eye, stand for its three coats—the strong sclerotic, and the double lining of the choroid and retina. The choroid is a delicate membrane which lines the inner surface of the sclerotic, and is covered on its inner surface with a black pigment. Immediately within the pigment, and close to it, lies the retina, which is the innermost coat of all. It is a delicate reticulated membrane, formed by the expansion of the optic nerve.

It is a well-ascertained fact that images painted upon the retina of the eye are inverted the same as they are in a camera obscura. Why, this being the case, the object should be seen, not inverted, but erect, is a question too abstruse to be here investigated. Philosophers are also involved in much perplexity as to which portion of the eye the seat of vision belongs, and likewise how impressions made by the rays of light are communicated to the brain. What is called the law of visible direction, is supposed to explain the phenomenon of erect position, for an explanation of which see Brewster's Optics, p. 292.

That although an image of any object looked at is formed upon each retina, and yet we should be sensible of perceiving only one object, is thus explained: In both eyes there are corresponding points equidistant, and in similar directions from the centres of the retinæ, called the points of distinct vision. At these centres the imaginary lines, called the axes of the eyes, terminate. When the two eyes are directed to any object at a greater distance than four or six inches, their axes meet at it, and the centres of the two retinæ are opposite to it. All the other points of the eyes have perfect mutual correspondence as regards that object, giving the sensation of single vision. If, however, the axes of the eye do not meet at the same point, the object will be seen double. This inability of one eye to follow the motions of the other is often the cause of squinting; but for the most part the orbs of vision are so wonderfully associated, that from earliest infancy they constantly move in perfect harmony.

The other phenomena and peculiarities of vision belonging to individuals we must sum up in a few words. The passage of a ray of light through the pupil, and various other portions of the eye, until it reaches the retina, including its refraction, will be distinctly understood from the foregoing description, in connection with the optical laws, as explained in an early part of this paper. Short-sightedness and long-sightedness arise from a change in the state of the crystalline lens, by which its density and refractive power, as well as its form, are altered. When by this change the rays are refracted too much, and come to a focus before they reach the retina, and then diverge from this focus, they produce on the retina a very indistinct image. This is the defect of short-sighted people. Now, by the use of a concave lens or eye-glass, the object is brought nearer the eye; and as the nearer it is to the eye, the more divergent the rays fall upon the crystalline humour, they are consequently not so soon conveyed to the focus; the perfect images in the eye are formed farther from the lens, and thereby on the retina itself. It is by using such an instrument that short-sighted people remedy their defect of sight. Those who have an opposite defect of vision—that is, those in whom the rays are not refracted sufficiently, and reach the retina before they are conveyed to a focus—employ just a remedy of an opposite description. As the nearer an object is brought to a lens, the farther the image formed recedes from it, so long-sighted people remove the object to a distance, and thus bring its image to a proper focus upon the retina. As the effect of a concave lens is to increase the divergence of the rays, the effect of a convex lens is to increase their convergency, which is what long-sighted people require. The defect of the eye, therefore, is remedied by employing a glass of this description. It makes up for the flatness in the crystalline, and enables the eye to converge the pencils flowing from near objects to distant foci on the retina.

UNUSUAL REFRACTION.

The elevation of coasts, ships, and mountains, above their usual level, when seen in the distant horizon, has been long known, and described under the name of *looming*. The name *mirage* has been applied by the French to the same class of phenomena; and the appellation *fata morgana* has been given by the Italians to the singular appearances of the same kind, which have been repeatedly seen in the Straits of Messina. When the rising sun throws his rays at an angle of 45° on the sea of Reggio, and neither wind nor rain ruffle the smooth surface of the water in the bay, the spectator on an eminence in the city, who places his back to the sun and his face to the sea, observes, as it were upon its surface, numberless series of pilasters, arches, and castles distinctly delineated; regular columns, lofty towers, superb palaces, with balconies and windows; extended vallies of trees, delightful plains with herds and flocks; armies of men on foot and horseback, and many other strange figures, in their natural colours and proper actions, passing one another in rapid succession. When vapours and dense exhalations, rising to the height of about twenty feet, accompany the state of the atmosphere above described, then the same objects are seen depicted as it were in the vapour, and suspended in the air, though with less distinctness than before. If the air be slightly hazy, and at the same time dewy, and fitted to form the rainbow, the above-mentioned objects appear only at the surface of the sea, but they are all brilliantly fringed with the prismatic colours. This description of the fata morgana, given by Antonio Minasi so recently as 1793, is no doubt overcharged, but there can be no hesitation in believing that the objects and movements which existed on the opposite coast were occasionally displayed in all the grandeur of aërial representation.

The phenomena of the mirage are most frequently seen in the case of ships when they are just beginning to appear above the visible horizon. The following is one of the most interesting cases of this description. In a voyage performed by Captain Scoresby in 1822, he was able to recognise his father's ship, when below the horizon, from the inverted image of it which appeared in the air. "It was," says he, "so well defined, that I could distinguish by a telescope every sail, the general rig of the ship, and its particular character; insomuch that I confidently pronounced it to be my father's ship the Fame, which it afterwards proved to be; though, on comparing notes with my father, I found that our relative position at the time gave our distance from one another very nearly thirty miles, being about seventeen miles beyond the horizon, and some leagues beyond the limit of direct vision. I was so struck by the peculiarity of the circumstance, that I mentioned it to the officer of the watch, stating my full conviction that the Fame was then cruising in the neighbouring inlet."

One of the most curious phenomena of this kind was seen by Dr Vince, on the 6th of August 1806, at 7 P.M. To an observer at Ramsgate, the tops of the four turrets of Dover Castle are usually seen over a hill between Ramsgate and Dover. Dr Vince, however, when at Ramsgate, saw the whole of Dover Castle, as if it had been brought over and placed on the Ramsgate side of the hill. The image of the castle was so strong and well defined, that the hill itself did not appear through the image.

In the sandy plains of Egypt, the mirage is seen to great advantage. These plains are often interrupted by small eminences, upon which the inhabitants have built their villages in order to escape the inundations of the Nile. In the morning and evening, objects are seen in their natural form and position; but when the surface of the sandy ground is heated by the sun, the land seems terminated at a particular distance by a general inundation: the villages which are beyond it appear like so many islands in a great lake, and between each village an inverted image of it is seen.

That the phenomena of the mirage are produced by variations in the refractive power of the atmosphere, can be proved by experiment. If the variation of the refractive power of the air takes place in a horizontal line perpendicular to the line of vision—that is, from right to left—then we have the lateral mirage; that is, an image of a ship may be seen on the right or left hand of the real ship, or on both, if the variation of refractive power is the same on each side of the line of vision. If there should happen at the same time both a vertical and a lateral variation of refractive power in the air, and if the variation should be such as to expand or elongate the object in both directions, then the object would be magnified as if observed through a telescope, and might be seen and recognised at a distance at which it would not otherwise have been visible. If the refractive power, on the contrary, varied so as to contract the object in both directions, the image of it would be diminished as if seen through a concave lens.

In order to represent artificially the effects of the mirage, Dr Wollaston views an object through a stratum of spirit of wine lying above water, or a stratum of water lying above one of syrup. These substances, by their gradual incorporation, produce a refractive power diminishing from the spirit of wine to the water, or from the syrup to the water; so that, by looking through the mixed or intermediate stratum at a word or object held behind the bottle which contains the fluids, an inverted image will be seen. The same effect, Dr Wollaston has shown, may be produced by looking along the side of a red-hot poker at a word or object ten or twelve feet distant. At a distance less than three-eighths of an inch from the line of the poker, an inverted image was seen, and within and without that an erect image.

The method employed by Sir David Brewster to illustrate these phenomena consists in holding a heated iron above a mass of water bounded by parallel plates of glass; as the heat descends slowly through the fluid, we have a regular variation of density, which gradually diminishes from the bottom to the surface. If we now withdraw the heated iron, and put a cold body in its place, or even allow the air to act alone, the superficial stratum of water will give out its heat, so as to produce a decrease of density from the surface to a certain depth below it. Through the medium thus constituted, the phenomena of the mirage may be seen in the finest manner.

THE RAINBOW.

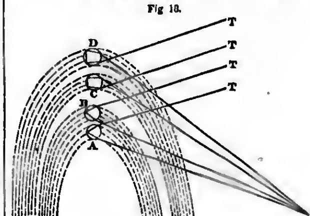
Every one knows that the rainbow is that brilliant and many-coloured arch which is occasionally seen spanning the sky opposite to the sun. In France and elsewhere, it is called the arc of the sky; and whilst to poets and other admirers of nature it is an object almost worshipped for its beauty, to the philosopher it is no less interesting and attractive. Rainbows are only visible when rain is falling between the spectator and that part of the sky which is opposite to the sun, which is in its centre, as if at the end of a straight line drawn from the sun through the eye of the spectator towards the opposite horizon; and being always under the horizon, the bow is less than a semicircle. It consists of two bows or arches, the one inner or primary, the other outer or secondary; and within the primary rainbow, and in contact with it, and without the secondary one, there have been seen supernumerary bows.

The primary or inner rainbow, which is commonly seen alone, is part of a circle whose radius is 41°. It consists of seven differently coloured bows, viz. violet, which is the innermost, indigo, blue, green, yellow, orange, and red, which is the outermost. These colours have the same proportional breadth as the spaces in the prismatic spectrum. This bow is therefore only an infinite number of prismatic spectra, arranged in the circumference of a circle; and it would be easy, by a circular arrangement of prisms, or by covering up all the central part of a large lens, to produce a small arch of exactly the same colours. All that we require, therefore, to form a rainbow, is a great number of transparent bodies capable of forming a great number of prismatic spectra from the light of the sun.

Sir David Brewster thus explains the cause of the arc of the sky:—As the rainbow is never seen, unless when rain is actually falling between the spectator and the sky opposite to the sun, we are led to believe that the transparent bodies required are drops of rain which we know to be small spheres. If we look into a globe of glass or water held above the head, and opposite to the sun, we shall actually see a prismatic spectrum reflected from the farther side of the globe. In this spectrum, the violet rays will be innermost, and the spectrum vertical. If we hold the globe horizontal, on a level with the eye, so as to see the sun's light reflected in a horizontal plane, we shall see a horizontal spectrum with the violet rays innermost. In like manner, if we hold a globe in a position intermediate between these two, so as to see the sun's light reflected in a plane inclined 45° to the horizon, we shall perceive a spectrum inclined 45° to the horizon, with the violet innermost. Now, since in a shower of rain there are drops in all positions relative to the eye, the eye will receive spectra inclined at all angles to the horizon, so that, when combined, they will form the large circular spectrum which constitute the rainbow.

To explain this more clearly, let A B, fig. 18, be drops of rain exposed to the sun's rays, incident upon

Fig 18.



them in the direction T A, T B, out of the whole beam of light which falls upon the drop; those rays which pass through or near the axis of the drop will be refracted to a focus behind it; but those which fall in the upper side of the drop will be refracted, the red rays least, and the violet most, and will fall upon the back of the drop with such sufficient obliquity, that many of them will be reflected, as shown in the figure. These rays will be again refracted, and will meet the eye at O, which will perceive a spectrum or prismatic image of the sun, with the red space uppermost, and the violet undermost. If the sun, the eye, and the drops A B, are all in the same vertical plane, the spectrum produced by A B will form the colours at the very summit of the bow, as in the figure. Let us now suppose a drop to be near the horizon, so that the eye, the drop, and the sun, are in a plane inclined to the horizon, a ray of the sun's light will be reflected in the same manner as at A B, with this difference only, that the plane of reflection will be inclined to the horizon, and will form part of the bow distant from the summit. Hence it is manifest that the drops of rain above the line joining the eye, and the upper part of the rainbow, and in the plane passing through the eye and the sun, will form the upper part of the bow; and the drops to the right and left hand of the observer, and without the line joining the eye and the lowest part of the bow, will form the lowest part of the bow on each hand. Not a single drop, therefore, between the eye and the space within the bow, is concerned in its production; so that, if a shower were to fall regularly from a cloud, the rainbow would appear before a single drop of rain had reached the ground.

If we compute the inclination of the red ray and the violet ray to the incident rays T A, T B, we shall find it to be 42° 2′ for the red, and 40° 17′ for the violet, so that the breadth of the rainbow will be the difference of those numbers, or 1° to 45′, or nearly three times and a half the sun's diameter. These results coincide so accurately with observation, as to leave no doubt that the primary rainbow is produced by two refractions and one intermediate reflection of the rays that fall on the upper sides of the drops of rain.

It is obvious that the red and violet rays will suffer a second reflection at the points where they are represented as quitting the drop, but these reflected rays will go up into the sky, and cannot possibly reach the eye at O. But though this is the case with rays that enter the upper side of the drop, as at A B, or the side farthest from the eye, yet those which enter it on the under side, or the side nearest the eye, may after two reflections reach the eye, as shown in the drops D C, where the rays T T enter the drops below. The red and violet rays will be refracted in different directions, and, after being twice reflected, will be finally refracted to the eye at O; the violet forming the upper part, and the red the under part of the spectrum. If we now compute the inclination of these rays to the incident rays T T, we shall find them to be 50° 58′ for the red ray, and 54° 10′ for the violet ray; the difference of which, or 3° 10′, will be the breadth of the bow, and the distance between the bows will be 8° 15′. Hence it is clear that a secondary bow will be formed without the primary bow, and with its colours reversed in consequence of their being produced by two reflections and two refractions. The breadth of the secondary bow is nearly twice as great as that of the primary one, and its colours must be much fainter, because it consists of light that has suffered two reflections in place of one.

Many peculiar kinds of rainbows have been observed, such as lunar ones, in which, however, the colours are faint and barely perceptible. Supernumerary rainbows are sometimes seen. "On the 5th of July 1828," says Sir D. Brewster, "I observed three supernumerary bows within the primary bow, each consisting of green and red arches, and in contact with the violet arch of the primary bow. On the outside of the outer or secondary bow I saw distinctly a red arch, and beyond it a very faint green one, constituting a supernumerary bow, analogous to those within the primary rainbow."

Red rainbows, distorted rainbows, and inverted rainbows on the grass, have been observed. The latter are formed by the drops of rain suspended on the spiders' webs in the fields. It is only necessary to mention that the iris, so frequently seen overarching the cataract, is produced by the refraction of light in passing through the misty vapour generated by the fall of the column of water.

OF HALOS, PARHELIA, &c.

The sun and moon frequently present very remarkable appearances according to the state of the atmosphere. When the latter is charged with dry exhalations the sun is occasionally as red as blood. When viewed through watery vapours, he is "shorn of his beams," but preserves a colourless disc. When light fleecy clouds pass over the sun and moon, they are often encircled with one, two, three, or even more coloured rings, like those of thin plates; and in cold weather, when particles of ice are floating in the higher regions, the two luminaries are frequently surrounded with the most complicated phenomena, consisting of concentric circles, circles passing through their discs, segments of circles, and mock suns, formed at the points where these circles intersect each other.

The term halo is indiscriminately applied to such appearances as are seen round either the sun or the moon. They are called parhelia (from two Greek words signifying "near the sun") when they are seen encompassing that luminary, and paraselenæ when seen round the moon. The large white halo, called in Scotland a *brough*, generally appears round the moon in cold weather, when the sky is of an uniform misty tint; and the prismatic halos, generally called coronæ, which are seen round the sun and moon, are commonly seen in fine weather; when white, thin, fleecy clouds float in the atmosphere. Owing to the dazzling effect of the sun's rays, the halos which surround his disk may be seen to most advantage when he is visible in a pool of water.

One of the most curious and best described combinations of halos and parhelia was observed by Hevelius at Dantzic, on Sunday the 20th February 1661, new style. We shall give an account of it as nearly as possible in the language of the observer:—

"A little before eleven o'clock, the sun being towards the south, and the sky very clear, there appeared seven suns together, in several circles, some white and some coloured, and these with very long tails waving and pointing from the true sun, together with certain white arches crossing one another. 1st, The true sun, being about 25° high, was surrounded almost entirely by a circle whose diameter was 45°, and which was coloured like the rainbow, with purple, red, and yellow, its under limb being scarcely 2½° above the horizon. 2d, On each side of the sun, towards the east and west, there appeared two mock suns, coloured, especially towards the sun, with very long and splendid tails of a whitish colour terminating in a point. 3d, A far greater circle, almost 95° in diameter, encompassed the sun and the other small circle, and extended itself down to the horizon. It was very strongly coloured in its upper part, but was somewhat duller and fainter on each side. 4th, At the tops of these two circles were two inverted arches whose common centre lay in the zenith, and these were very bright and beautifully coloured. The diameter of the lower arch was 96°, and that of the upper one was 45°. Thus the small circle had the largest arch inverted upon it. In the middle of the lower arch, where it coincided with the small circle, there appeared another mock sun, but its light and colours were dull and faintish. 5th, There appeared a circle much bigger than the former, of an uniform whitish colour, parallel to the horizon, at the distance of 25°, and 136° in diameter, which arose as it were from the collateral mock suns, and passed through three other perhelia of an uniform whitish colour like silver, one almost 96° from the true sun towards the east, another towards the west, and a third in the north, diametrically opposite to the true sun, all of the same colour and brightness. There passed also two other white arches of the greatest circle of the sphere, through the eastern and western mock suns, and also through the pole of the ecliptic. They went down to the horizon, crossing the great white circle obliquely, so as to make a white cross at each parhelion; so that seven suns appeared very plain at the same time: and if I could have seen the phenomenon sooner from an eminence, I do not question but I should have found two more, one directly below the sun, and another at the bottom of the small inverted arch, which would have made nine in all; for there remained in these places such marks as made the suspicion not improbable.

This most delightful and extraordinary sight lasted from 30 minutes past 10 to 51 minutes past 11, though it had not the same appearance all that while, but sometimes one and sometimes another. It appeared in the perfection of this description at about 11 o'clock, and then degenerated by degrees. The northern mock sun vanished first of all, together with a part of its circle; the other parhelia, with their arches, lasted till 10 minutes past 11; then the eastern mock sun, and after that the western, vanished with both the crosses. Soon after this, the collateral parhelia suffered several changes; sometimes one was brighter than the other, in light and colours, and sometimes fainter and darker; for at 18 minutes past 10, the eastern parhelion vanished, while the western parhelion remained very conspicuous; and at 24 minutes past 11, the eastern one was very bright again, and remained so, while the western one disappeared at 40 minutes past 11, although this western one had always the longer tail; for the tip of it was frequently extended for 30°, and sometimes 90°, but the tail of the eastern one was scarcely above 20°. At 30 minutes past 11 the great vertical circle which enclosed the small one next to the sun was destroyed, but the inverted arches, together with the collateral parhelia, continued to the last."

A halo of a different kind, and exhibiting all the prismatic colours, was discovered by Mr Huygens in 1652. "I observed," says he, "a circle about the sun as its centre; its diameter was about 46°, and its breadth the same as that of a common rainbow. It had also the same colours, though very weak, and scarcely discernible, but in a contrary order: the red being next the sun, and the blue being very dilute and whitish. All the space within the circle was possessed by a vapour duller than the rest of the air; of such a texture as to obscure the sky with a sort of continued cloud, but so thin that the colour of the blue sky appeared through it. The wind blew gently from the north."

Philosophers have agreed to ascribe those halos of 47° and 94°, such as so frequently occur in cold weather, and especially in northern regions, to the refraction of light produced by small particles of ice floating in the atmosphere. In freezing, water assumes a great variety of forms; and hence crystals of every conceivable shape are continually floating in the air, and giving rise to the numerous kinds of halos.

Halos may be artificially produced by crystallising various salts upon plates of glass. When the crystals are granular and properly formed, they will produce the finest effects. A few drops of a saturated solution of alum spread over a plate of glass so as to consolidate quickly, will cover it with an imperfect crust, consisting of flat octohedral crystals, scarcely visible to the eye. If an observer places the glass between him and the sun, or a candle, the clear surface being next the eye, he will perceive three fine halos at different distances encircling the source of light.

Among the luminous phenomena of the atmosphere, those of converging and diverging solar beams may be mentioned. The phenomenon of diverging beams is of frequent occurrence in summer, and when the sun is near the horizon. It is caused by a portion of the sun's rays passing through openings in the clouds whilst the adjacent portions are obstructed by the clouds. The phenomenon of converging rays is not of frequent occurrence, and is always seen opposite to the sun, and generally at the same time with the former phenomenon, as if another sun placed diametrically opposite to the real one were below the horizon, and threw off his divergent beams.

COLOURS OF BODIES.

It is to Sir Isaac Newton that we are indebted for the first scientific investigation of this interesting subject. Sir David Brewster considers Sir Isaac's theory of colours as applicable only to a small class of phenomena, while it leaves unexplained the colours of fluids and transparent solids, and all the beautiful hues of the vegetable kingdom. He observes, "In numerous experiments on the colours of leaves, and on the juices expressed from them, I have never been able to see the complementary colour which disappears, and I have almost invariably found that the transmitted and the reflected tint are the same. Whenever there was an appearance of two tints, I have found it to arise from their leaving two differently coloured juices existing in different sides of the leaf. The Newtonian theory is, we doubt not, applicable to the colour of the wings of insects, the feathers of birds, the scales of fishes, the oxidated films on metal and glass, and certain opalescences. The colours of vegetable life and those various kinds of solids, arise, we are persuaded, from a specific attraction which the particles of these bodies exercise over the differently coloured rays of light. It is by the light of the sun that the coloured juices of plants are elaborated, that the colours of bodies are changed, and that many chemical combinations and decompositions are effected. It is not easy to allow that such effects can be produced by the mere vibration of an ethereal medium; and we are forced, by this class of facts, to reason as if light was material. When a portion of light enters a body, and is never again seen, we are entitled to say that it is detained by some power exerted over the light by the particles of the body. That it is attracted by the particles, seems extremely probable; and that it enters into combination with them, and produces various chemical and physical effects, cannot well be doubted; and without knowing the manner in which this combination takes place, we may say that the light is absorbed, which is an accurate expression of the fact.

Now, in the case of water, glass, and other transparent bodies, the light which enters their substance has a certain small portion of its particles absorbed, and the greater part of it which escapes from absorption, and is transmitted, comes out colourless, because the particles have absorbed a proportional quantity of all the different rays which compose white light, or, what is the same thing, the body has absorbed white light.

In all coloured solids and fluids in which the transmitted light has a specific colour, the particles of the body have absorbed all the rays which constitute the complementary colour, detaining sometimes all the rays of a certain definite refrangibility, a portion of rays of other refrangibilities, and allowing other rays to escape entirely from absorption; all the rays thus stopped will form by their union a particular compound colour, which will be exactly complementary to the colour of the transmitted rays. In black bodies, such as coal, &c. all the rays which enter these substances are absorbed; and hence we see the reason why such bodies are more easily heated and inflamed by the action of the luminous rays. The influence exercised by heat and cooling upon the absorptive power of bodies, furnishes an additional support to the preceding views."

ABSORPTION OF LIGHT.

All bodies, even the most transparent in nature, absorb light, but philosophers have not as yet ascertained the power by which they do it. Some have thought that the particles of light are reflected in all directions by the particles of the absorbing body, or turned aside by the forces resident in the particles; while others are of opinion that they are detained by the body, and assimilated to its substance. The most absorptive body in nature is charcoal, then follow coal of all kinds, metals in general, and so on, air and gases being the lowest in the list. Some bodies, but very few in number, absorb all the rays of the spectrum in equal proportions; ink diluted is an example of this quality of bodies, and it was on this account applied by Sir William Herschel as a darkening substance for obtaining a white image of the sun.

There are many familiar instances of what are called accidental colours being seen. If a bright red wafer be placed upon a sheet of paper, and steadily looked at for some time, and the eye then withdrawn and fixed upon the white paper, a circular spot of bluish green light of the same size as the wafer will be seen. If the experiment be made with wafers of a different colour, other tints will be observable. The phenomenon is thus explained. When the eye has been for some time fixed upon one particular colour, the retina becomes as it were deadened to it, insensible to the particular rays which it reflects; and when it is turned upon the paper which throws off white light, it will see it of that colour which results from a mixture of all those colours but that to which it has become insensible.

Upon the subject of optical instruments it is impossible to present more details than those already given in a previous part of this paper. In Brewster's Optics, to which the reader is referred, they will be found fully treated of.

NATURAL THEOLOGY.

"ENDEAVOUR," says Isaac Watts, "to derive some instruction or improvement of the mind from every thing which you see or hear, from every thing which occurs in human life, from every thing within you or without you. Fetch down some knowledge from the clouds, the stars, the sun, the moon, and the revolutions of all the planets. Dig and draw up some valuable meditations from the depths of the earth, and search them through the vast oceans of water. Extract some intellectual improvement from the minerals and metals; from the wonders of nature among the vegetables and herbs, trees and flowers. Learn some lessons from the birds, and the beasts, and the meanest insect. Read the wisdom of God, and His admirable contrivance, in them all: read His Almighty power, His rich and various goodness, in all the works of His hands." And assuredly it is a great part of wisdom to draw a lesson from every thing we see around us and above us, and appertaining to the universe to which we also belong. There is no lesson more important than the one conveyed with greater or less force by every department of nature; a lesson which must strongly inculcate the truth of the existence of an all-wise and infinitely good God, who was at first the author, and has ever since been the upholder, of all things. That this truth should ever have been doubted, might surprise us, even though we were extremely ignorant of the arguments by which it has been confirmed. And it is well worthy of remark, as showing the depth and solidity of the foundation on which rests the existence of a supreme, intelligent, and beneficent First Cause, that the farther we push our discoveries, the more clearly are the divine perfections exhibited. It is not merely true, that, on a superficial view, we perceive the necessity of believing that a limited and changing world, such as that on which we dwell, could neither exist without being produced, nor be the author of its own existence; and that there must, therefore, be, beyond the range of our senses, an independent and uncreated essence, without beginning, without bounds, incapable of change, intelligent, ever-active, all-pervading; but it is also certain, that those *primâ facie* views, as they may be called, are not only uncontradicted, but fully established by the most minute survey of the objects within the sphere of our vision; so that he who penetrates the deepest into the secrets of nature, only multiplies proofs of that most sublime and most animating truth, that "verily there is a God" who made and rules the universe. It is difficult to understand that strange moral obtuseness which has induced a certain class of writers to reject this; for grant but one assertion, which is—and it is not easily to be questioned—that wherever there exist indisputable traces of design, planned with wisdom, directed by goodness, and accomplished by power, there also must of necessity have been a wise, a good, and a powerful designer.

Let us suppose ourselves cast ashore upon some island previously unknown to us; we immediately proceed to examine the appearances which present themselves, in order to discover if any traces exist of human inhabitants. To ascertain that if such beings did there exist, it would not be necessary that they should actually be seen by us. In our wanderings we might come upon a hut bearing all the marks of occupation; we might see the roots of the trees which had been felled to form it, and other tokens of the recent presence of man upon the spot; and did we desire to discover something of their character and habits before we presented ourselves to their notice, it is most probable that sufficient data would be also afforded on which to found an opinion. Were the habitations we discovered merely wigwams, or such enclosures destitute of the conveniences of civilised life, or were the furniture, the weapons, or the instruments in and around them, such as barbarous nations generally use, we might reasonably argue that we had found the dwelling of an untamed savage. But if, instead of this, we find the surrounding land trenched, enclosed, and cultivated; should we find the common articles of European husbandry and the common utensils of an European household, we should naturally draw the inference that we had reached the abode of an emigrant, who had thus reared around him the attributes of civilised life. Much more, a few additional observations might reveal to us and enable us to form conjectures, bearing the aspect of probability, concerning the people among whom we had fallen. Now, it is in this way alone that we can argue respecting the Author of all things, and discover proofs and demonstrations of a first supreme cause. To prove that the formation of all things was the result of design, it is only necessary to show that they are in general, or in so far as we can discover, admirably suited to the uses and purposes to which they are to be applied—that their arrangement is perfectly harmonious, and that it is impossible that any chance could have thrown them together in a way so happy. To discover if this design can be evidenced or demonstrated, it is necessary to seek through the various works of creation with which we are surrounded; and the more minute we make our inspection, the more likely shall we be to perceive the deduction. If there be some departments to which our senses have a readier access than to others, and which we can therefore more readily examine, from these especially we ought to deduce our result. It may be that we shall find many things, which, from the deficiency of our observing faculties, we cannot understand, nor discover the uses nor consequent design which they display; but still, if, in the course of our inspection, particularly of bodies which we can observe minutely, we find every part admirably adapted for a specific purpose, and teeming with the most convincing evidences of design, then we may with safety and true philosophy infer that in those objects, which, from their nature and our imperfection, we cannot so completely investigate, a greater degree of light would tend to confirm the result to which our previous observations, among other things, had led us.

DESIGN IN THE PLANETARY SYSTEM.

We now proceed to contemplate the various kingdoms of nature, beginning with the most sublime of all, the Starry Heavens; in which, if we do not find the very best field for the discovery of design, we shall at least perceive the footsteps of a God, a beneficent First Cause, an originator and maker of all, alike infinite in skill to plan and in power to create.

To the uninstructed eye, the earth which we inhabit appears on a clear night to be surrounded by a numerous host of radiant points, which, rising in the east, move majestically through the sky until they reach the western horizon, when they set or disappear; and so completely does this idea commend itself to the mind of an observer, that it requires a considerable effort to conceive how it can be otherwise. But science has taught us that this is a mere illusion, and the discoveries of Copernicus and Sir Isaac Newton have established the truth suggested by Pythagoras upwards of 2000 years before the time of either of them, that the apparent motion of the heavens is the consequence of the real revolution of the earth every twenty-four hours upon its axis; that, with relation to the earth, the sun is stationary, while the earth every year completes a journey round him; that the planets are globes similar to our own, revolving at once upon their own axis, and round the sun; that the moon is a satellite or attendant upon the earth, accompanying it in its course, and at the same time describing every month a circular orbit round it; and that to several of the planets are attached similar moons or satellites, bearing to them a corresponding relation.

By turning to our article ASTRONOMY, in which the number of the planets, and their distances from the sun, with other particulars, are noted, it will be seen that the earth which we inhabit is but a very small point, even in the solar system (as the concourse of planets round the sun has been called), and that it forms but a part of one magnificent and resplendent whole. But to ascertain the marks of a designing mind in this mighty mass of brilliant wonders, let us turn our attention to some of those particulars regarding them with which we are acquainted; and it must be confessed, that, if we are to suppose them mere masses of matter unclothed with aught bearing analogy to our vegetable productions, and uninhabited by beings either sentient or rational, it will be difficult to see why any of the arrangements connected with these bodies, so far at least as they themselves are concerned, and apart from their attractive influence upon our own world, should be either beneficial or the contrary. It is solely on the *conjecture* that there are organised beings on their surface to be warmed, and nourished, and upheld, that we can argue regarding such arrangements; and making this conjecture, we shall find that there are some very remarkable apparent contrivances for ministering to their comfort and happiness. It has been supposed that a planet so far distant as Herschel, or even Jupiter or Saturn, must suffer from an extreme deficiency both of light and heat; and hence it has been argued that they are necessarily unfit for the sustenance either of animal or of vegetable life. But when we consider that even Herschel, the most distant from the sun, possesses 248 times the light afforded by our full moon, it will not be difficult to believe, that, with a somewhat more acute power of vision than we possess, the inhabitants of that planet, if formed like ourselves, may be quite able to engage in employments which require considerable minuteness of perception. Besides, to compensate for the deficiency of light derived directly from the sun to this planet in common with Jupiter and Saturn, there is afforded the subsidiary benefit of several moons or satellites to reflect light upon the surface when the sun has withdrawn his beams; neither is it probable that the inhabitants should miserably perish from cold; for, putting out of view the possibility that they may be formed with constitutions adapted to a more frigid climate than that of any portion of our world, we must remember that heat is not dependent altogether upon the body from which it originates, but is regulated in a very great measure by the nature of the body to which it is transmitted. Keeping this in view, the planet Mercury may be as cool, and Herschel as warm, as our own globe, although they be at such different distances from the great source of heat. This, however, can be the subject of conjecture alone; and it is only valuable, as showing that we have no reason to suspect the goodness of the Creator in having placed some of his worlds in situations which, at first sight, might be supposed necessarily incapable of affording even the most essential accommodations to organic existences.

Of all the planets, Saturn presents us with the most singular example of design in reference to this subject. When viewed through a telescope, this beautiful orb is seen to be surrounded by a double circle 30,000 miles distant from any part of its surface. This apparatus consists of two concentric rings, separated from each other by a space nearly 3000 miles in breadth, and moving round the planet at the extraordinary rate of a thousand miles a minute. Now, there is one use of this appendage, whatever may be its other purposes, which is very apparent: it must contribute much to enlighten and beautify the globe to which it is attached; and a very little reflection will show the effect it must have in this respect. What a magnificent brilliant spectacle must these rings present to the inhabitants of Saturn! During its more than fourteen years of summer, the night must be enlivened by the bright reflection of this brilliant arch extending its luminous curve from the eastern to the western horizon; while even during the day, the sun must be materially aided by it in shedding light upon the world to which it belongs. "There is no planet in the solar system," says a late writer, "whose firmament will present such a variety of splendid and magnificent objects as that of Saturn. The various aspects of his seven moons, one rising above the horizon while another is setting; a third approaching the meridian; one entering into an eclipse, and another emerging from it; one appearing as a crescent, and another with a gibbous phase; and sometimes the whole of them shining together in one bright assembly: the majestic motions of the rings, at one time illuminating the sky with their splendour, and eclipsing the stars; at another, casting a deep shade over certain portions of the planet, and unveiling to view the wonders of the starry firmament, are scenes worthy of the majesty of the Divine Being to unfold, and the rational creature to contemplate." Of the other planets it is unnecessary individually to speak; our knowledge of them is extremely limited, and we may simply remark, that, in most of them, the same causes exist which in our globe produce the various seasons. To the causes of the seasons, further than that they are the result of the influences of the celestial bodies, we will not here allude to. To the arrangement of these, and to the forethought and all-pervading knowledge and goodness of Him who designed them, are we, in a word, indebted for the opening beauties of spring—the full glow of summer, arrayed in flowers and clothed with verdure—the sober and sear leaves of autumn, with its aureate fields and happy harvests—and the cold but not desolate winter, which even in its frigidity serves a valuable purpose in the scheme of the natural world.

In these arrangements, we see proofs of the care, the power, and the beneficence of that great Being who was the cause of all things. To what else, indeed, shall we trace the primary fact, that, of all the heavenly bodies connected with our system, the sun alone, situated as he is in the centre, possesses undivided light, while the planets which surround him are all dark bodies receiving their light from him? There is no reason, in the nature of things, why a body placed in the centre of a system should give forth light and heat, while those revolving round it should be destitute of them. And yet we find it to be so: and we perceive the consequence of this arrangement to be not only most beneficial, but absolutely indispensable to the existence of the organic beings with which these orbs may be clothed or peopled.

But there is another view of the system of worlds to which our earth belongs, that strongly corroborates the existence of a creating and presiding Being. We mean the provision which is made for its perpetuity. Notwithstanding the existence of so many conflicting forces, any one of which, if the system were differently arranged to what we find it to be, might in the course of ages derange the relations which the different bodies composing it possess towards each other, and precipitate the whole into confusion, only equalled by that chaos from which, by might and power, it was called. It will hardly be necessary minutely to explain the causes by which the earth and the other planets are kept in a continual state of rotation round the sun; but as perspicuity is one of the chief objects at which we aim, a few words on this subject will not be out of place. Let it be understood, then, that in every body of matter there exists a certain tendency to rush towards every other body, and that the larger, and denser, and nearer, any two bodies are, the greater is that tendency, and it will easily be comprehended that the sun, the largest of all the bodies in our system, should attract every other orb with a degree of force regulated by the size, the density, and the distance of each; so that, had all these bodies at first been placed in a state of rest in the universe, they would immediately have begun to move towards the sun, and thus, in the course of time, would, one after the other, have reached and been amalgamated with him in the form of one vast and irregular mass. But at the creation, this result was prevented by communicating to the planets an impulse at right angles to the diameter of their orbits, which, combining with the force of attraction—that is, the power of the sun in drawing or attracting the planets towards himself—caused the planets to revolve round the sun. If each of the planets, however, were to revolve round the sun, with no other prevailing power to interfere with their motions except these two, viz. the attraction of the sun, and the original impulse at creation, they would of course continue as they are throughout all ages; but this is not the case. In the words of Mr Whewell, "each of them is acted on by all the rest. The earth is constantly drawn by Venus, by Mars, by Jupiter, bodies of various magnitudes perpetually changing their distances and positions with respect to the earth. The earth, in return, is perpetually drawing these bodies. What in the course of time will be the result? The cause acts perpetually, and it has the whole extent of time to work in. Is it not, then, easily conceivable, that, in the lapse of ages, the derangements of the planets may accumulate, their orbits may change their form, their mutual distances may be much increased or much diminished? Is it not possible that these changes may go on without limit, and end in the complete subversion and ruin of the system?" What might have been the case had the balance of powers, so to speak, in our system, been differently disposed, it is not easy to say; but that all which is here suggested as possible, would actually take place, were a capricious or ignorant hand to interfere in the distribution of these forces, may assuredly be affirmed. We should soon have "years of unequal length and seasons of capricious temperature; planets and moons of portentous size and aspect, glaring and disappearing at uncertain intervals; tides like deluges sweeping over whole continents; and, perhaps, the collision of two planets, and the consequent destruction of all organisation in them both." As the solar system exists, however, so nicely is it adjusted, that the deep inquiries of several of the philosophers of the last century, founded on the most complicated calculations, have shown that its arrangements are stable—that although there are and may be perturbations, there are invariably proportionate compensations; so that, whenever a maximum has been reached in the derangements of the system, it must necessarily begin to revert to its ancient order, and the restoration must in the end be as complete as was the derangement. It would require a hardihood greater than we can easily conceive to exist in the human mind, to view this subject, and to deny, after all, that a perfectly wise, beneficent, and powerful being, originally made and has since sustained and governed all things; for had the original impulse of which we have spoken been a little stronger or a little weaker—had the relative inclination of the orbits of the planets to one another been greater—had one or more of them moved in a direction opposite to the rest—had any one of these causes operated, the whole solar system must sooner or later have been precipitated into chaotic confusion. Will any man, then, deny the proof here afforded of design and skill?

We cannot leave the heavenly bodies without adverting to the fixed stars; and if little be known respecting the planets, still less has been ascertained regarding these more distant bodies. But it is by no means an unedifying employment to contemplate, through them, the immensity of creation, and, thus elevated, to draw the conclusion that the Being by whom they originated must indeed be infinitely glorious. Had there been no other design on His part than thus to strike the mind of man with a sense of His magnificence and grandeur, no surer method could have been adopted to impart the lesson. The mind is bewildered when it dwells upon the glories which astronomy developes; and it cannot find words lofty enough to express its sense of the intelligence it discovers, or the proofs of the power and wisdom and goodness it perceives.

RELATIONS BETWEEN MAN AND EXTERNAL NATURE.

Leaving the evidences of design that are to be deduced from the contemplation of the heavens, let us regard some of the relations that exist between man and external nature, and consider the wonderful adaptations to each other which they exhibit. There can be no blank in nature, and, consequently, no body is isolated; all more or less influence each other, and it is of some of these relative influences that we are about to speak. Man is attached by the laws of gravitation to the earth which he inhabits, and is surrounded by an atmospheric medium capable of exercising certain influences upon him; these influences are modified by the Almighty Power to be subservient to his wants, and *designed* to be adapted not only to his necessities, but to those of every living thing, whether plant or animal, that exists. The air which surrounds us exercises, in consequence of its extent, a pressure on the human body equal to about 33,600 pounds. But why do we not sink and miserably perish beneath this immense weight? It is by the reaction of the elastic fluids contained within our bodies that we are enabled to support so enormous a pressure. Here we find a mutual relation between us and the air, which cannot be interrupted without mutual injury. Suppose this weight to be withdrawn from our bodies, what would be the result? The expansibility of the fluids contained within us would have no restraint; they would dilate, burst through the solids which contain them, and destroy the individual. Place any animal beneath the receiver of an air-pump, and withdraw the air, the result is very apparent. One of the causes of the inconveniences that are experienced when on the summit of a very high mountain, is, that the air is less dense, and does not oppose so much pressure to the body; and this, too, occasions the violent bleedings from the ears, eyes, and mouth, that sometimes attack those so situated. The effect of a cupping-glass, when applied to the skin, has the same cause. We feel more or less the effects of any sudden change of atmospheric pressure, but still the density of the air is well adapted to the wants of man; had it been greater, our energies would have been oppressed as by an unnatural load; and if less, insufficiently sustained as by a defective support. The senses of hearing and smelling, too, which depend for their perfection on a medium density of the air, would have either been insupportably intense or defective. Again, the atmospheric pressure materially affects temperature. If a certain quantity of air contains a certain quantity of heat, it is clear that it must be equally diffused throughout it; and if the same air be contained in less bulk, or if the pressure be greater, the heat is increased in the same ratio. In the same manner, if the pressure be lessened, the air expands, and with it the heat is diffused over a greater surface. By compressing air, we can produce a sufficient concentration of heat to produce ignition. This influence of the air upon the body is as universal as the former, and the adaptation of the one to the other as constant. With the exception of some countries near the equator, and there only in the hot season and the middle of the day, the temperature of the atmosphere is always below that of man; and as heat always tends towards an equilibrium, it is obvious that a constant subtraction of heat from the body must be going on. Now, we are so organised as to allow of this universal subtraction; and, indeed, were it suddenly stopped, or even diminished, we should soon perish. Again, if the subtraction became increased, or went on more rapidly than the vital principle could replace it, our temperature would sink, our humours and fluids freeze, and in this case, too, we should soon perish. But there are intermediate points between these two extremes; and as we before said, our organisation is such that it adapts itself to the degree. All organic bodies are capable of resisting to an extraordinary extent, and of modifying the action of, heat and cold; indeed, this principle of self-preservation is in them so striking as to have been regarded from a very early period as the most essential attribute of life. The power possessed by the higher classes of animals, of preserving a more or less uniform degree of heat, is almost unlimited. In very cold climates, the thermometer not unfrequently sinks to 50° or 55° below the freezing point, while in very hot ones it is sometimes 120° or 125° above it, making a difference of 170° or 180°; still, however, the temperature of the body remains unchanged. What unanswerable evidence of design is this, and how limitless must be that Power who could create such wonderful adaptations!

If the atmospheric pressure produces in some measure the regulation of heat and cold, in no less degree does it affect moisture and its concomitants—clouds, mist, rain, snow, and hail; and thus we are dependant for many of our comforts and for most of our necessities upon the due adjustment of atmospheric influences. Winds, too, arise from any unwonted atmospheric pressure disturbing the equilibrium of the atmosphere, and are the efforts of nature to restore the balance. All the changes of weather, the most violent storms and tempests, own the same cause; and why the whole machinery—if we may use the term—is not utterly destroyed, its balance lost—why

> "Hot, cold, moist, and dry, four champions fierce
> Striving for mastery, bringing to battle
> Their embryon atoms,"

do not annihilate the world, and reduce it to its pristine chaos, is, that it is a God who rules, and who in his mercy has so adapted cause and effect, that they shall regulate each other, and blend together in harmonious concord.

Connected with this subject, as evidencing design, is the composition of the air, which is precisely that best adapted to support respiration. It consists, besides small proportions of aqueous vapour and carbon, of two fluids, or gases, called oxygen and nitrogen. In a separate state these gases are inimical to life. Lavoisier proved by experiment that pure air, or oxygen gas, if respired for a certain time, rarifies the blood too much, and increases the rapidity of the circulation, the effects of which are violent fever, inflammation of the lungs, and death. Nitrogen is equally destructive to life, as not yielding that principle on which the purification of the blood depends. It is their combination that renders them salutary to the constitution, neither consuming life by too much stimulus and excitement, nor deadening its energies by a languid circulation and depression of spirits. Why should the air have been composed exactly of twenty-one parts of oxygen and seventy-nine of nitrogen? Why were all other proportions excluded? It could not have been owing to a blind and fortuitous chance. The fact that we find two deadly ingredients so united as to become not only harmless, but salutary, must strike every mind with an unanswerable evidence of design. Atmospheric air is absolutely necessary both to animal and vegetable life, and both classes of beings are fully adapted for its reception. The boldest Epicurean could scarcely imagine that so necessary a substance has by mere chance surrounded this globe for the support of its inhabitants, upon whom, without it, God would have bestowed his power and wisdom and goodness in vain; nay, even had men, according to the doctrine of Epicurus, sprung up like mushrooms from the earth without an atmosphere, they could not have existed upon it. Has not, then, the hand of a wise Creator been here visibly employed, or why were we supplied with instruments that render the air available to us?—enabling us to resist its dreadful pressure, and to avail ourselves of its unutterable advantages. If we contemplate for a moment the evils which would have followed had not divine intelligence presided at the constitution of our globe, and placed an atmosphere around it, how fearful and dreary it would have been! The moon has no atmosphere, and hence its climate must be very extraordinary: either the fiercest sunshine must reign, or the keenest frosts endure. If our earth had been similarly situated, no organic being would have adorned its surface; neither plant nor animal could have existed; no reflection of light could have taken place; no dawn or twilight would have prepared us for morning or for night; a dome blacker than darkness would have surrounded the earth, and light only have become manifest when the eye received it directly from the sun. The blue sky which now surrounds us, and which is owing to the thin watery vapours floating in the atmosphere, and reflecting peculiar rays of light, the blue and the violet, would not have been there. And where can we find such evidences of design as the blue colour which the sky exhibits? Of all hues we could imagine, is there any to surpass that mild and soft ethereal tint, harmonising with all around us, and on which the eye, fatigued with more brilliant and dazzling objects, turns for relief and repose? The unbeliever may say that this colour was the result of chance; but suppose any other, a bright yellow, a dazzling white, a glaring red, a fearful colour, how uncomfortable and painful would it have been for the vision of man! Again, an atmosphere is necessary to hearing; it enlarges the field of vision, and contributes also to the means of smell: and not only do the beings on earth enjoy life through its means, but it contributes to the sustenance of the finny tribes, enabling them not only to exist, but to rest in the water, or ascend and descend in it in quest of food.

There are still other relations existing between men and external nature, to which we would shortly allude as illustrative of design; and they are such, that without them certain important functions could not be performed, and, consequently, man could not exist. These relations, which may be termed *organic*, are the more numerous and necessary to life, as the organisation of the individual is the more developed or complete; and while they may be all included in the two functions of nutrition and sensation, they are the more multiplied as the operations of the former are more complex, and the extension of the latter greater; and hence they are more numerous in man than in any other animal. As in the physical relations, to some of which we have already alluded, so in the organic we must assign the first rank to the atmosphere, so necessary to life and so admirably adapted to sustain it. It is the medium, also, through which we receive heat, light, and electricity, of which we appear to be as much in need as of that principle of air which purifies our blood, and fits it for the performance of its several operations. These matters are inherent in all living bodies; and if simple elementary bodies do exist, these are they. Many physiologists recognise the greatest analogy between the nervous fluid and electricity, and there is great reason for believing that it assists considerably in the maintenance of the vital phenomena. We know, however, that all these agents exercise a great influence upon life, from the demand that living bodies make upon them. Observe how plants languish and become weak when deprived of light, and how solicitously they move in the direction that will the most expose them to its invigorating influence. Nor is it less necessary to animal existence. Eggs cannot be hatched when deprived of it; and the transformations to which many insects are exposed, go on more slowly when in a darkened place. But let us suppose that this element was only given for the purpose of enlightening the earth, what a wonderful relation, then, does it bear to the eye which perceives it! No one who considers the eye attentively can resist the impression of the evidence of design and skill which its construction exhibits. At the same time, it must be obvious that this construction of the eye would not answer its purposes, unless the constitution of light corresponded to it. Light is an element of the most peculiar kind and properties, and such an element can hardly be conceived to have been placed in the universe without some regard to its operations and functions. As the eye is made for light, so light must have been made, at least among other ends, for the eye. What we have said of light is equally applicable to colour. It is obvious that the vital energy of plants is much diminished, even suspended, during winter, while with the return of summer they again shoot forth their leaves and flowers; the same alternation obtains also among hybernating animals. Heat is evidently the cause of these changes; so much so, indeed, that vegetables may be forced to invert the order of the seasons. The climates in fact demonstrate the influence of heat. How stunted is both animal and vegetable life in polar regions, and how exuberant do the same individuals become under warmer skies. Electricity undoubtedly exists in the atmosphere in all its states; but we know very imperfectly the laws of this agent, and are still more ignorant of its atmospheric operation. The present state of science, while it permits us to hazard an opinion, does not enable us to perceive those adaptations of its laws to its uses, which we can discover in those cases where the laws and the uses are both of them more apparent. "It is at any rate very probable," says Whewell, "that electricity has its important purposes in the economy of the atmosphere. And this being so, we may see a use in the thunderstorm and the stroke of the lightning. These violent events are, with regard to the electricity of the atmosphere, what winds are with regard to heat and moisture. They restore the equilibrium where it has been disturbed, and carry the fluid from places where it is superfluous, to others where it is deficient. We are so constituted, however, that these crises impress every one with a feeling of awe. The deep lowering of the gloom of the thundercloud, the overwhelming burst of the explosion, the flash from which the steadiest eye shrinks, and the irresistible arrow of the lightning which no earthly substance can withstand, speak of something fearful, even independently of the personal danger which they may whisper. They convey, far more than any other appearance does, the idea of a superior and mighty Power, manifesting displeasure and threatening punishment. Yet we find that this is not the language which they speak to the physical inquirer; he sees these formidable symptoms only as the means or the consequences of good. What office the thunderbolt and the whirlwind may have in the *moral* world, we cannot here discuss; but certainly *he* must speculate as far beyond the limits of philosophy as of piety, who pretends to have learnt that these work more of evil than of good. In the *natural* world, these apparently destructive agents are, like all other movements and appearances of the atmosphere, parts of a great scheme, of which every discoverable purpose is marked with beneficence as well as wisdom."

We think we have now sufficiently shown the wonderful adaptations and relations that exist between some of the phenomena of external nature and organised existences. It does not accord with our purpose to enter deeply or at greater length into the subject, but even the little we have said, must, we hope, carry with it the conviction, that verily it is a God who made and rules the universe.

DESIGN IN THE STRUCTURE OF THE EARTH.

In considering the structure and theory of the earth, we cannot but perceive many evidences in the adaptations these discover to the beings which inhabit it; and this alone will show that the whole must have been the result of a superior and intelligent Being, whose powers our senses are inadequate to conceive or to understand. Still it is not surprising that many should be led into the general opinion, that the study of the mineral kingdom is a dry and uninteresting one. The mere inspection of minerals, and the business of labelling and assorting them according to certain artificial systems, are no doubt very mechanical employments. But yet there is not a more philosophical study than that of geology, or one that is calculated to impress the mind more forcibly with the power, and majesty, and awful justice of a great and superintending Being. In studying geology, if we open our eyes to plain facts that are every day before us, and look through the unprejudiced medium of our senses, avoiding the doctrines of inveterate theorists, we cannot fail to perceive that the world must at first have been called into existence, and fashioned into land and water, mountain and valley, by the direct fiat of an omnipotent Creator; and that, from the very nature of things, and the physical laws of matter, it could not have been so arranged from any inherent influence of mere matter itself. We shall see that after this world had been formed, and existed for a considerable space—that after it had been clothed with luxuriant vegetation, and peopled with myriads of all classes of living beings, a great and sudden catastrophe must have taken place by which the face of the earth was completely overwhelmed, and every plant and animal swept off and scattered amid the general wreck, throughout every quarter of the deluged sphere. We shall find that after this a new order of things arose—that new soil and new vegetation began gradually to cover the devastated globe, and that animated beings again enlivened its dismal solitudes. We shall find, too, what is a very singular circumstance, that a great proportion of the plants and animals of the old and antediluvian world differ entirely from the vegetation and the animated beings at present existing on this globe. As far as the investigation of fossil remains has yet gone, and the number of species already amounts to some hundreds, the entire difference of many of these from any species now extant is quite apparent.

From a minute examination of our coal-fields, it is allowed that coal is an accumulation of vegetable matter, subjected to long chemical action under considerable pressure, and excluded from the influence of the atmosphere. In many coal strata, the remains of leaves, and stems, and large trunks of vegetables, are every day found, evidently component parts of this mass: and when a thin piece of pitch coal is pared off with a sharp knife, and examined with a microscope, the woody fibre and texture is distinctly visible. Now, all our coal-beds must be the accumulated remains of antediluvian vegetation, for they are uniformly found covered by an earthy stratum, that bears all the marks of having been accumulated and deposited by water. Thus we observe a beautiful provision of nature, which has stored up the luxuriant vegetation of tropical climates, and of long-forgotten ages, as it were in cellars, to cheer the gloom and enliven the long wintry periods of these our northern regions. It is also to these diluvian currents that we owe a great many of the stratified masses of our most useful and most easily wrought quarrying-stones for the purposes of architecture; as, for instance, most of our sandstones, and in all probability many of our newer limestones.

It is vain and absurd to endeavour to explain the first formation of the earth, upon the presumption that it was originally a fluid or a smooth sphere, or to attempt to describe the manner in which the various rocks and minerals assumed form and identity. With equal reason might we speculate upon the manner in which the first human body organized its bones, and muscles, and arteries, and skin. The true province of geology consists in marking the present state of the earth's surface, and in tracing, as far as facts justify our conclusions, the changes that have there occurred. A prevailing opinion of the present day seems to be, that the earth is infinitely older than history describes it, having remained for ages an uninhabited mass, previously to the existence of plants and animals; and that, instead of one great catastrophe or deluge, it has suffered various local and partial changes, whereby its surface has been greatly altered. Another opinion is, that a series of operations is continually going on, by which an incessant change is brought about in every portion of the globe, and that this may have commenced at the creation, an indefinite period in past time, and may go on perpetually without limits as to future time. In whatever manner the changes may have been effected upon the body of the earth, it is at least obvious that these changes have operated to the benefit of mankind. Ample deposits of coal and metals have thus been formed at commodious depths from the surface, which cannot be ascribed to mere chance, but must have taken place through the agency of laws framed by the Creator for a beneficent purpose.

DESIGN IN ANIMAL PHYSIOLOGY.

The earth, whose structure we have just briefly noticed, serves as the place of habitation for two kinds of existences—the animal and vegetable—in whose formation and functions we discover the beautiful dispensations of Providence, extending on every side over a vast range of beings, and demonstrating the unity of plan on which organised creation has been devised. And, first, the whole circle of our knowledge does not afford greater evidence of design than comparative anatomy; in it we find innumerable contrivances for the comfort and happiness of the different tribes of beings adapted to the peculiarities of their condition; in each animal we see the same organ repeated, but modified to render it more available to the habits of its possessor; and among all the wonders of creation, there are none which strike the inquiring mind more forcibly than this change or modification of formation for the obvious purpose of accommodation to circumstances. Were all animals formed alike, or did the differences which exist between them bear no relation to their habits or destinies, it would be less easy to refute the doctrine which assigns all things to material causes, and excludes the designing hand of an intelligent Creator. Although even then the argument would be totally untenable, still the demonstration which disproves it would have been less satisfactory and perfect, as the surprising skill and beneficent care by which the structure of every animal is adapted to its individual habits and necessities, could not have been so well displayed. A single tool in the hands of the carpenter is a proof of contrivance, but that proof is much multiplied and rendered more forcible when we find the same instrument modified into a thousand forms to suit the different operations of the workman. Few of the functions of animated beings better illustrate this than that of alimentation, which we shall now briefly trace, though the humble zoophytes and worms up to birds and mammiferous animals. This may add to the number of the instances of obvious design we may adduce; but this and thousands more would merely give us a faint idea of the stupendous extent of the wisdom and goodness of God which the animal creation displays. Nutrition is common to all animals without exception; and the numerous and varied modifications of the means employed to effect it, are obvious proofs of the design and intelligence of the Creator. There are some animals so nearly allied to plants as to be scarcely distinguishable from them; and in these, as in them, nutritive matter is in like manner introduced by mere imbibition. Fixed like plants to the spot where they grow, any other organs would have been superfluous; while to those which are not so attached, but seek their food and obtain it through their locomotive powers, organs for seizing and preparing it are necessary. In them, therefore, we find lips variously and curiously modified; glands about the mouth for furnishing fluids for lubricating dry alimentary matters; a tongue, or something analogous to it; teeth and jaws for breaking down hard substances, and rendering them fit for swallowing; with a passage called the œsophagus, or gullet, leading from the mouth to the stomach, in which the food is at last assimilated, and rendered fit for nourishing the animal. But it is not until we advance some way in the great chain of animal life that these parts become sufficiently obvious, or their offices clearly defined. In quite the lowest orders, the mouth and stomach are one continuous tube, or all stomach, as it may be called, and so simple in construction, that the animal may be turned inside out without detriment to it; that which was external being now internal, and performing, apparently with equal facility, all the offices of what was previously the stomach. As we advance, however, we find the nutritive organs ceasing to be a mere sucking apparatus, or a receptacle for imbibed fluids. In those whelks which are furnished with proboscides, we find its cavity occupied by the aperture of the œsophagus, a tongue, and teeth; while the snail possesses a perfectly formed mouth and lips. Among the worms, whose stomachs are generally membranous bags, we find examples of wonderful contrivance and design. Thus, the powerful stomach of one species contains three hard calcareous shells, by which the individual is enabled to bruise and masticate the shelled animals on which it feeds. The discoveries of Ehrenberg respecting the animalculæ inhabiting different vegetable infusions, have extended, in an extraordinary degree, our knowledge of the stupendous power of God; and the inimitable proofs of design displayed in beings to whom, in relative size, the mite is as an elephant, afford astonishing displays of a minute and most beneficent attention to the preservation of these curious creatures, in whose organisation and instincts new and admirable indications of creative wisdom are revealed. By the aid of the microscope, we are enabled to perceive the Creator of the universe minutely busy among the worlds of living creatures to which he has given birth on a blade of grass, or in a drop of water, and to discover fresh scenes of wonder, and interest, and evident design, among hosts of animated beings, infinite in number as in minuteness. These discoveries, of which an able analysis was lately given by Dr Gairdner in the Edinburgh New Philosophical Journal, have dissipated the obscurity in which the animalculæ were plunged, and displayed the wonders of their organisation. To render their digestive organs more conspicuous, he supplied them with coloured food, which communicated its tinge to the cavities through which it passed. The moment a minute particle of a highly attenuated solution of pure indigo was applied to the drop of water on the field of the microscope, in which were some of the infusory animalcules, the most beautiful phenomena presented themselves. Presently their bodies, which had been hitherto quite transparent, became dotted with a number of spots of a dark blue colour, evidently produced by particles of indigo accumulated in these situations. In some species, particularly those which had a contracted part, or neck, between the head and the body, these particles were to be traced in a continuous line in their progress from the mouth to these internal cavities. In this way, by the employment of colouring matters, Ehrenberg succeeded in ascertaining the existence of a system of digestive cavities in all the known species of this tribe of animals; one of the largest of which he found to possess a highly complicated structure with regard to many organs: with respect to the nutritive function, he found a head provided with a regular apparatus for mastication, consisting of jaws having from two to six teeth, which were seen actively opening and shutting when the animal was taking its food.

As we ascend higher in the scale of existence, we find the digestive apparatus ceasing to be simple cavities, or canals hollowed out of the substance of the body, and becoming distinct organs formed by membranes and coats proper to each; and among these, the first example occurs in the sea anemone, in which we find spaces intervening between the coats of the stomach and the skin of the animal: here, however, the stomach is still a blind pouch, one aperture serving alike for receiving and ejecting the alimentary matters. In the *echini* or sea-urchins these organs are still more perfect. Those of mastication are peculiarly developed; an œsophagus or gullet also presents itself, and a stomach continued into a regular intestine, which takes two turns in the body before it terminates.

DESIGN IN THE FORMATION OF INSECTS.

In the digestive organs of insects we meet with a multitude of new and peculiar formations, while most of the simple forms found in the lower animals are here repeated. The organs of mastication, deglutition, and suction, present such remarkable differences, that the arrangements of modern systems of entomology have been chiefly founded on them. In this order of animals, nutrition by vegetable substances is much more common than in those below it; indeed, as Blumenbach has observed, the business of nutrition in insects does not seem to have for its object the mere preservation of the individual, as in most red-blooded animals, but chiefly the consumption of organised matter, which will appear from considering the structure of their alimentary canal. In most of those which are subject to a metamorphosis, the stomach in the larva state is of a great size in comparison with the short intestinal canal; while those, on the contrary, which take little or no nourishment in their perfect state, have this organ remarkably diminished, and, as it were, contracted. How beautifully does the great size and straight course of the intestinal apparatus of the animal, when in its caterpillar state, coincide with its enormous voracity and quick digestion! It has been computed that caterpillars sometimes devour and digest no less than three times their own weight of aliment in four-and-twenty hours. On the other hand, during the subsequent metamorphosis which the animal undergoes, no food is taken; but nature, or rather the God of nature, has wonderfully, and with beneficent design, provided against any necessity for this, by causing insects to become very fat, as observed by Malpighi, on the approach of these changes; so that this fat, being absorbed into the blood while these are going on, serves all the purposes of a supply of alimentary matters from without. The insects now under consideration exhibit at different periods of their existence the greatest contrasts, not only in external form, but also in their habits, instincts, and modes of subsistence. The larva, as we have seen, is remarkable for its voracity, requiring large supplies of food, and consuming enormous quantities of vegetable matter; the perfect insect or butterfly, having attained its full dimensions, is sufficiently supported by small quantities of a more nutritious food, consisting either of animal juices or of the fluids prepared by flowers, which are generally of a saccharine quality, and contain nourishment in a highly concentrated form. It is evident that the same apparatus which is necessary for the digestion of the bulky food taken in during the former period, would not be suited for the assimilation of that which is received during the latter; and that, in order to accommodate it to this altered condition of its function, considerable changes must be made in its structure. Who can believe that these changes are made without wisdom, or persuade themselves that all this is to be brought about by causes divested of knowledge and understanding? Dr Roget, in his admirable Bridgewater Treatise, has beautifully illustrated the subject, by very clear and correct drawings by Mr Newport, of the three different states of the entire alimentary canal of the privet hawkmoth (*Sphinx ligustri*): first, when a caterpillar; then as a chrysalis; and, lastly, as the moth: and of these, taking our text from Roget, or rather from Herold, we shall endeavour to give some account. We have seen that in the caterpillar the stomach forms by far the most considerable portion of the alimentary canal, bearing some resemblance in its structure and capacity to the stomachs of certain worms. This is followed by a large but short and perfectly straight intestine. In the chrysalis, these organs have undergone considerable modifications; the whole canal, but more especially the stomach, being contracted both in length and width: the shortening of the intestine not being proportionate to that of the whole body, obliges it to be folded upon itself for a certain length. In the moth, the contraction of the stomach has proceeded much farther, and an additional cavity, which may be considered as a kind of craw, is developed; the small intestine takes a great many turns during its course, and a large pouch has been formed at the part where it joins the large intestine. "When we consider," say Kirby and Spence, speaking of the phenomena which we have detailed, "the adaptation of all these changes of form, the loss of old organs and the acquisition of new ones, to the functions and mode of life of the animal, we see evidently the all-powerful hand of that Almighty Being who erected the universe, upholding by his providence, and the law that he has given to every creature, the system that he at first brought into existence."

In insects, all parts concerned in digestion are in general smaller and less complicated in the carnivorous than in the herbivorous tribes, apparently from the matters on which the former subsist being already animalised, and requiring, therefore, less preparation before they are received into the blood; and it is no slight indication of design, to observe in them how admirably parts are adapted to the animal necessities. Thus, scorpions, spiders, millepedes, and others which live for the most part on hard animal substances, are furnished with jaws of a firm horny texture, in many cases very large, when compared with the size of the animal; dragon-flies and beetles, particularly the stag-beetle, are examples in which the jaws are very large and manifest, often possessing tooth-like edges; and these, too, feed on smaller insects than themselves. In another description, of which the bee, wasp, and ant, are examples, we find the animal deserting the coarser kinds of food, living chiefly on juices; and in them also we again find the same mode of taking in nourishment, as in the lowest stages of the animal kingdom, viz. by means of organs of suction, which here, however, are combined with organs for mastication. These organs of suction are still more developed in insects, such as gnats, house-flies, &c.; in them they consist of a tube, of which the sides are strong and fleshy, and moveable in every direction, like the trunk of an elephant, and having at its extremity a double fold, resembling lips which are well adapted for suction. The gnat, and other insects which pierce the skin of animals, have for this purpose instruments termed *lancets*, from their shape and office. In the gnat they are five or six in number, finer than a hair, exceedingly sharp, and generally barbed on one side; while in the house-fly they are flat, like the blade of a knife. In the butterflies, however, which are almost wholly independent of solid nutritive matter, these organs present themselves in the greatest perfection, and without any addition of teeth. The proboscis of this order of insects is a double tube, constructed by the two edges being rolled longitudinally till they meet in the middle of the lower surface, thus forming a tube on each side, but leaving also another tube, intermediate to the two lateral ones. This middle tube is formed by the junction of two grooves, which, by the aid of a curious apparatus of hooks, lock into each other, and can be either united into an air-tight canal, or be instantly separated at the pleasure of the animal.* It would be quite incompatible with the nature of this essay to enter at greater length into the evidences of design, deducible from the digestive apparatus of insects. "This immense class," says Cuvier, "in the structure of their alimentary canal, exhibit as many variations as those of all the vertebral animals together: there are not only the differences that strike us in going from family to family, and from species to species, but one and the same individual has often a canal quite different, according as we examine it in its larva or imago state;† and all these variations have relations very exact, often easily estimable, with the temporary or constant mode of life of the animals in which it is observable." That this statement is correct, we have seen; and no one can be blind enough to deny that it evinces an origin of things quite incompatible with mere brute and uncertain chance.

DESIGN IN THE FORMATION OF FISHES.

Still ascending in the scale of creation, we come to the contemplation of fishes. We ask, was it by mere chance that the respiratory apparatus of fishes was so formed that their blood receives its vivifying principle from the air which is held in solution by the water in which they move? And who cannot, in this one instance, but discern the hand of a ruling Providence, adapting the structure of animals to the habits which are to characterise them? Was it by chance that, in the plaice, the sole, the turbot, and other flat fishes, the eyes are placed both on one side of the body, an isolated instance of a want of uniformity in the two sides? No; the design is obvious: for as these animals are destined to continue always with one side in the mud at the bottom of the water, an eye on this side would have been superfluous and inconvenient to them. The same design and evident adaptation of structure to circumstances is apparent in the Surinam sprat. This singular animal generally swims so near the surface, that its eye is partly in and partly out of the water; and all its parts correspond with this strange peculiarity, the pupil being partially divided into an upper and a lower portion, and the lens consisting of two globes, an upper and a lower one attached together. It appears that the superior part of the eye is, like that of terrestrial animals, adapted to refract rays transmitted by air, and the inferior part, like that of aquatic animals, those transmitted by water, and that the refracting power of the several parts of the eye is accordingly much less above than below. With regard to the function of hearing, we find in fishes the Creator still proceeding on one vast plan or unity of design; with the exception of one species, all the parts of the ear are buried within the skull, and send no process to the surface; and this is precisely what we should have looked for in beings destined to hear through the medium of water, the vibrations of which, being so much more powerful than those of air, would render the complicated apparatus requisite in terrestrial animals, in them superfluous. In the class of fishes, we see the lowest condition of the alimentary canal as it is found in vertebral animals. Fishes, voracious to a proverb, subsist almost entirely on animal food. The ocean teems chiefly with animal life. It is a dense, and rich, and moving, and tempestuous element, where vegetation is comparatively small, contrasted with its developement in the light and unresisting element of the atmosphere. This rich and resisting element of water abounds in every latitude and in every drop, with all forms of animated beings. Thus, fishes have the means of easily satisfying their voracious appetites with a selection of all kinds of food. Their teeth, more instruments of prehension than mastication, are sharp, recurved, dense, and pointed cones, adapted to grasp and retain every living thing that moves in the waters, and placed in all parts of the mouth of these all-devouring animals; their œsophagus or gullet is very wide and short, and directly opening into their capacious stomach. Thus, the food of fishes not being masticated in the mouth, does not dwell there; and as they are surrounded with an abundance of moisture, they require no salivary glands for lubricating the food, and they have none. Like larvæ, their stomachs are very large; and like them, also, they are chiefly intent upon the gratification of their appetites. All other senses seem to be absorbed in this. Their brain is very small, and their senses correspondingly obtuse.* The intestine of fishes varies considerably in length, according to the kind of food; but, generally speaking, it is not longer than their bodies; whereas, in most reptiles—which compose the next class of animals in the ascending scale—it is considerably longer; a provision unnecessary in fishes, perhaps, from the matters on which they for the most part feed, being almost always of the same nature as their own bodies, and, therefore, requiring comparatively little preparation.

Relinquishing our plan of illustrating design by an account of the digestive apparatus, let us consider, in reptiles, the organs subservient to the function of respiration, which, though somewhat similar to birds and mammiferous animals, differ from it in some remarkable particulars. The former are indeed furnished, like the two latter, with a kind of lungs, but, unlike them, they are membranous and not fleshy; that is to say, the cells which they contain are so much larger as to give them a membranous and not a fleshy appearance; nay, in many reptiles the lungs consist of one membranous bag, very similar to the air-bladder of fishes. These lungs or bags are situated in the abdomen, and are loose and floating among the entrails; and they receive their supply of air, in general, not as in birds and mammiferous animals, in consequence of the formation of a vacuum around them, but by a process very similar to that of swallowing. Hence, reptiles, unlike the higher classes of animals, can still continue to breathe if their bodies are cut open, because they do not require a vacuum round the lungs. The air thus received is subservient to the purification of the blood in the usual manner; but it is not so immediately vitiated as air received into fleshy lungs, owing to the larger size of the cells, which do not immediately allow the whole of it to come into contact with their sides. This is one reason why reptiles can sustain an impediment to their respiration for a much longer time than birds and mammals; but another and a much better reason is to be found in the distribution of their blood-vessels, those going to the lungs not forming a necessary part of the general circulating system, but constituting, as it were, only an appendage to it, which may for a time cease to transmit blood without inconvenience. A fish was destined always to be in the water,

* Roget, vol. ii., p. 114.

† Imago or perfect state.

* Grant's Lectures.

and a bird or quadruped always in the air; and hence the structure of their respiratory, as well as circulating system, is such as to incapacitate them each for the other element.

DESIGN IN THE FORMATION OF BIRDS.

We come now to birds; and whether we consider their external form or anatomical structure, or in whatever light it is possible to view them, the same conclusion presents itself to the mind. Inexhaustible contrivance, vast and comprehensive intelligence, are every where conspicuous. Behold, in their pointed bill, and gradually enlarging head and neck, a means of penetrating the yielding air; then the prow-like breast, the flexible rudder tail, the equipoised wings, and feathers at once adapted for lightness, for strength, and for tenacity, and all bearing relations, not only to each other, but to the air in which the animal is to fly: the wise contrivance of these could not be the result of chance. The investing membranes of their lungs, prolonged from various parts of their surface in the form of tubes, and expanding into bags, enveloping almost all the entrails, so as to keep them constantly surrounded with air, and similar prolongations extending also into the cavity of their bones, serving to inflate these in the same manner—are not these peculiarities for the obvious purpose of giving lightness to the animal, and thus enabling it to support itself in the air?—and does not this palpable subserviency of one part of the structure of birds to the rest, irresistibly inculcate the truth that one master-hand has regulated the whole? Can this correspondence be the work of a blind chance?—or does it imply an unity of design, an extent of benevolence, and a vastness of power, indicative of a ruling Providence?—the great architect alike of the star of the firmament and of the mite which plays in the sunbeam—whose hand is traced equally in the immensities of magnitude and minuteness—the Almighty Father of the universe, and of every thing which astounds and delights us in its construction.

In the beaks or bills of birds, various as are their forms, we can trace an exact adaptation to the food of the species. In those that tear their prey, as the eagle and hawk—or bruise hard fruits, as the parrot—or penetrate the bark of trees, as the woodpecker—the bills are of extraordinary hardness, and, in form, intimately connected with the habits of the animal. In those to whom a sense of feeling in this part is necessary to enable them to find their food in mud or water, as the duck, it is very soft, generally flattened, and so constructed that fluids may filter through it, while the solid food is retained. A bill hooked at the end, with sharp edges, characterises birds of prey. Another species of strong sharp-edged bill, of an elongated shape, but without a hook, serves to cut and break, but not to tear; and this is the form of the bill in birds which live upon animals which make resistance in the water; some of these are straight, as in the heron—others curved, some downwards, some upwards. Some sharp-edged bills have their sides approximating, like the blade of a knife to its handle, and thus adapted to seize small substances; as the penguin. The small, conical, arched bill of poultry, serves only to take up grain. The bills of the smaller birds present all the varieties of the conical form, from the broad-based cone of the hawfinch to the thread-like cone of the humming-bird. Such of them as have strong short bills, live on grain; those with long thin ones, on insects. Where the bill is short, flat, opening very anteriorly, as in martens and swallows, the bird seizes flies and butterflies in the air; and if it be long and curved, possessing some strength, we find it grubs up worms for its food. The same evidence of design which we discover in the bills of birds adapting them to procure the kind of food on which the individual is to subsist, is apparent also in the conformation of their digestive organs. As the food of birds varies from the softest animal matter to the hardest grain, so we observe every gradation in the structure of their stomachs, from the membranous sac of the carnivorous tribes to the true muscular gizzard of granivorous birds varying according as the food consists of animal or vegetable materials, or presents more or less resistance from the cohesion of its texture.

In no branch of natural history do we find more remarkable evidences of design, than in the varieties of kinds of covering of animals adapted to their wants and situations on the globe. The covering of birds, in particular, "cannot (says Paley) escape the most vulgar observation. Its lightness, its smoothness, its warmth:—the disposition of the feathers all inclined backward, the down about their stem, the overlapping of their tips, their different configuration in different parts, not to mention the variety of their colours, constitute a vestment for the body, so beautiful, and so appropriate to the life which the animal is to lead, as that, I think, we should have had no conception of any thing equally perfect, if we had never seen it, or can now imagine any thing more so. Let us suppose (what is possible only in supposition) a person who had never seen a bird, to be presented with a plucked pheasant, and bid to set his wits to work how to contrive for it a covering which shall unite the qualities of warmth, levity, and least resistance to the air, and the highest degree of each; giving it also as much of beauty and ornament as he could afford. He is the person to behold the work of the Deity, in this part of his creation with the sentiments which are due to it.

The commendation which the general aspect of the feathered world seldom fails of exciting, will be increased by farther examination. It is one of those cases in which the philosopher has more to admire than the common observer. Every *feather* is a mechanical wonder. If we look at the quill, we find properties not easily brought together—strength and lightness. I know few things more remarkable than the strength and lightness of the very pen with which I am writing. If we cast our eye to the upper part of the stem, we see a material, made for the purpose, used in no other class of animals, and in no other part of birds; tough, light, pliant, elastic. The pith, also, which feeds the feathers, is, amongst animal substances, *sui generis*; neither bone, flesh, membrane, nor tendon.

But the artificial part of a feather is the beard, or, as it is sometimes I believe called, the vane. By the beards are meant, what are fastened on each side of the stem, and what constitute the breadth of the feather; what we usually strip off from one side or both, when we make a pen. The separate pieces or laminæ of which the beard is composed, are called threads, sometimes filaments, or rays. Now, the first thing which an attentive observer will remark is, how much stronger the beard of the feather shows itself to be, when pressed in a direction perpendicular to its plane, than when rubbed, either up or down, in the line of the stem; and he will soon discover the structure which occasions this difference, viz. that the laminæ whereof these beards are composed, are flat, and placed with their flat sides towards each other; by which means, whilst they *easily* bend for the approaching of each other, as any one may perceive by drawing his finger ever so lightly upwards, they are harder to bend out of their plane, which is the direction in which they have to encounter the impulse and pressure of the air, and in which their strength is wanted, and put to the trial.

This is one particularity in the structure of a feather: a second is still more extraordinary. Whoever examines a feather, cannot help taking notice that the threads or laminæ of which we have been speaking, in their natural state *unite*; that their union is something more than the mere apposition of loose surfaces; that they are not parted asunder without some degree of force; that nevertheless there is no glutinous cohesion between them; that, therefore, by some mechanical means or other, they catch or clasp among themselves, thereby giving to the beard or vane its closeness and compactness of texture. Nor is this all: when two laminæ which have been separated by accident or force are brought together again, they immediately *reclasp*: the connection, whatever it was, is perfectly recovered, and the beard of the feather becomes as smooth and firm as if nothing had happened to it. Draw your finger down the feather, which is against the grain, and you break, probably, the junction of some of the contiguous threads; draw your finger up the feather, and you restore all things to their former state. This is no common contrivance: and now for the mechanism by which it is effected. The threads or laminæ above mentioned are *interlaced* with one another, and the interlacing is performed by means of a vast number of fibres, or teeth, which the laminæ shoot forth on *each side*, and which hook and grapple together. A friend of mine counted fifty of these fibres in one twentieth of an inch. These fibres are crooked, but curved after a different manner; for those which proceed from the thread on the side towards the extremity of the feather, are longer, more flexible, and bent downwards; whereas those which proceed from the side towards the beginning, or quill end of the feather, are shorter, firmer, and turn upwards. The process, then, which takes place, is as follows:—When two laminæ are pressed together, so that these long fibres are forced far enough over the short ones, *their* crooked parts fall into the cavity made by the crooked parts of the others, just as the latch that is fastened to a door enters into the cavity of the catch fixed to the door-post, and there hooking itself, *fastens* the door; for it is properly in this manner that one thread of a feather is fastened to the other.

This admirable structure of the feather, which it is easy to see with the microscope, succeeds perfectly for the use to which nature has designed it; which use was, not only that the laminæ might be united, but that, when one thread or lamina has been separated from another by some external violence, it might be reclasped with sufficient facility and expedition.

In the *ostrich*, this apparatus of crotchets and fibres, of hooks and teeth, is wanting; and we see the consequence of the want. The filaments hang loose and separate from one another, forming only a kind of down; which constitution of the feathers, however it may fit them for the flowing honours of a lady's head-dress, may be reckoned an imperfection in the bird, inasmuch as wings, composed of these feathers, although they may greatly assist it in running, do not serve for flight.

But under the present division of our subject, our business with feathers is, as they are the *covering* of the bird. And herein a singular circumstance occurs. In the small order of birds which winter with us, from a snipe downwards, let the external colour of the feathers be what it will, their Creator has universally given them a bed of *black* down next their bodies. Black, we know, is the warmest colour: and the purpose here is, to *keep* in the heat arising from the heart and circulation of the blood. It is farther likewise remarkable, that this is not found in larger birds; for which there is also a reason:—Small birds are much more exposed to the cold than large ones; forasmuch as they present, in proportion to their bulk, a much larger surface to the air. If a turkey were divided into a number of wrens (supposing the shape of the turkey and the wren to be similar), the surface of all the wrens would exceed the surface of the turkey, in the proportion of the length and breadth (or of any homologous line) of a turkey to that of a wren; which would be, perhaps, a proportion of ten to one. It was necessary, therefore, that small birds should be more warmly clad than large ones; and this seems to be the expedient by which that exigency is provided for.

The *oil* with which birds prune their feathers, and the organ which supplies it, is a specific provision for the winged creation. On each side of the rump of birds is observed a small nipple, yielding upon pressure a butter-like substance, which the bird extracts by pinching the pap with its bill. With this oil or ointment thus procured, the bird dresses its coat, and repeats the action as often as its own sensations teach it that it is in any part wanted, or as the excretion may be sufficient for the expence. The gland, the pap, the nature and quality of the excreted substance, the manner of obtaining it from its lodgment in the body, the application of it when obtained, form, collectively, an evidence of intention which it is not easy to withstand. Nothing similar to it is found in unfeathered animals. What blind *conatus* of nature should produce it in birds? should not produce it in beasts?"

As we have entered so fully into this subject when treating of other classes of beings, we shall not here revert to it, or bring forward illustrations of the truth of our proposition; the facts already detailed seem sufficient to display the wisdom which the great Creator has evinced in this department of the animal world. Nothing can be more worthy of remark than the exhaustless contrivances by which every difficulty is obviated, and nature moulded to the will of its Almighty Author. How many obstacles were to be overcome before a heavy body like that of an eagle or the mighty condor could be rendered buoyant in the air, and made to track its adventurous course so high above the earth as to be almost lost to human gaze! How many conditions were necessary to give safety and enjoyment to the smallest of the winged tribes, even after the first obstacles were overcome! Yet how wonderfully simple and efficacious the means by which the whole has been accomplished! That man is indeed to be pitied who can turn even a transient glance on such a subject, without being lost in astonishment and admiration.

THE STRUCTURE OF MAN AND OTHER ANIMALS.

We now arrive at the consideration of the mammalia, or those animals which suckle their young; and at the head of this great class we find man proudly pre-eminent. We have already seen, that, as the materials on which the function of digestion is to be performed are numerous and diversified, so a difference exists in the parts which are subservient to it. Without altering the general plan of the function, or the essential parts of the organs concerned in it, nature makes such additional provisions, in the instincts by which the reception of food is guided, and in the organs by which it is assimilated, as are suited to the circumstances in which the animal is placed, to the food on which it is to subsist, and to the ulterior purposes which it is to serve in the world. Such evidences of design are very remarkable in the mammalia; and in few organs are they more powerfully instanced than in the teeth, between which, in form, structure, and position, and the kind of food on which each animal of this class is intended to subsist, the most intimate connections present themselves. These relations—which indeed may be also traced in the shape of the jaw, in the mode of its articulation with the head, in the proportional size and distribution of the muscles which move the jaw, in the form of the head itself, in the length of the neck and its position on the trunk, and, in fact, in the whole conformation of the skeleton—have been noticed from very early ages, and frequently described.

The purposes answered by the teeth are principally those of seizing and detaining whatever is introduced into the mouth, of cutting it asunder and dividing it into smaller pieces, of loosening its fibrous structure, and of breaking down and grinding its harder portions. Four principal forms have been given to teeth, which accordingly may be distinguished into the conical, the sharp-edged, the flat, and the tubercolated teeth; though we occasionally find a few intermediate modifications of these forms. It is easy to infer the particular functions of each class of teeth, from the obvious mechanical actions to which, by their form, they are especially adapted. The conical teeth, which are generally also sharp-pointed, are principally employed in seizing, piercing, and holding objects; such are the offices they perform in the crocodile and similar reptiles, where all the teeth are of this structure: and such also are their uses in most of the cetacea or whale tribe, where similar forms and arrangements of teeth prevail. The animals subsist on fish, and their teeth are therefore constructed very much on the model of those of fish; while those cetacea, on the other hand, which are herbivorous, as the manatus and dugong, have teeth very differently formed.

The sharp-edged teeth perform the office of cutting and dividing the yielding textures presented to them: they act individually as wedges or chisels; but when co-operating with similar teeth in the opposite jaw, they have the power of cutting like shears or scissors. The flat teeth, of which the surfaces are generally rough, are used, in conjunction with those meeting them in the opposite jaw, for grinding down the food by a lateral motion, in a manner analogous to the operation of millstones in a mill. The tuberculated teeth, of which the surfaces present a number of rounded eminences, corresponding to depressions in the teeth opposed to them in the other jaw, act more by their direct pressure in breaking down hard substances, and pounding them, as they would be in a mortar.

The apparatus for giving motion to the jaws is likewise varied according to the particular movements required to act upon the food in the different tribes. The articulation of the lower jaw to the skull is somewhat similar to a hinge; but considerable latitude is given to its motions by the interposition of a moveable cartilage between the two surfaces of articulation, a contrivance admirably answering the intended purpose. Hence, in addition to the principal movements of opening and shutting, which are made in a vertical direction, the lower jaw has also some degree of mobility in a horizontal or lateral direction, and is likewise capable of being moved backwards or forwards to a certain extent. In the conformation of the teeth and jaws, a remarkable contrast is presented between carnivorous and herbivorous animals. In the former, of which the tiger may be taken as an example, the whole apparatus for mastication is calculated for the destruction of life, and for tearing and dividing the fleshy fibres. The teeth are armed with pointed eminences, which correspond in the opposite jaws so as exactly to lock into one another, like wheelwork, when the mouth is closed, and the muscles which close it are of enormous size and strength. In the herbivorous animals, on the contrary, as in the antelope, the greatest force is bestowed, not so much on the motions of opening and shutting, as on those which are necessary for grinding, and which act in a lateral direction. The surfaces of the teeth are flattened and of great extent; and they are at the same time kept rough, like those of millstones, their office being in fact very similar to that performed by these implements of grinding. The *Rodentia*, or gnawing quadrupeds, are formed for subsisting on dry and tough materials, such as the bark and roots, and even the woody fibres of trees, and the harder animal textures; and their teeth are expressly adapted for gnawing, nibbling, and wearing away, by continued attrition, the harder texture of organised bodies. They are all furnished with two front teeth, generally very long, and having the exact shape of a chisel; while the molar or back teeth have surfaces irregularly marked with raised zig-zag lines, rendering them very perfect instruments of trituration. The beaver and rat are examples among omnivorous rodentia, and the hare and rabbit among those that are principally herbivorous.

The *Quadrumana*, or monkey tribes, approach nearer to the human structure in the conformation of their teeth, which are adapted to a mixed kind of food; while the other orders of mammalia exhibit gradations in the structure of their teeth corresponding to the varieties in the nature of their food. Thus, the teeth and jaws of the hyæna are formed more especially for breaking bones, while those of the sea-otter have rounded eminences, which peculiarly fit them for breaking shells.

"On comparing the structure of the digestive organs of man," continues Dr Roget,* "with those of other animals belonging to the class mammalia, we find them holding a place in the series intermediate between those of the purely carnivorous and exclusively herbivorous tribes, and in some measure uniting the characters of both. The powers of the human stomach do not indeed extend to the digestion of either the tough woody fibres of vegetables on the one hand, or the compact texture of bones on the other; but still they are competent to extract nourishment from a wider range of alimentary substances than the digestive organs of almost any other animal. This adaptation to a greater variety of food may also be inferred from the form and disposition of the teeth, which combine those of different kinds more completely than in most mammalia. In addition to these peculiarities, we may also here observe, that the sense of taste in the human species appears to be affected by a greater variety of objects than in the other races of animals. All these are concurring indications that nature, in thus rendering man omnivorous, intended to qualify him for maintaining life wherever he could procure the materials of subsistence, whatever might be their nature, whether animal or vegetable, or a mixture of both, and in whatever soil or climate they may be produced; and for endowing him with the power of spreading his race, and extending his dominion over every accessible region of the globe. Thus, then, from the consideration of the peculiar structure of the organs of his frame, may be derived proofs of their being constructed with reference to faculties of a higher and more extensive range than those of any, even the most favoured, species of the brute creation."

There is one circumstance connected with the function of digestion, as displayed in certain of the mammalia, to which, as evidencing great and wonderful design and accommodation in structure to circumstance, we would particularly allude; it is the facility and power of the camel of abstaining long from drinking—a power which he is often necessitated to bring into effect during the long period of nine, ten, or even twelve days. In Arabia, the camel is the chief beast of burden; and travelling through a country such as it, it is only at long intervals that water can be obtained; a country, as described by Buffon, without verdure, without water, possessing a burning sun, an air always parched, sandy plains, mountains still more scorched, which the eye runs over without perceiving a single animated being; a dead earth perpetually tossed with the winds, and presenting nothing but bones, scattered flints, rocks perpendicular or overturned; a desert totally void, where the traveller never breathes under a shade, where nothing accompanies him, nothing recals the idea of animated nature; absolute solitude, more dreadful than that of the deepest forests, more solitary and naked, more lost in an unlimited void; he every where beholds space surrounding him as a tomb. The light of day, more dismal than the darkness of night, serves only to give him a clearer view of his own wretchedness and impotence, and to conceal from him the barriers of the void, by extending around him that immense abyss which separates him from the habitable parts of the earth; an abyss which in vain he should attempt to traverse, for hunger, thirst, and scorching heat, haunt every moment that remains to him between despair and death. Frightful as is this picture, the desire of lucre, or the gratification of a curiosity, and a love of enterprise no less insatiable, often tempt men to traverse the sandy deserts of Arabia. For their own necessities they may provide, but no human means could afford the possibility of conveying water sufficient to satisfy the longings of the beasts of burden which accompany these expeditions. It is by the singular structure of the camel's stomach that it is enabled to pass several days without drinking, and to take at a time a prodigious quantity of water, which remains in reservoirs pure and limpid, because these wells are so contrived that neither the fluids of the body nor of digestion can mix with it. What design is here!—and how redolent of wisdom, and how full of mercy! But let us endeavour to explain the nature of this structure which so evidently adapts the camel to be the inhabitant of the sterile and arid regions of the east:—Ruminating quadrupeds, or those which chew the cud, have two, three, or four stomachs, distinguished—when there are four—by the names of paunch, bonnet, many-plies, and caille. When the food is swallowed for the first time, it passes directly from the gullet into the paunch, where it undergoes some necessary changes, and it is then transmitted to the bonnet, to be mixed with the fluids of the cavity. This process is going on during the time the animal is grazing, when, from the incessant occupation of nipping off the grass, for which its teeth are so admirably suited, it has not leisure to chew it sufficiently. When afterwards reposing itself, however, the half chewed aliment is brought again, in successive little balls, from the bonnet into the mouth, where it is subjected to a perfect mastication; and when again swallowed, it passes directly to the many-plies, thence, after some time, to the caille, and ultimately to the intestines. In the camel, however, the paunch has two deep cellular appendages; and the bonnet, or second stomach, has its internal membrane hollowed into numerous deep cells, serving as reservoirs of water, to be used only as occasion requires; while the third stomach is alone appropriated to the immediate necessities of the body. Between the end of the gullet, then, and the orifice of this third stomach, extends, through the two first, a long muscle capable of drawing up the third stomach, so as to receive alimentary matters directly from the gullet, when the immediate wants of the animal are to be supplied; but when the fluid taken is meant to be used only in its long journeys through the deserts, this muscle is relaxed, and it is thus received into the two first stomachs, and transmitted onwards by these only at the necessary intervals. The Arabs who traverse these extensive plains, accompanied by these useful animals, are, it is said, sometimes obliged, when faint and in danger of perishing from thirst, to kill one of their camels, for the sake of the water contained in these reservoirs, which is always found pure and wholesome. It is stated by those who have travelled in Egypt, that camels, when accustomed to go journeys during which they are for a long time deprived of water, acquire the power of dilating the cells, so as to make them contain a more than ordinary quantity, as a supply for their journey.

COMPENSATION OF PARTS IN ANIMATED NATURE.

The evidences of design in creation are beautifully developed in what is called the compensatory structure of animals. By this is signified the supplying the defects of one organ by the structure of another part or organ. Paley has summed up a few striking instances of this nature. "The short unbending neck of the elephant (says he) is compensated by the length and flexibility of his *proboscis*. He could not have reached the ground without it; or, if it be supposed that he might have fed upon the fruit, leaves, or branches of trees, how was he to drink? Should it be asked, Why is the elephant's neck so short? it may be answered, that the weight of a head so heavy could not have been supported at the end of a longer lever. To a form, therefore, in some respects necessary, but in some respects also inadequate to the occasions of the animal, a supplement is added, which exactly makes up the deficiency under which he laboured.

If it be suggested that this proboscis may have been produced, in a long course of generations, by the constant endeavour of the elephant to thrust out his nose (which is the general hypothesis by which it has lately been attempted to account for the forms of animated nature), I would ask, How was the animal to subsist in the meantime, during the process, *until* this prolongation of snout were completed? What was to become of the individual whilst the species was perfecting?

Our business at present is simply to point out the relation which this organ bears to the peculiar figure of the animal to which it belongs. And herein all things correspond. The necessity of the elephant's proboscis arises from the shortness of his neck; the shortness of the neck is rendered necessary by the weight of the head. Were we to enter into an examination of the structure and anatomy of the proboscis itself, we should see in it one of the most curious of all examples of animal mechanism. The disposition of the ringlets and fibres, for the purpose, first, of forming a long cartilaginous pipe; secondly, of contracting and lengthening that pipe; thirdly, of turning it in every direction at the will of the animal; with the superaddition, at the end, of a fleshy production of about the length and thickness of a finger, and performing the office of a finger, so as to pick up a straw from the ground—these properties of the same organ taken together, exhibit a specimen not only of design (which is attested by the advantage), but of consummate art, and, as I may say, of elaborate preparation, in accomplishing that design.

The hook in the wing of a *bat* is strictly a mechanical, and also a *compensating*, contrivance. At the angle of its wing there is a bent claw, exactly in the form of a hook, by which the bat attaches itself to the sides of rocks, caves, and buildings, laying hold of crevices, joinings, chinks, and roughnesses. It hooks itself by this claw; remains suspended by this hold; takes its flight from this position: which operations compensate for the decrepitude of its legs and feet. Without her hook, the bat would be the most helpless of all animals. She can neither run upon her feet, nor raise herself from the ground. These inabilities are made up to her by the contrivance in her wing; and in placing a claw on that part, the Creator has deviated from the analogy observed in winged animals. A singular defect required a singular substitute.

The *crane* kind are to live and seek their food amongst the waters, yet, having no web-feet, are incapable of swimming. To make up for this deficiency, they are furnished with long legs for wading, or long bills for groping; or usually with both. This is *compensation*. But I think the true reflection upon the present instance is, how every part of nature is tenanted by appropriate inhabitants. Not only is the surface of deep waters peopled by numerous tribes of birds that swim, but marshes and shallow pools are furnished with hardly less numerous tribes of birds that wade.

The common *parrot* has, in the structure of its beak, both an inconveniency and a *compensation* for it. When I speak of an inconveniency, I have a view to a dilemma which frequently occurs in the works of nature, viz., that the peculiarity of structure by which an organ is made to answer one purpose, necessarily unfits it for some other purpose. This is the case before us. The upper bill of the parrot is so much hooked, and so much overlaps the lower, that if, as in other birds, the lower chap alone had motion, the bird could scarcely gape wide enough to receive its food; yet this hook and overlapping of the bill could not be spared, for it forms the very instrument by which the bird climbs; to say nothing of the use which it makes of it in breaking nuts and the hard substances upon which it feeds. How, therefore, has nature provided for the opening of this occluded mouth? By making the upper chap moveable, as well as the lower. In most birds the upper chap is connected, and makes but one piece, with the skull; but in the parrot, the upper chap is joined to the bone of the head by a strong membrane placed on each side of it, which lifts and depresses it at pleasure.

The *spider's web* is a *compensating* contrivance. The spider lives upon flies, without wings to pursue them; a case, one would have thought, of great difficulty, yet provided for, and provided for by a resource which no stratagem, no effort of the animal, could have produced, had not both its external and internal structure been specifically adapted to the operation.

In many species of insects the eye is fixed, and, consequently, without the power of turning the pupil to the object. This great defect is, however, perfectly *compensated*, and by a mechanism which we should not suspect. The eye is a multiplying glass, with a lens looking in every direction, and catching every object; by which means, although the orb of the eye be stationary, the field of vision is as ample as that of other animals, and is commanded on every side. When this lattice-work was first observed, the multiplicity and minuteness of the surfaces must have added to the surprise of the discovery. Adams tells us that fourteen hundred of these reticulations have been counted in the two eyes of a drone-bee.

* Bridgewater Treatise.

In other cases the *compensation* is effected by the number and position of the eyes themselves. The spider has eight eyes, mounted upon different parts of the head; two in front, two in the top of the head, two on each side. These eyes are without motion, but, by their situation, suited to comprehend every view which the wants or safety of the animal render it necessary for it to take.

The Memoirs for the Natural History of Animals, published by the French Academy in the year 1667, furnish us with some curious particulars in the eye of a chameleon. Instead of two eyelids, it is covered by an eyelid with a hole in it. This singular structure appears to be *compensatory*, and to answer to some other singularities in the shape of the animal. The neck of the chameleon is inflexible. To make up for this, the eye is so prominent, as that more than half of the ball stands out of the head; by means of which extraordinary projection, the pupil of the eye can be carried by the muscles in every direction, and is capable of being pointed towards every object. But then, so unusual an exposure of the globe of the eye requires, for its lubricity and defence, a more than ordinary protection of eyelid, as well as a more than ordinary supply of moisture; yet the motion of an eyelid, formed according to the common construction, would be impeded, as it should seem, by the convexity of the organ. The aperture in the lid meets this difficulty. It enables the animal to keep the principal part of the surface of the eye under cover, and to preserve it in a due state of humidity without shutting out the light; or without performing every moment a nictitation, which, it is probable, would be more laborious to this animal than to others.

But the works of the Deity are known by expedients. Where we should look for absolute destitution, where we can reckon up nothing but wants, some contrivance always comes in to supply the privation. A *snail*, without wings, feet, or thread, climbs up the stalks of plants, by the sole aid of a viscid humour discharged from her skin. She adheres to the stems, leaves, and fruits of plants, by means of a sticking-plaster. A *mussel*, which might seem, by its helplessness, to lie at the mercy of every wave that went over it, has the singular power of spinning strong tendinous threads, by which she moors her shell to rocks and timbers. A *cockle*, on the contrary, by means of its stiff tongue, works for itself a shelter in the sand. The provisions of nature extend to cases the most desperate. A *lobster* has in its constitution a difficulty so great, that one could hardly conjecture beforehand how nature would dispose of it. In most animals, the skin grows with their growth. If, instead of a soft skin, there be a shell, still it admits of a gradual enlargement. If the shell, as in the tortoise, consists of several pieces, the accession of substance is made at the sutures. Bivalve shells grow bigger by receiving an accretion at their edge; it is the same with spiral shells at their mouth. The simplicity of their form admits of this. But the lobster's shell being applied to the limbs of the body, as well as to the body itself, allows not of either of the modes of growth which are observed to take place in other shells. Its hardness resists expansion, and its complexity renders it incapable of increasing its size by addition of substance to its edge. How, then, was the growth of the lobster to be provided for? Was room to be made for it in the old shell, or was it to be successively fitted with new ones? If a change of shell became necessary, how was the lobster to extricate himself from his present confinement? how was he to uncase his buckler, or draw his legs out of his boots? The process which fishermen have observed to take place, is as follows:—At certain seasons, the shell of the lobster grows soft; the animal swells its body; the seams open, and the claws burst at the joints. When the shell has thus become loose upon the body, the animal makes a second effort, and by a tremulous spasmodic motion, casts it off. In this state, the liberated but defenceless fish retires into holes in the rock. The released body now suddenly pushes its growth. In about eight-and-forty hours, a fresh concretion of humour upon the surface, *i. e.* a new shell, is formed, ad[illegible]ed in every part to the increased dimensions of the animal. This wonderful mutation is repeated every year."

In the changing of the colour of the chameleon, we see one of the beautiful compensatory provisions of nature. This little animal, which is common in the East Indies and some other Asiatic countries, lives upon flies, beetles, or other insects, which it catches by climbing up shrubs or trees, and darting out its tongue; but its pace is slow, and as insects have good eyes to perceive the approach of an enemy, they would be sure to make their escape in the present case, unless the chameleon approached them in disguise. This, therefore, it invariably does. As it passes among green leaves, it is of a green colour; and when it glides by any of a red or yellow tinge, so does it change its hue to red or yellow. So closely does it assume not only the shades and colours, but even the shapes of the leaves around, that a spectator might look at the tree for some minutes before discovering it. How wisely, therefore, has the Creator endowed this poor reptile with the wonderful gift of altering the colour of its skin! for if it were not possessed of such a property, it would inevitably die of hunger.

BEAUTY.

The wisdom of the great original Contriver is eminently manifested in that property of inanimate and animate objects which we call beauty. Here there is an evident fitness betwixt the taste and habits of animals, human beings included, and what can be seen by the eye. We feel pleasure in contemplating the works of nature most obvious to our senses; and we cannot but remark, that that which is loathsome is not ordinarily presented to the eye. The splendid colouring of the vegetable kingdom, the smooth or spotted skins of the brute creation, and the lovely plumage of the feathered tribe, all give us delight in the contemplation. Consider, also, how beautiful is the outward appearance of the human form. Reflect on what the parts and materials are of which the fairest body is composed, and no farther observation will be necessary to show how well these things are wrapped up, so as to form a mass which will be capable of symmetry in its proportion, and of beauty in its aspect; how the bones are covered—the bowels concealed—the roughness of the muscle smoothed and softened; how over the whole is drawn an integument, the skin, which converts the disgusting materials of a dissecting-room into an object of attraction to the sight, or one upon which it rests at least with ease and satisfaction.

The more minutely that we inspect the works of nature, the greater cause have we to wonder at the extraordinary perfection and beauty every where prevalent. The microscope developes splendours in the creation of insects which we can hardly comprehend. The back of a diamond-beetle exhibits an assemblage of brilliant colours and glittering gems more splendid than any artificial arrangement of the most precious stones. The colours of the feathers of birds in tropical climates, and the skins of the fishes of Ceylon, are incomparable for their beauty. And why is all this the case? Because it yields a pleasure to the sight, both of men and other living creatures; for the Creator has not denied the feeling of delight to the meanest reptile which crawls. All is beautiful, it would appear, in the estimation of one or other of living creatures. The most insignificant little flower, now blooming far from the haunts of men, in some remote wilderness, does not, as has been said, waste its sweetness on the desert air. It furnishes an object of pleasing gratification to some description of sentient creatures, perhaps so small as to be imperceptible to our naked eye.

Placing agreeableness of aspect entirely out of the question, there is another purpose answered by the skin, and that is concealment. Were it possible to view through this integument the mechanism of our bodies, the sight would frighten as much as it would disgust us. Durst we make a single movement or stir a step from the place we were in, if we saw our blood circulating, the tendons pulling, the lungs blowing, the humours filtrating, and all the incomprehensible assemblage of fibres, tubes, pumps, valves, currents, pivots which sustain an existence at once so frail, and so presumptuous?

In clothing the human frame with a covering of skin, the Creator has not omitted to vary its character according to local necessities. The skin is most beautiful on the face, because the face is most exposed to observation; it is softest where least liable to injury, and hardest or firmest in texture where it is most subject to be pressed upon. There is not less sign of contrivance in the manner in which it ceases at the extremities of the toes and fingers. A man has only to look at his hand, to observe with what nicety and precision that covering, which extends over every other part, is here superseded by a different substance, and a different texture. Why do we find the skin cease at our fingers' ends, or on the back part of the fingers, and not the fore part? Because something hard or horny was required on these parts, by which we could hold fast or lift nimbly objects which we wished to grasp or seize upon. Nails therefore supersede the skin on such places. The same forethought is visible in the covering of our heads. What could have been a more beautiful or appropriate substance wherewith to cover the head and preserve the hard bony skull from injury, than the hair, a substance at once light, warm, and graceful.

DESIGN IN VEGETABLE PHYSIOLOGY.

In accordance with our intentions of glancing through most of the natural sciences, and bringing home to the main object of our labours treasures illustrative of design from them all, let us now turn our attention to those afforded by the vegetable kingdom of nature. And first, of the mutual relations that exist between animals and vegetables; in considering which, we shall find that these two great organised kingdoms of the creation are made to co-operate in the execution of the same design; each ministering to the other, and preserving that due balance in the constitution of the atmosphere, which adapts it to the welfare and activity of every order of beings, and which would soon be destroyed were the operations of any one of them to be suspended. "It is impossible to contemplate so special an adjustment of opposite effects, without admiring this beautiful dispensation of Providence, extending over so vast a scale of being, and demonstrating the unity of plan on which the whole system of organised creation has been devised." We said in a former part of this essay, that two principles of atmospheric air were oxygen and carbon; that the former was as essential to animal life as the latter was obnoxious to it; but that, on the other hand, carbon was indispensable to the continuance of vegetable organisations. We will now endeavour to explain this by a short account of the phenomena of respiration as displayed in the two kingdoms. Among animals, the function of respiration is that by which the blood, received into its vessels from the alimentary canal, is, during its subsequent circulation, kept in a state of requisite purity. This is in all cases effected by bringing it, at intervals, into contiguity, either with atmospheric air alone, or with water containing this air diffused through it; when such is the mutual action of the blood and the air upon each other, that the former is purified, and passes in general from a dingy purple to a bright scarlet colour, while the latter is in the same degree rendered impure, and after a time becomes inadequate to support either respiration or combustion. Now, whether the aërating organs be lungs or gills, it appears to be the object of nature, in their construction, to expose a large surface to the contact of air. This object is accomplished by their division into numerous cells or leaf-like processes, or by their extension on the walls of cavities, or the surface of pectinated ridges. The blood brought to these organs is there distributed by their terminating branches. Although still retained in vessels, it can nevertheless be easily acted upon by the air on the exterior. Priestley found the colour of blood changed by the air when enclosed in a moistened bladder, and the same effect was observed by Hunter when it was covered with goldbeaters' skin. It is scarcely possible to determine by direct observation what is the exact nature of the changes that the blood undergoes in its passage through the lungs; the most obvious is its change of colour; and the chemical differences between the dark purple blood in the veins before it has reached the lungs, and the bright vermilion colour it exhibits in the arteries after it has circulated through the lungs, and been exposed to the influence of the air, may be collected from the changes made in the air itself. Atmospheric air is known to consist of certain principles in definite proportions; when it has acted upon the blood, and is returned from the lungs, it is found that a certain proportion of oxygen which it contained has disappeared, and that the place of this oxygen is almost wholly supplied by an addition of carbonic acid gas and watery vapour. For our knowledge of the fact of the disappearance of oxygen, we are indebted to Dr Priestley, the great founder of pneumatic chemistry. It had indeed been long before suspected by Mayow, that some portion of the air inspired is absorbed by the blood; but the merit of the discovery that it is the oxygenous part of the air that is thus consumed, is unquestionably due to Dr Priestley. The exact quantity of oxygen which is lost in natural respiration, varies in different animals, and even in different conditions of the same animal. Birds, for instance, consume larger quantities of oxygen by their respiration, and hence require, for the maintenance of life, a purer air than other vertebrated animals. Vauquelin, however, found that many species of insects and worms possess the power of abstracting oxygen from the atmosphere in a much greater degree than the larger animals; thus, snails are capable of living for a long time in the vitiated air in which a bird had perished. Some insects which conceal themselves in holes, or burrow under ground, have been known to deprive the air of every appreciable portion of its oxygen. It is observed by Spallanzani, that those animals whose modes of life oblige them to remain for a great length of time in these confined situations, possess this power in a greater degree than others which enjoy more liberty of moving in the open air; so admirably have the faculties of animals been, in every instance, accommodated to their respective wants.

Now, bearing in mind that the air coming in contact with the blood of animals parts with its oxygen, and receives in its place carbonic acid gas, let us consider the function of respiration, or more properly aëration, as it occurs in vegetables. It was necessary that some means should be appointed by which this great quantity of carbon given out into the air by animals, and so injurious to animal life, should be removed from it. We have said that this principle was necessary to vegetable life; and here we find the means, not only by which in a very considerable degree it is procured, but also by which it is removed from the atmosphere. The leaves of plants are analogous to the lungs of animals, and it is in them principally that the decomposition of the carbonic acid absorbed from the air is effected. When exposed to the action of the sun, they decompose that gas, retain its carbon, and disengage its oxygen. Solar light is an essential agent in effecting this chemical change; for it is never found to take place at night, nor while the plant is kept in the dark. That the carbon resulting from this decomposition of carbonic acid is retained by the plant, has been most satisfactorily proved by the experiments of Saussure, who found that this process is attended with a sensible increase in the quantity of carbon which the plant had previously contained. "Thus, the great object to be answered by this vegetable aëration," says Dr Roget, speaking at considerable length of this undeniable evidence of design to which we have thus shortly alluded, "is exactly the converse of that which we see effected by the respiration of animals; in the former, it is adding carbon to the vegetable organisation; in the latter, it is that of discharging the superfluous quantity of carbon from the animal system. On the whole, therefore, the atmosphere is continually receiving from the vegetable kingdom a large accession of oxygen, and is at the same time freed from an equal portion of carbonic acid gas, both of which effects tend to its purification, and to its remaining adapted to the respiration of animals."

We have not much space to devote to the contemplation of vegetables, but we are unwilling to leave the subject without alluding to some other evidences of design which we find displayed in them. Among these, nothing more beautifully demonstrates that nature, or rather the Almighty Creator of nature, proceeds on a uniformity of plan and design, than the fact that plants as well as animals are possessed of the means of reproducing and continuing their species. The pistil which occupies the centre of the flower is destined to produce the seeds, while the stamens of the plant contain the dust necessary for fertilising them, and without which the seeds would not produce young plants. Nature has guarded with nice care this precious dust, so as on its preservation depends the continuance of the species. The apparatus by which in many flowers it is defended from injury, is very curious; nor are the means that are provided by which it comes in contact with the stigma of the pistil less demonstrative of a great, a wise, and a beneficent Providence. In some plants where the organs are in the same flower, the stamens are placed above the stigma, upon which the dust, or pollen, falls by its own gravity; in others, we find the contrary is the case, the pistil being the longest; but here the flower is generally drooping. To assist the emission of the pollen, and its contact with the stigma, in many plants the stamens possess a very apparent moving power. When ripe, the ten stamens of the rue are seen alternately to bend down upon the stigma, deposit their portion of pollen, and return to their former position. The stalks or filaments of the pellitory of the wall are possessed of a remarkable elasticity, and thus forcibly scatter the pollen. This is very apparent if touched by the point of a needle; immediately it acts with a jerk, which dashes the pollen with some force on the stigma. The same arrangement is met with in the barberry bush, in which the six stamens remain sheltered under the concave tips of the flower-leaves or petals, till some extraneous body, as an insect in search of honey, touches the filament, which instantly contracts, and also dashes the pollen against the stigma. But all plants have not their stamens and pistils sheltered under the same veil; in many they are in different flowers, and in others even placed on different plants. Here, again, we have to admire the wise measures nature has taken for the accomplishment of her designs. In many the scattering of the pollen is effected by the winds; to favour the access of which, we find in some, as the hazel, the leaves are not evolved until after the seed has been perfected; or, if the plants be evergreens, the leaves are needle-shaped, so as to present very little obstacle to the passage of the pollen, which is secreted in much larger quantity than usual. Various species of insects, and especially the bees, are selected by nature for this purpose. In the pink we observe numerous small insects creeping to and fro, and thus depositing the pollen on the stigma. In flowers where the stamens and pistils are on different plants, often at a considerable distance from each other, bees, and other flying insects, are peculiarly accessory to the great end of nature. These insects, it is true, do not visit the flower for the purpose of scattering the pollen; they only seek for the sweet juice which exudes from its nectary. Their hairy body, which nature did not bestow without design, is seen covered with pollen, often in such quantities as to impede the progress of the animal; this, whenever they visit another flower, is rubbed against the stigma; and it is a fact, no less wonderful than calculated to fill us with admiration at the wise provision of nature, that many insects are peculiar to one flower, and that others, as the bee, will only visit one species in each journey from its hive.

The various methods which nature employs to disperse the different varieties of seeds over the earth, are truly wonderful. Many plants, when the seed is fully ripe, discharge it from its covering, with a jerk or elastic spring. The common oat is thrown out in this way; and the loud crackling of the pods of the broom in a dry sunshiny day, or, as Drummond has it, "bursting seed-balls crackling in the sun," is caused by their bursting and scattering about the contained seeds, and must have been frequently noticed. "Who has not listened," again asks Sir James Edward Smith, "in a calm and sunny day, to the crackling of the furze bushes, caused by the explosion of their elastic little pods; or watched the down of innumerable seeds floating on a summer breeze, till they are overtaken by a shower, which, moistening their wings, stops their farther flight, and at the same time accomplishes its final purpose, by immediately promoting the germination of each seed in the moist earth! How little are children aware, when they blow away the seeds of the dandelion, or stick burs in sport upon each other's clothes, that they are fulfilling one of the great ends of nature!" These downy appendages to which Sir J. E. Smith alludes, buoy up the lighter seeds, as the thistles, and carry them floating through the air to great distances; then there are the currents of rivers which bear the seeds from one part of the country to another; and even seas and oceans, whose tides and currents float along the germs of vegetation to the various regions of the globe. Birds, too, by feeding on particular seeds, carry them to great distances, where, being often voided entire, they vegetate. There is evident design in this. It could not have been by mere chance, that in flowers which stand erect, the pistil is shorter than the stamens, permitting the pollen as it falls to descend upon the stigma; and when the flower is drooping, that the contrary arrangement is effected. And surely no one will be so blind or hardy enough to assert that the mechanical means, to which we have alluded, for the dispersion of seeds, with all the beauty and aptitude of its arrangement, was not the result of divine wisdom—a wisdom which will be still more apparent when we extend our views from the power which called into being such various and beauteous existences, and gave the means of distributing them over the globe, and consider the laws that govern that distribution which we so much admire.

It is not here out of place to remark, that there is scarcely a vegetable production on which some species of animal does not subsist; and, generally speaking, wherever that peculiar production is to be found, there also is the animal to which it furnishes wholesome food. With some striking examples of this kind, the most uneducated man is acquainted; he knows that the partridge is on the plain, the woodcock in the forests, the grouse on the moors, and the ptarmigan on the loftiest peaks of the mountains. He knows, too, that other species migrate from country to country, seeking their food in distant regions, over trackless oceans, when it fails in their native haunts; and among the animal kingdom so universal is this, as to form an example of the wonderful adaptations which exist between it and the vegetable world. Vegetables, like animals, are adapted to varieties of climate and temperature; and when we consider their distribution over the globe, we shall find that those which are most essential to the maintenance of man, bear a variety of climate better than most others. This is the case with greens, carrots, potatoes, and many kinds of grain. Warm climates are much more favourable to vegetation than cold. In Spitsbergen, the whole number of plants with conspicuous flowers, natives of the country, is found by botanists scarcely to exceed thirty species; while in the warmer regions of the West Indies, in Madagascar and the coast of Coromandel, Willdenow enumerates from four to five thousand different species of indigenous plants. Now, observe how admirably this distribution of plants corresponds with the wants and necessities of man. The inhabitants of warm climates generally prefer a vegetable diet; and there we find that kind of food most abundant.

It is impossible for a reflecting individual to walk beside a field of growing barley, without being impressed with the conviction, that, in the economy of this description of grain, the design of a Creator has been wonderfully manifested. An ear of barley differs from one of wheat or oats. Each of the grains is furnished with a long slender bristle or beard, which is prickly to the touch, and seems to serve as a protection to the ear. These bristles form a roof, if we may so call it, to carry off the rain from the ear, and yet, by their elegant disposition, do not prevent the heat of the sun and the light from influencing the grain. And why should such be the case with barley, when the ears of wheat, oats, &c., do not possess any such protective process? Because barley is a grain easily injured by wet, which, if not carried off, would cause the ear to sprout even while on the stalk, and, consequently, be entirely useless to man.

In speaking of the economy of vegetable life, it should not pass unnoticed that there is a remarkable instance of creative wisdom in the means which have been arranged for the growth of plants from putrescent matter. All kinds of vegetable and animal substances, when deprived of life, as well as excrementitious matter, have a tendency to decomposition—that is, to resolve themselves into those elementary gases of which they have been chiefly composed. This process of dissolution, as every one knows, produces a most disagreeable odour, which is often inimical to animal life. But this is not an evil; it displays a bountiful provision in nature; for it tells us in a way not to be misunderstood, that the substance undergoing, or about to undergo, the putrifactive process, should be buried underground; and so being there deposited, it immediately proceeds to supply its no longer useful gases to the infant plants and crops of grain which flourish on the surface. Thus do we see another striking evidence of the harmonious design which every where prevails between the animal and vegetable creation.

Considering the alimentary regimen of the different nations of the earth, it will be clearly seen that a vegetable diet is preferred by the inhabitants of warm countries: to them sobriety is an easy virtue and a happy consequence of the climate. Northern regions, on the contrary, are voracious from instinct and necessity. They swallow enormous quantities of food, and prefer those substances which in digestion produce the most heat. Obliged to struggle incessantly against the action of cold, their life is but a continual act of resistance to external influences. Let us not reproach them with voracity, and their avidity for ardent spirits and fermented liquors. Those nations which inhabit the confines of the habitable world, in which man is scarcely able to withstand the severity of the climate, the inhabitants of Kamtschatka, the Samoiedes, &c. live on fish, that, in the heaps in which they are piled up, have already undergone a certain degree of putrifactive fermentation. In them there is a necessity for this inward excitement, which in our climate would be inevitably attended with disease, and probably death. The abuse of spirituous liquors is fatal to the European transported to the burning climate of the West Indies. The Russian drinks spirituous liquors with a sort of impunity, and lives on to an advanced age, amidst excesses under which an inhabitant of the south of Europe would sink.

The influence of climate not only affects alike the regimen of man in health, but of man in sickness; and it has been justly observed of medicine, that it ought to vary according to the places in which it is practised. A few substances, for the most part obtained from the vegetable kingdom, sufficed to Hippocrates in the treatment of diseases; and physicians who practise in a climate such as Greece, may imitate the simplicity of the father of medicine. Opium, bark, wine, spirits, aromatics, and the most powerful cordials, are, on the other hand, the medicines suited to the inhabitants of the north; and thus we are enabled to use freely those medicines which elsewhere would be attended with the utmost danger.

We are now prepared to understand the beautiful and wonderful harmony that exists between the distribution of man and plants over the globe; and no one, we think, can deny their meed of praise and admiration for the care and beneficence this universal adaptation thus exhibits.

The frigid zone contains but few species of plants, and the verdure of those countries which lie within the polar circle is confined chiefly to the hills having a southern aspect, and the trees are of very diminutive growth. Besides mosses and lichens, there exist ferns, creeping plants, and some shrubs yielding berries of an agreeable flavour. The arctic regions of Europe are peculiarly favoured; for in certain parts of Lapland there are fine forests, and even rye and leguminous plants are produced.

In the high latitudes of the northern temperate zone are the pine and the fir, which show their adaptation to a cold climate by retaining their verdure in the midst of the regions of winter. To these, as advancing southward, succeed the oak, the elm, the beech, the lime, and other forest-trees. Several fruit-trees, among which are the apple, the pear, the cherry, and the plum, grow better in the northern half of this zone; while to its more southern parts, especially, belong the more delicate fruits, such as the olive, the lemon, the orange, and the fig, and, among trees, the cedar, the cypress, and the cork.

The space comprised between the 30th and the 50th parallels of latitude may be considered as the country of the vine and the mulberry. Wheat extends as far north as the 60th degree; oats and barley a few degrees farther. In the southern parts of this zone maize and rice are more commonly cultivated.

The vegetation of the torrid zone is characterised by a wealth, a variety, and a magnificence, which are nowhere to be found in the regions of the globe. Under the beams of a tropical sun, the most juicy fruits arrive at perfection; and innumerable productions supply the wants and administer to the luxuries of man. There the grounds yield the sugar-cane, the coffee-tree, the palm, the bread-tree, the pisang, the immense baobab, the date, the cocoa, the vanilla, the cinnamon, the nutmeg, the pepper, the camphor, and numerous other fruits and aromatics. In South America is the remarkable tree called the *cow-tree*, which, when incisions are made in its trunk, yields abundance of a glutinous and nourishing milk.

The vegetable forms near the equator are in general more majestic and imposing, and the varnish of the leaves more brilliant. The largest trees are adorned with flowers, larger, more beautiful, and more odoriferous, than those of the herbaceous plants in our zone; and it is scarcely possible for an inhabitant of temperate regions to picture to himself the beauty and the grandeur of the vast forests of equinoctial America. Trees, which attain a stupendous height and size, are covered with a profusion of climbing plants, which, creeping on the surface of the earth, reach the tops of the trees, and pass from one another at the height of more than one hundred feet.

But we must hasten to conclude our interesting subject, which might, were we so inclined, extend our labours through several numbers of our Information for the People. Illustrations of design might be produced from the works of nature without end; every link in the chain of creation teems with proofs of it; in none can any one affirm with truth that it is wanting. Cursory as our remarks have been, they still must lead to the general conclusion that not only design, but unity of design and identity of operation, pervade the works of nature, in as far as relate to organised existences; and even among those circumstances of creation which are not organic, there even do we find the same unwearied labour, the same evident design to render them subservient to the wants and necessities of those which are. To several of these we have alluded, and it did not accord with our plan to allude to more; and we do think, that such is the innate force of the evidence we have adduced, that no candid person can rise from the perusal of these pages, without unhesitatingly according his assent to our proposition, that "verily it is a God who made and rules the universe."

MORAL PHILOSOPHY.

The human being differs from all other animated creatures, not only in certain peculiarities of his physical formation, but by the possession of what is variously termed the mind, or the understanding, in which are comprehended the intellectual and moral faculties. The lower animals are furnished with a principle called instinct, by which they unerringly pursue those plans best suited for their subsistence and comfort; but such instinct is to be considered as an irrational, unimprovable faculty, and therein lies its inferiority to human intelligence. The lower animals, being thus for ever doomed to the possession of this inferior faculty, are consequently not responsible for any thing which they may do; they but follow their nature and propensities. Man, the higher animal, has very different destinies. His mind enables him to think, to reason, to improve; he can transmit his thoughts and his experience to his successors; and by education he can train the intellectual and moral faculties into vigour. But man, exalted as is his understanding, and lofty as are his conceptions and feelings, is still an animal. His reason may be a scintillation of divine intelligence, but it is associated with propensities or passions which are little, if at all, superior to those which characterise the brute and other species of animals, and which, if not kept in due subjection, weigh him down below the dignity of human nature.

A thing so remarkable as the human understanding, and the manner in which it operates, could not fail, long ere now, to attract the attention and employ the searching investigations of men endowed with superior degrees of intelligence. Nor can there be any doubt of the utility of making such inquiries. If the faculties be liable to improvement, as they certainly are, it becomes a duty to make ourselves acquainted with their nature and properties, for purposes of cultivation. The more that we can instruct ourselves in what composes the various animal, moral, and intellectual powers, the better shall we adapt ourselves to the circumstances in which we are placed, and the more happy shall we become. The desire to think, to reason on the understanding, is implanted in the soul of man; and the rudest as well as the most profound speculations are alike proofs that this desire cannot be extinguished, that this anxious feeling cannot be lulled into apathy. Unfortunately for the world, the desire to reason on the nature of mind, and the feelings which influence its operations, have in most instances, both in ancient and modern times, taken a direction the opposite of practical utility. Instead of endeavouring to convey an outline of the propensities and faculties, so that those which were discovered as having a tendency to evil might be depressed, and those which had a tendency to good might be more fully developed by culture, teachers and writers of philosophy have proceeded in the most wild and profitless researches into the causes of universal creation, the nature of the soul, and its alliance with spiritual essences. They have asked, What is time, space, cause, effect? What is truth, justice? What is necessity? How do we know any thing? Can we know any thing? Millions of thoughts and words, and thousands of volumes, have been spent in theorising upon these abstract questions, and at the end of thousands of years mankind are obviously not the wiser. They at present know as little of the precise nature of the soul, of time, space, cause, effect, and eternity, as they did five hundred years before the Christian era. It is our object, in the article now before us, to give a succinct view of what has thus been done in exposition of the human mind, and of what still remains to be accomplished, in the way of improvement.

Investigations into the nature of mind and ultimate causes are usually included under the term *Metaphysics*—a Greek compound, signifying *after*, or *beyond* physics, the latter being the observation of material nature. Such abstract investigations are likewise indicated by the term *Philosophy*, another Greek compound, traced to Pythagoras, a Grecian, who refused the title *sophos*, wise, as too assuming, and contented himself with the more modest appellation of *philo-sophos*, which means, a friend or lover of wisdom. The title of *Philosopher* was hence applied to men eminent for wisdom, and hence also the term *Philosophy*. In later times, for the sake of distinction, the kind of investigations we are speaking of have been frequently comprehended under the appellation *Moral Philosophy*, while investigations into physical and mathematical science were designated *Natural Philosophy*. Moral philosophy or metaphysics, therefore, means the science of mind. Yet there is something excessively vague in all that pertains to the definitions respecting philosophy, at least there is a great poverty in the nomenclature. Metaphysics, for instance, has been said to signify the science of the ultimate causes of all being; while the term *Ethics* has been applied to the science of the moral nature and destiny of man. In this sense, religion may be described as a system of ethics, though that is by no means a correct phrase when applied to Christianity. Again, in modern times, philosophy—that is, moral philosophy—has been divided into theoretical and practical. The theoretical philosophy was considered to have for its object the investigation of the highest truths respecting God, the world, nature, and mind; the practical, their application. Some call theoretical philosophy the explanatory or illustrative philosophy, as it has for its object that which exists without our aid, and is the subject of our knowledge; while they term practical philosophy the imperative or preceptive, as it gives precepts of human action. Further, the term *Æsthetics* (signifying *perception*) has been applied to that branch of philosophy which treats of the beautiful and the various applications of its principles. Finally, philosophy has in the above manner been divided, with reference to the three highest ideas of man—the ideas of the true, of the good, and of the beautiful—into the theoretical, practical, and æsthetical.

ANCIENT PHILOSOPHY.

The history of philosophy is commonly divided into the ancient, middle, and modern. The first period begins with the Greek, because, though the disposition to philosophise is confined to no particular nation, but is inherent in all, so that every tribe forms philosophical notions as soon as its religious conceptions pass over into reflection, and its feelings into doubt, yet philosophy was first studied scientifically by the Greeks. This was the earliest known demonstration of the free striving of reason for the knowledge of the ultimate causes of natural phenomena, and carries within it the germs of all the subsequent philosophies. From the time of Thales, six hundred years before Christ, for a period of from four to five hundred years, there flourished a series of philosophers, Pythagoras, Socrates, Plato, Aristotle, Zeno, Epicurus, &c., all of whom propounded their own theories, less or more peculiar, regarding mind, and the destiny of man. Each taught his own doctrines to pupils, and their several systems hence received the appellation of schools.

Philosophy of Socrates.

Socrates (about 422 B. C.) may be considered as having been the most profound of the Grecian philosophers, and his doctrines as the most excellent. He opposed the notions of a class called Sophists, whose theories threatened to destroy moral principle. He gave philosophy quite a new direction. Having been deeply impressed by the inscription on the temple of Apollo, at Delphi, "Know thyself," he began to study his own nature, to reflect upon the phenomena of his own mind, and to meditate on the destiny of mankind, and determined to devote his life to instructing his fellow-citizens in their highest good, by making them wise, honest, and pious.

All the Grecian philosophies sink into insignificance when compared with that of Socrates, whose moral teaching places him in a rank which far transcends that of mere theorists on cause and effect. The attention of Socrates was directed to practical philosophy, which had been previously neglected, and, according to Aristotle, he was the first to lay down general precepts of morality. In this view, it may well be said that he brought philosophy down from heaven to the abodes of men. All his inquiries took a practical turn, and he valued speculation and theory only as connected with practice; for the end of all knowledge, he affirmed, is virtue. He was fully convinced of the existence of an all-ruling, almighty, wise, good, omniscient, and invisible being. The system of nature, and especially the admirable structure of the human frame, seemed to him a positive proof of a Creator; and as man is capable of thought, the same power, he argued, must exist in a still higher degree in the author of reason. The existence of the Deity is as little to be doubted because he is neither visible nor tangible, as the existence of powers concealed from the senses, but known from their effects. He esteemed it rash to speculate upon the substance of this lofty being, and deemed it sufficient to set in a clear light his spiritual nature. It is evident that he worshipped one God, as the Creator of the world and the Judge of mankind, because Xenophon represents him as speaking expressly, several times, of one God only, although in other places he speaks of gods, which he seems to have regarded as subordinate to the Supreme Being. To the good providence of that God he traced all human blessings, and maintained that the omniscient and omnipresent Deity knows every thing, and observes all the secret thoughts and actions of men. For this reason, he esteemed it a sacred duty for men to worship him with all their powers, complying, indeed, with the forms of religious service prescribed by the customs or laws of their country, but particularly striving to do his will in all things. Socrates entertained no less elevated ideas concerning the human soul. He considered it certain that it is of divine origin, wholly distinct from every thing material, and connected with the Deity by reason and the power of thought. He did not deny the difference between it and the divine nature, but maintained that exercise and cultivation would improve the spiritual principle in men. To this cultivation he exhorted his hearers and friends with a godlike zeal. He declared the improvement of the mind to be the highest good of which man is capable. As the chief means, he recommended self-knowledge, and he esteemed those as consummately foolish who knew every thing but themselves. Socrates distinguished, also, a sensible and a reasonable soul. Of the immortality of the soul he was firmly convinced. This doctrine he inferred from its native dignity; likewise from the supposition that the soul gives life to the body; from the phenomena of dreaming; from the opinion of former ages, and from the nature of the Divine Being from whom the soul proceeds. Hence he viewed death to the good as merely a transition to a better life, and spoke of his hopes with affecting certainty and admirable clearness. His pure soul was enraptured with the thought of meeting the virtuous men of earlier ages. He feared not to stand before the holy Judge of the world; and, in the regions of the blessed, he hoped to find unmingled happiness, with the consciousness of having laboured after truth and struggled for virtue. The images and terms by which he describes the wretchedness of the vicious are terrible. Souls which have become diseased by wickedness, covered, as it were, with stains and ulcers, in consequence of their licentiousness, effeminacy, or unlawful desires, and stamped with the hateful impress of perjury and injustice, are plunged into abodes of pain, to be reformed by punishment, or to serve as examples to others. This account of the effect of vice on the substance of the soul, though all plainly symbolical, surpassed, in fearful distinctness, all that had been said on the subject. Socrates founded his morality on his religion. God wishes men to be virtuous, and therefore they should act well. The performance of duty is the only way to happiness. Although he did not exclude the desire of happiness from the motives to virtue, he was far from representing it as the only motive. He thus made an intimate connection between religion and virtue. The native dignity of virtue he painted in the most delightful colours. The dominion over the senses he declared to be the highest state of freedom; he said that virtue only was true wisdom, and that vice was insanity. He exhibited no regular system of morals; but this principle may be considered as lying at the foundation of his views of morality: Do what the Deity commands thee. The true interpreter of this command he considered to be a moral sense which distinguishes between justice and injustice, magnanimity and meanness; in short, between virtue and vice. He did not entertain the idea of moral freedom. On the contrary, he maintained that every man who is acquainted with good, practises it, because every one acts agreeably to his knowledge. Virtue he declared to be the striving to make one's self and others as perfect as possible. All virtue he reduced to two heads, temperance and justice; the former embracing all the duties which man owes to himself, and the latter those which he owes to his fellow-men. The temperance of Socrates included dominion over every sensual impulse. This self-government he regarded as the basis of all other virtues, which, by its aid, will unfold themselves from the promptings of the moral nature, and the increasing knowledge of good. The beneficial influence of this virtue he describes with a genuine inspiration, and draws a frightful picture of excess. His representation of a just man, one who faithfully performs all his duties to God and man, is highly interesting. Injustice he held to be a great evil. He declared that justice was due even towards enemies; and that a man should never transgress the laws of his country, however unjustly they might be administered. His views of friendship, society, conjugal affection, and the pleasures of life, were excellent. He maintained in every thing the golden mean. All his precepts were equally removed from excessive rigour and pernicious laxness; and whoever follows them will be a good man. To his precepts was added his example, so superior to all reproach, that Xenophon, his friend and disciple, in his Memorabilia, says none ever saw him perform a vicious or unworthy action. There can be no question that Socrates was the most faultless of all the great men in ancient times. The principal error into which he appears to have fallen, arose from his enthusiasm in the pursuit of a pure philosophy; he believed himself to be an ambassador sent by God, and that divine revelations were made to him by a genius, which always invisibly attended him. Socrates, like many benefactors to mankind, was ill rewarded for his valuable admonitions. He was falsely charged with denying the ancient divinities of the state, and of corrupting the youth, and, through the influence of the populace, was condemned to die by drinking poison, a fate to which he submitted with extraordinary magnanimity. Among his most distinguished disciples were Alcibiades, Crito, Xenophon, Antisthenes, Aristippus, Phædon, Æschines, Cebes, Euclid, and Plato. The sagacious and philanthropic propositions of Socrates were afterwards reduced to a system by his pupil Plato, the founder of the academic school; and this philosophic system was fully developed by Aristotle, the founder of the peripatetic school. Plato was distinguished for the warmth and vividness of his conceptions; Aristotle aimed at cool and patient reflection on the nature of things. By the side of the schools of Plato and Aristotle, the Stoic school, founded by Zeno, and the Epicurean, placed themselves in opposition.

Philosophy of Zeno.

According to Zeno, philosophy is the way to wisdom; wisdom itself is the knowledge of human and divine things; and virtue is the application of wisdom to life. The chief heads of his doctrine—logic, physics, and morals—were connected into a systematic whole. In logic, which he defined the science of distinguishing truth and falsehood, he made experience the basis of all knowledge; ideas, or conceptions, which in all respects resemble their objects, he called true, and the power of judging according to principles, the mark of a sound reason. In his physics, he refers to nature itself for the highest standard of human duties, and derives the moral precepts from the laws of the universe. He assumes two uncreated and eternal, but material principles of all things—the passive matter, and the active intelligence, or God, which resides in matter, and animates it. The Deity is the original intelligence, and of an ethereal fiery nature: he made the world, as an organic whole, out of matter and form, by the separation of the elements; and he also rules the world, but is limited in his operations by unchangeable fate or the necessary laws of nature. The universe, according to Zeno, is penetrated by the divine intelligence as by a soul, and is therefore living and rational, but destined to be destroyed by fire. He considers the heavenly bodies, and the powers of nature, of a divine character, and therefore admits the worship of several gods, and teaches that their connection with men may be beneficial to the latter. The human soul he considers as produced by the union of the creative fire with air, and endowed with eight faculties—the five senses, the powers of generation, speech, and reason: the latter, as the active principle, governs the whole soul. The ethics of the Stoics treats the will of God (which also animates the soul of man), or nature, as the source of the moral law, which binds men to aim at divine perfection, since this only can lead to a virtuous life, harmonising with God and nature, which is the only true happiness. Their practical maxim is, Follow nature, live according to nature, or, which amounts to the same thing, Live in accordance with the laws of consistent reason. They considered virtue the highest good, and vice the only evil; every thing else is indifferent, or only relatively agreeable or disagreeable. They call human actions honest, when they have a reasonable foundation in the nature of the agent; perfectly proper, and therefore obligatory, when good in themselves; intermediate or lawful, in so far as, indifferent in themselves, they are expedient or allowable only in certain relations, but criminal when they are inconsistent with the reason of the agent. Virtue they accordingly explain as the true harmony of man with himself, independent of reward or punishment, to be attained by correct moral judgment, and the mastery over the passions and affections: this virtue presupposes the highest inward tranquillity and elevation above the pleasures and pains of sense; it makes the wise man not destitute of feeling, but invulnerable, and gives him a dominion over his body which permits even suicide. Virtue, therefore, is represented chiefly under the character of self-denial. Such was the philosophy of Zeno, or the Stoics (from *stoa*, a porch, the place where it was taught), which it will be perceived contains a strange mixture of correct and improper principles. As if to prove the value of his theory, Zeno put himself to death at an advanced age, and his example was followed by his pupil Cleanthus, who killed himself by starvation.

Philosophy of Epicurus.

The philosophy of Epicurus had a resemblance in some points to that of Zeno, yet differed very considerably from it. After travelling through various countries, in order to cultivate his mind and to collect information, he settled in his thirty-sixth year at Athens, where he began to teach. He was soon surrounded by crowds of scholars. He taught that the greatest good consists in a happiness, springing not from sensual gratification or vicious pleasures, but from virtue, and consisting in the peace and harmony of the soul with itself. He accordingly renounced vice, and embraced virtue, not for their own sakes, but for their connection with happiness, vice being as incompatible with it as virtue is essential to it. He recommended wisdom, moderation, temperance, seclusion from political affairs, gentleness, forbearance towards the self-love of men, firmness of soul, the enjoyment of decent pleasures (so far as it does not incapacitate us for new pleasures), and contempt of life. Freedom from pain he regarded as desirable, but, at the same time, he bore with fortitude the most excruciating pains of body. Although he distinctly showed the meaning of his doctrines by his own exemplary life (which some, however, charged with pride and envy), yet they have been often misunderstood or misrepresented. His doctrine of the origin of the universe, borrowed from Democritus, is atomical and material. Proceeding upon the axiom, that nothing can be produced from nothing, he assumed two necessary, eternal, and infinite first causes—space, and atoms, or indivisible bodies, arranged in endless variety. These atoms, by virtue of their natural gravity, moved in space, and mingled with one another. To make the union possible, he supposed them to move, not in straight, but in curved lines. By these motions, they crossed and hit each other in all possible ways; and from their numberless combinations and intervolutions, arose bodies and beings of all kinds. Although single atoms had no other qualities than figure and gravity, they produced, when combined in bodies, the various qualities that affect the senses, as colour, sound, smell, &c. He further taught, that as all things arose from the union of atoms, so all things will be again destroyed by their dissolution; that there are multitudes of worlds, formed by chance, which are continually rising and falling. The world, as it has had a beginning, must have an end; and out of its ruins a new one will be formed. He found no difference between men and brutes, and ascribed the origin of the soul to the same material process above described. The gods, he thought, lived in eternal tranquillity, unconcerned about the world. This doctrine, which was not unjustly charged with atheism and materialism, drew upon him much opposition and calumny. He lived to the age of 72, dying 270 years before the Christian era. The philosophy of Epicurus, with much to condemn as conjectural and ridiculous, has, it will be noticed, several good points, and these certainly have been misunderstood. It has been supposed that it was the principle of the Epicureans to indulge in sensual gratifications, at whatever risk of after-pain or misery; whereas it is clear that Epicurus never taught so short-sighted a doctrine.

Plato and Aristotle.

We learn from the philosophical writings of Plato, that he was inspired with the most lofty and glowing desire to show the connection of the human soul with what he terms the original fountain of light and perfection; we see the conceptions of a mind to which the greatest earthly good appeared to be the union of kindred souls in the love and zealous search for truth—the Platonic love; of a mind which conceived the human soul to contain, in its present state of lost perfection, all the germs of regeneration. Plato first introduced the word *idea* into philosophy, but his doctrine upon this subject had somewhat peculiar. He agreed with the rest of the ancient philosophers in this, that all things consist of matter and form; and that the matter of which all things were made, existed from eternity, without form; but he likewise believed that there are eternal forms of all possible things which exist, without matter; and to these eternal and immaterial forms he gave the name of *ideas*; maintaining that they are the only object of true knowledge. It is of no great moment to us whether he borrowed these notions from Parmenides, or whether they were the issue of his own creative imagination. The later Platonists seem to have improved upon them, in conceiving those ideas, or eternal forms of things, to exist, not of themselves, but in the divine mind, and to be the models and patterns according to which all things were made.

Aristotle had no good affection to the word *idea*, and seldom or never uses it but in refuting Plato's notions about ideas. He thought that matter may exist without form, but that form cannot exist without matter. But at the same time he taught, that there can be no sensation, no imagination, nor intellection, without forms, phantasms, or species in the mind; and that things sensible are perceived by sensible species, and things intelligible by intelligible species. His followers taught more explicitly, that those sensible and intelligible species are sent forth by the objects, and make their impressions upon the passive intellect; and that the active intellect perceives them in the passive intellect. And this seems to have been the common opinion while the Peripatetic philosophy retained its authority.

The theories of Zeno, Epicurus, Plato, and other eminent Grecian sages, did not survive unhurt from the destruction of liberty in Greece. They were afterwards adopted by Cicero, Seneca, and other distinguished Romans; and among them they suffered still farther injury from the contests, or wars of opinion and words, of the sceptics and dogmatists. Grecian philosophy rallied, and took new forms at Alexandria, in Egypt, where an attempt was made to reconcile the Platonic philosophy with the Jewish Scriptures. After the promulgation of Christianity, a mixed system of ethics was similarly put together, entitled the Eclectic Philosophy, which was an attempt to combine the theories of the Grecians and the Jews with the doctrines of the Christians.

THE SCHOLASTIC PHILOSOPHY.

After this period, we hear no more of philosophy till it was taken up by a class of men who arose in the middle ages, and have since received the appellation of Scholastics, or Schoolmen. The name Scholastic Philosophy is derived from the circumstance that it originated in the schools instituted by Charlemagne for the education of the clergy. The philosophy therein taught consisted in a collection of logical rules and metaphysical notions, drawn from the Latin commentators on Aristotle. These, under the name of Dialectics, composed the theoretical philosophy, which had the defence of the dogmas of the church for its primary object. It is almost needless to add, that the scheme of nature in connection with the intellectual faculties, and the deductions therefrom, as propounded or compounded by the Scholastics, has met with the same oblivion, so far as practical utility is concerned, which attended the theories of the Grecian sages and their Roman followers.

MODERN PHILOSOPHY.

The philosophy of the schools sank in the fifteenth century, and then arose a third or modern period of philosophic investigation. A free and more independent mode of inquiring and penetrating deeper and deeper into ultimate causes now commenced. The human mind was let loose upon itself. Some reasoned from the results of experience; some took the consciousness of thought and existence as the foundation of their philosophy; many doubted every thing; and some went the length of attempting to prove that both mind and matter were equally imaginary—that good and evil were purely ideal.

Descartes.

Among those who in this manner came forward to establish new schools of philosophy, none became so conspicuous as Descartes, a Frenchman (born 1596, died 1650), who did much to give metaphysical inquiry a new direction, and whose theories have generally received the appellation of the Cartesian system of philosophy. Descartes founds his belief of the existence of a thinking being on the consciousness of thought: "I think, therefore I exist" (*cogito, ergo sum*). He developed his system with much ingenuity, in opposition to the empiric philosophy of the English and the Aristotelian Scholastics, and adopted the rigorous, systematic, or mathematical method of reasoning. From his system originated the notion among the moderns, that the very existence and certainty of philosophy consists in definitions, arguments, and a methodical arrangement of them. "The thinking being," says Descartes, "or the soul, evidently differs from the body, whose existence consists in space or extension, by its simplicity and immateriality (whence also its immortality), and by the freedom that pertains to it. But every perception of the soul is not clear and distinct; it is in a great degree involved in doubt, and is so far an imperfect, finite being. This imperfection of its own leads it to the idea of an absolutely perfect being." He placed at the head of his system the idea of an absolutely perfect being, which he considers as an innate idea, and deduces from it all farther knowledge of truth. The principal problems of metaphysics he conceived to be substantiality and causality. He contributed greatly to the advancement of mathematics and physics. He made use of the discoveries and observations of others, defining them accurately, and assigning them their place in his system. The higher departments of geometry (to which he successfully applied analysis), as well as optics, dioptrics, and mechanics, were greatly extended by him, their method simplified, and thereby the way prepared for the great discoveries made in the sciences by Newton and Leibnitz.

Spinoza.

The propositions of Descartes met with approval in different parts of Europe, and were at first followed by none more zealously than Baruch Spinoza, who was born in 1632 at Amsterdam, of a Jewish Portuguese family, and early gave proofs of a reflecting mind and an independent spirit. Becoming dissatisfied with the instructions of his Jewish teachers, Spinoza sought out new doctrines, and for this met with no small degree of persecution. He nevertheless, in following a humble profession, pursued his philosophical investigations, and published his theories concerning the connection of mind with matter. The doctrines of Spinoza are so abstruse as to be beyond our comprehension, and we must refer to his works for a perfect knowledge of his system. He seems to have felt, like every other philosopher, the longing to elevate himself to a point at which the struggle between matter and mind, liberty and necessity, &c. is done away, and all discord ceases. This led him to the idea of an original substance embracing all existence. Substance, of course, in this sense, means something very different from what we usually understand by the word. This original substance, in which all contradictions cease, and all subjects of finite consciousness disappear, he called God; by which he understood that which has an independent existence, and the understanding of which requires not the idea of any thing else. This substance, according to him, is infinite, and nought else exists; it is incapable of creating any thing material or intellectual, for all matter and mind are comprehended in itself; its attributes are infinite thought and infinite extension. God, this all-embracing being, can act only in accordance with the established order, for otherwise we must suppose him capable of a change of nature, or that there exists a nature different from his own. Thought and extension, spirit and matter, the finite and infinite, motion and repose, good and evil, causes and effects, are attributes of this sole substance, which produces nothing but modifications of itself. All that exists is only a necessary succession of modes of being in a substance for ever the same. Such is something like the idea which he endeavoured to illustrate and establish, which it will be allowed is by no means intelligible, or consistent with observation and experience. His extravagant theories, which have been called Spinozism, are now considered to be synonymous with atheism. Spinoza also wrote a political and theological treatise, which does not come under our notice, and is only mentioned from its containing the proposition, "that freedom of thought can exist without endangering the public peace and virtue, but that it must necessarily stand or fall with it." Spinoza died in 1677, before which period philosophical inquiry had considerably advanced in this country.

ENGLISH PHILOSOPHY.

Bacon.

Modern philosophy in England is dated from Bacon, who flourished at the beginning of the seventeenth century, and was thus coeval with Descartes. In his *Novum Organum*, published in 1620, he takes a path directly opposite to that universally followed in his time; and instead of appealing by dialectics to the notions of the understanding, he attempts to restore knowledge by the aid of observation through induction. He was not the founder of a sect; he did not deliver opinions; he taught no modes of philosophising; he did not attempt to discover new principles, but to render observation and experience the predominant character of philosophy. His services consist in his dethroning scholastic theorems, directing the attention to nature and observation, and rejecting final causes from physical inquiries. Bacon was friendly to the culture of the human faculties, and his notions regarding civil society and government were what would now be termed liberal. His observations on the laws of memory and imagination are considered to be among the best of his writings on the nature of mind.

Hobbes.

Thomas Hobbes, born in the latter part of the sixteenth century, and the friend of Bacon, was the next to propound his theories respecting the nature of the human understanding. If Bacon was a liberal, Hobbes was an advocate for despotism; and in all his writings he lays down the precise laws which regulate mind in a way not to be disputed. He was a dogmatist, and the founder of the sensual school of philosophy. Bacon was the friend, Hobbes the enemy, of virtue. According to this "bold thinker," "all knowledge is derived from the sense by motion; thoughts are representations of the qualities of bodies without us; the cause of sense is the pressure of the external object on the organ of sense; what we call *sensible* qualities are nothing but motion in us; imagination is nothing but decaying sense, and understanding is imagination raised by words or other voluntary signs. Besides sense and thought, and train of thoughts, the mind has no other motion. Whatever we imagine is finite; therefore there is no idea of any thing infinite. Reasoning is nothing but reckoning; that is, adding or subtracting. The passions are internal voluntary motions; when appetites and aversions, hopes and fears, arise alternately about the same thing, the whole sum of these motions is deliberation; and the last appetite or aversion in deliberation is will, not the faculty, but the act of willing." This may be exceedingly excellent, but we are compelled to confess that it is beyond our comprehension. Sir James Mackintosh, in his invaluable Treatise on English Philosophy (Dissertation Second, Encyclopædia Brit. vol. I. new edit.) thus speaks of Hobbes's confusion of the principle of *thought* and *feeling*:—"The multiplicity of errors which have flowed into moral science from this original confusion, is very great. They have spread over many schools of philosophy, and many of them are prevalent at this day. Hence the laws of the understanding have been applied to the affections; virtuous feelings have been considered as just reasonings; evil passions represented as mistaken judgments; and it has been laid down as a principle, that the will always follows the last decision of the practical intellect. By this great error, Hobbes was led to represent all the variety of the desires of man, as being only so many instances of objects deliberately and solely pursued; because they were the means, and at the time perceived to be so, of directly or indirectly procuring organic gratification to the individual. The human passions are described as if they reasoned accurately, deliberated coolly, and calculated exactly. It is assumed that, in performing these operations, there is and can be no act of life in which a man does not bring distinctly before his eyes the pleasure which is to accrue to himself from the act. From this single and simple principle, all human conduct may, according to him, be explained, and even foretold. Many besides him have really represented *self* as the ultimate object of every action; but none ever so hardily thrust forward the selfish system in its harshest and coarsest shape. Having thus struck the affections out of the map of human nature, it is no wonder that we should find in it not a trace of the moral sentiments. Moral good he considers merely as consisting in the signs of a power to produce pleasure; and repentance is no more than regret at having missed the way: so that, according to this system, a disinterested approbation of, and reverence for, virtue, are no more possible than disinterested affections towards our fellow-creatures. There is no sense of duty, no compunction for our offences, no indignation against the crimes of others, unless they affect our own safety; no secret cheerfulness shed over the heart by the practice of well-doing. From his philosophical writings, it would be impossible to conclude that there are in man a set of emotions, desires, and aversions, of which the sole and final objects are the voluntary actions and habitual dispositions of himself, and of all other voluntary agents, which are properly called *moral sentiments*; and which, though they may vary more in degree, and depend more on cultivation than some other parts of human nature, are as seldom as most of them found to be entirely wanting."

Locke.

The paradoxes of Hobbes excited general alarm among moralists, and were answered or refuted by Cudworth with considerable effect, and they have at length come to be looked upon as beautifully and correctly written fallacies. After Hobbes came Locke (born 1632, died 1704), one of the greatest of our writers on the mental faculties. In order to study the human soul, he went neither to ancient nor modern philosophers for advice, but turned within himself, and after having long contemplated his own mind he gave his reflections to the world. He considers that the understanding attains the knowledge of itself through experience and observation. Rejecting innate ideas, Locke teaches that sensation and reflection are the only sources of knowledge, external objects furnishing the mind with the ideas of sensible qualities, and the mind furnishing the understanding with ideas of its own operations. Sensation convinces us of the existence of solid extended substance, and reflection of the existence of thinking ones, of the cause and nature of which two kinds of being we can know nothing. Perception is a communication between the mind and external objects carried on by means of images present to the mind; these he calls *ideas*, which he defines to be the immediate objects about which the mind is employed in thinking. Having treated at length of the origin, nature, and qualities of ideas, he proceeds to consider the instrument by which men communicate their ideas to each other; and his remarks on this subject (Book iii., of Language) form the most valuable dogmatic part of his work. Knowledge is the perception of the agreement or disagreement of ideas, which consists in identity or diversity, relation, coëxistence, and real existence. Of the existence of ourselves and of God we have intuitive knowledge, which is the immediate perception of the agreement or disagreement of ideas: demonstrative knowledge is the discovery of it by the intermediation of other ideas: and these two sorts of knowledge yield complete certainty. Sensitive knowledge leads to the belief of the existence of other beings, and carries with it a reasonable confidence. Judgment is a supposition or opinion of the agreement or disagreement of ideas, and supplies the want of knowledge. Its conclusions are only probable. By thus making experience, or the conviction of our senses, the basis of our knowledge, both of mind and matter, Locke has been called an empiric or quack in the schools of philosophy; and his system was keenly opposed by Leibnitz, Hume, and others. It would appear that Locke had it less in view to extend our knowledge of the nature of the mind than to make us sensible how little we possibly can know. He expresses his desire "to prevail with the busy mind of man to be cautious in meddling with things exceeding its comprehension; to stop when it is at the utmost extent of its tether; and to sit down in quiet ignorance of those things, which, upon examination, are found to be beyond the reach of our capacities." He continues in a strain which it would have been creditable to the common sense of philosophers had they duly regarded. "My right hand writes, whilst my left hand is still. What causes rest in one and motion in the other? Nothing but my will, or thought of my mind; my thought only changing, my right hand rests, and the left hand moves. *This is matter of fact, which cannot be denied.* Explain this, and make it intelligible, and then the next step will be to understand creation. . . . . . In the meantime, it is an overvaluing ourselves, to reduce all to the narrow measure of our capacities; and to conclude all things impossible to be done, whose manner of doing exceeds our comprehension. . . . . If you do not understand the operations of your own finite mind, that thinking thing within you, do not deem it strange that you cannot comprehend that eternal infinite mind, who made and governs all things, and whom the heaven of heavens cannot contain." Whatever may be said of the empiricism of Locke, it is acknowledged by all that he was an acute thinker, and his labours, as demonstrated in his Essay on the Human Understanding, which was nineteen years in preparing, will always be acknowledged with gratitude in the history of philosophy; but at the same time it must be remembered, that, in attempting to analyse the human soul, as an anatomist proceeds in investigating a body piece by piece, and to derive all ideas from experience, he has unintentionally supported materialism. His declaration, that God, by his omnipotence, can make matter capable of thinking, has been considered dangerous in a religious point of view.

Shaftesbury.

During the period in which Locke flourished, English ethical philosophy was considerably advanced by Anthony Ashley Cooper, third Earl of Shaftesbury, whose writings appeared between the years 1709 and 1713, when he died. In the last-mentioned year, his collected works were published, under the title of Characteristics of Men, Manners, Opinions, and Times. The attention of Shaftesbury was directed principally to the writings of antiquity, on which he built a civil, social, and theistic kind of philosophy; one of his chief aims seems to have been to write elegantly and neatly, and he often indulges in a vein of humour altogether at variance with sound reasoning. According to the opinion of one who, it will be allowed, was well able to judge in matters of this nature—the late Sir James Mackintosh—Shaftesbury's "Inquiry Concerning Virtue" is entitled to a place in the first rank of English tracts on moral philosophy. "Among the most important of Shaftesbury's suggestions (says Sir James, in his already quoted dissertation, Encyclopædia Britannica, vol. i., new edition, which we here take the opportunity of recommending to perusal), is, that goodness consists in the prevalence of love for the system of which we are a part, over the passions, pointing to our individual welfare; a proposition which somewhat confounds the motives of right acts with their tendency, and seems to favour the melting of all particular affections into general benevolence, because the tendency of these affections is to general good. The next, and certainly the most original, as well as important, is, that there are certain affections of the mind, which, being contemplated by the mind itself through what he calls a *reflex sense*, become the objects of love, or the contrary, according to their nature. So approved and loved, they constitute *virtue* or *merit*, as distinguished from mere goodness, of which there are traces in animals who do not appear to *reflect* on the state of their own minds, and who seem therefore destitute of what he elsewhere calls a moral sense. . . . It should never be forgotten that we owe to these hints the reception into ethical philosophy of a moral sense, which, whatever may be thought of its origin, or in whatever words it may be described, must always retain its place in such theory as a main principle of our moral nature. His demonstration of the utility of virtue to the individual far surpasses all attempts of the same nature, being founded, not on a calculation of outward advantages or inconveniences, alike uncertain, precarious, and degrading, but on the unshaken foundation of the delight, which is the very essence of social affection and virtuous sentiment; on the dreadful agony inflicted by all malevolent passions, upon every soul that harbours the hellish inmates; on the all-important truth, that to love is to be happy, and to hate is to be miserable—that affection is its own reward, and ill will its own punishment; or, as it has been more simply and more affectingly, as well as with more sacred authority, taught, that to give is more blessed than to receive, and that to love one another is the sum of all human virtue. The relation of religion to morality, as far as it can be discovered by human reason, was never more justly or more beautifully stated. If he represented the mere hope of reward and dread of punishment as selfish, and therefore inferior motives to virtue and piety, he distinctly owns their efficacy in reclaiming from vice, in rousing from lethargy, and in guarding a feeble penitence; in all which he coincides with illustrious and zealous Christian writers." Yet, according to Shaftesbury, "if by the hope of reward be understood the love and desire of virtuous enjoyment, or of the very practice and exercise of virtue in another life, an expectation or hope of this kind is so far from being derogatory from virtue, that it is an evidence of our loving it the more sincerely *for its own sake*." This elegantly expressed sentiment bears a resemblance to that of Jeremy Taylor, when he says, in his Sermon on Growth in Grace, "he that is grown in grace pursues virtue purely and simply for its own interest. When persons come to that height of grace, and love God for himself, that is but heaven in another sense." Shaftesbury's Characteristics were received with enthusiastic favour by Leibnitz, the German philosopher.

Berkley.

The sensualism or materialism of Locke led Berkley (who flourished during Queen Anne's reign, and was bishop of Cloyne in Ireland) to form a peculiar theory regarding ideas. His Theory of Vision, which is reckoned the most valuable part of his labours, was the first exposition of the difference between the original and acquired perceptions of the eye, and now forms an essential part of the science of optics. Berkley was an exceedingly amiable man, and elegant writer; but his ideas about ideas can only now be considered an amusing absurdity. He maintains that the belief in the existence of an exterior material world is false and inconsistent with itself; that those things which are called sensible material objects are not external, but exist in the mind, and are merely impressions made on our minds by the immediate act of God, according to certain rules, termed laws of nature, from which he never deviates; and that the steady adherence of the Supreme Spirit to those rules is what constitutes the reality of things to his creatures. It is very difficult to understand what the philosopher means by this denial of the existence of matter; he is more intelligible when he tells us, "that the end to which God requires the concurrence of human actions must be carried on by the observation of certain determinate and universal rules or moral precepts, which in their own nature have a necessary tendency to promote the well-being of mankind, taking in all nations and ages, from the beginning to the end of the world."

Hume.

The visionary ideas of Berkley brought David Hume forward to combat the whole system of Locke and his followers. About the year 1738, he published his Treatise of Human Nature, which was an attack on all the principles of knowledge and belief. Discarding experience and observation as utterly futile, he proved to his own satisfaction, and perhaps that of many others, that nothing was known, and that nothing could be known; demonstrating that we are doomed for ever to remain in total ignorance of ourselves, of God, and of all nature. He laid down the proposition, that whatever has a beginning has a cause, is not intuitively certain, but is derived only from custom and belief, and is rather an act of the sensitive than of the cogitative part of our nature. In this argument he proceeds on the ground that all certainty arises from a comparison of ideas, and the discovery of their unalterable relations, which are resemblance, proportions in quantity and number, degrees of quality and contrariety, and none of which is implied in the proposition above stated. All the objects of knowledge are impressions and ideas; the former are our more lively perceptions, when we hear or see, love or hate, or desire or will; the latter are the less lively perceptions of which we are conscious when we reflect on the former, and are copies of impressions. The existence of these perceptions as objects of consciousness cannot be denied; but to admit the existence of a percipient being, the I, is to assume that of mind, which is no more an object of knowledge than matter. There can therefore be no objective knowledge; and we are reduced to consciousness, the phenomena of which it takes cognisance, and their subjective relations. Hume's system of scepticism is not scepticism antecedent to study and philosophy, but consequent to science and inquiry, holding the absolute fallaciousness of the mental faculties, bringing the senses themselves into dispute, and thus sapping the foundations of all knowledge, and rejecting the existence of God, a providence, and a future state. "It is true (says Sir James Mackintosh, in the work to which we formerly referred) that such a system of universal scepticism never can be more than an intellectual amusement—an exercise of subtlety—of which the only use is to check dogmatism, but which perhaps oftener provokes and produces that much more common evil. As those dictates of experience which regulate conduct must be the objects of belief, all objections which attack them in common with the principles of reasoning must be utterly ineffectual. Whatever attacks every principle of belief can destroy none. As long as the foundations of knowledge are allowed to remain on the same level (be it called certainty or uncertainty) with the maxims of life, the whole system of human conviction must continue undisturbed. When the sceptic boasts of having involved the results of experience and the elements of geometry in the same ruin with the doctrines of religion and the principles of philosophy, he may be answered, that no dogmatist ever claimed more than the same degree of certainty for these various convictions and opinions; and that his scepticism, therefore, leaves them in the relative condition in which it found them. No man knew better, or owned more frankly, than Mr Hume, that to this answer there is no serious reply. Universal scepticism involves a contradiction in terms—*it is a belief that there can be no belief*. It is an attempt of the mind to act without its structure, and by other laws than those to which its nature has subjected its operations. To reason without assenting to the principles on which reasoning is founded, is not unlike an effort to feel without nerves, or to move without muscles. *No man can be allowed to be an opponent in reasoning, who does not set out with admitting all the principles, without the admission of which it is impossible to reason*. It is indeed a puerile, nay, in the eye of wisdom, a childish play, to attempt either to establish or to confute principles by argument, which every step of that argument must presuppose. The only difference between the two cases is, that he who tries to prove them can do so only by first taking them for granted; and that he who attempts to impugn them falls at the very first step into a contradiction from which he never can rise." It is impossible to withhold a tribute of admiration to the genius and logical powers of Hume, as they are developed in his celebrated Essay on Cause and Effect, and other papers; but his works in the main must be considered as little else than elegant quibbles, and, as such, may be safely left to the appreciation of the recluse.

Hartley.

At about the same time with Hume, a new philosophic writer sprung up, under the name of Hartley. This individual attempted to account for all the phenomena of the mind, by the single principle of the association of the ideas, and for this principle, by vibrations and vibratiuncles in the medullary substance of the brain. In connection with this plan of materialism, he defended the doctrine of necessity, representing God as the only cause of all natural effects and all human actions. To this Hartleian school belonged Priestley, Darwin, and Horne Tooke.

THE SCOTCH PHILOSOPHERS.

Speculations upon the nature of mind are considered to have originated in Scotland with Dr Francis Hutcheson, of the University of Glasgow. Hutcheson, who was a man of cultivated understanding, and delivered some valuable lectures, is, however, less remembered than Dr Thomas Reid, of the same eminent seminary, who in 1764 published his Inquiry into the Human Mind, and in 1785, his Essay on the Intellectual Powers. Philosophic inquiry was subsequently advanced by Dr Thomas Brown, and, more lately, by Dugald Stewart, both professors in the University of Edinburgh. This class of inquirers has the merit of having first strongly and largely inculcated the absolute necessity of admitting certain principles as the foundation of all reasoning, and as being the indispensable condition of thought itself. According to the Scotch philosophers, certain simple ideas are implied and involved in certain intuitive judgments of the mind; thus, identity, cause, time, number, truth, certainty, probability, are ideas peculiar to a rational mind, and necessarily arise in the human understanding, when employed in the exercise of its different faculties. Reid, therefore, while he rejected the Cartesian theory of ideas or images in the mind being the only objects of thought, directed his inquiries to an analysis of the various powers and principles of our constitution, in order to discover the fundamental laws of belief, which form the groundwork of human knowledge. Though professing to build only on experience, he did not limit experience to the relations of sense and its objects. Without claiming for man more than a relative knowledge of existence, and restricting the science of mind to an observation of the fact of consciousness, he analysed that fact into a greater number of more important elements than had been recognised in the sensualist school. He showed that phenomena are revealed in thought, which cannot be resolved into any modification of sense; that intelligence supposes principles, which, as the conditions of its activity, cannot be the result of its operations; and that the mind contains notions, which, as primitive, necessary, and universal, are not to be explained as generalisations from the contingent and particular, about which alone our external experience is conversant. His enumeration of the faculties of the mind, which he does not, however, give as complete, comprises perception, memory, conception, abstraction, judgment, reason, taste, moral perception, consciousness. The representation of consciousness as a special faculty, when in reality it is the generic condition of all mental activity, was a pregnant error in Reid's philosophy; while his doctrine of the immediate or intuitive knowledge of mind and matter, which involved the overthrow of the ideal system, and the scepticism (or rather *nothingism*) deduced from it, was an important step in the progress of philosophy. Stewart, with some deviations, followed in the track of his master; but Brown, while he adopted many of the principles of Reid, departed, in many points of fundamental importance, from his philosophy. He assumes the existence of the primary intuitions of direct belief, which are not only necessary to reasoning, but to thought itself; all our conceptions imply the idea of form, which is derived from relation in space (*coëxistence*), and of power, which is derived from relation in time (successive existence); cause is only the invariable antecedent, effect the invariable consequent, power the invariable antecedence, in any sequence of phenomena. All feelings and thoughts are the mind itself existing in certain states; consciousness is not a distinct faculty, but a general term for all the states of the mind. Mental (personal) identity is an intuitive law of thought, it being impossible to conceive of successive states but as modifications of the permanent being—the I. The different states are divided by Brown into the external states (sensations) produced by the presence of external objects, and the internal states, arising in consequence of preceding affections of the mind itself. The latter class is divided into intellectual states and emotions, which are all referable to one generic susceptibility—suggestion (association of ideas). The laws of suggestion are resemblance, contrast, and nearness in time or place, which are all reducible to proximity. That capacity of suggestion which revives conceptions, Brown terms simple suggestion, and that which gives rise to feelings of relation, relative suggestion. To the former are reducible those mental states commonly called the faculties of conception, memory, imagination, and habit; to the latter, those of judgment, reasoning, and abstraction. Brown's philosophy is considered to involve many radical inconsistencies, which cannot be particularised in so general a sketch. With the death of Stewart (1828), the Scotch school of philosophy may be said to have become extinct.

It is worthy of observation that Scotland has been much more indebted to Dr Adam Smith, who, besides his well-known treatise on the Wealth of Nations, composed a work entitled the "Theory of Moral Sentiments," than to those eminent individuals whose attention was almost exclusively directed to metaphysics. The Wealth of Nations is a work which abounds in valuable truths in relation to the welfare of mankind in communities, and ought to be carefully perused by all young men.

FRENCH PHILOSOPHY.

Mallebranche.

We have already mentioned Descartes, whose inquiries into the nature of mind had such an effect upon the philosophy of modern times. From him we pass to Mallebranche, a priest and a philosopher, who published his famous Treatise on the Search after Truth, in the year 1673. This elegant writer held doctrines founded upon Cartesian principles, and in some particulars Platonic. His theory is principally distinguished by the maintenance of a mysterious union betwixt God and the soul of man, and the doctrine that the human mind immediately perceives God, and sees all things. Mallebranche was highly venerated for his elevated genius; and nothing could be more amiable and simple than his conversation and manners. As a philosopher, although he agreed with those who preceded him, in conceiving ideas to be the immediate objects of perception, he distinguished, more than any previous metaphysician, the object from the sensation which it creates, and thereby led the way to a right understanding, both of our external senses and mental powers.

Bayle.

It is necessary that we should mention Bayle in the history of French philosophy, although little else can be said of him than that he was one of the most insidious doubters who ever published his opinions on the nature of mind. Bayle was born in Languedoc in 1647, and died in 1706. In 1696, while a refugee in Holland, where he was known to Shaftesbury, he published his celebrated Historical and Critical Dictionary, which was forthwith attacked on account of the religious opinions which it developed. Bayle was most subtile in his metaphysical disquisitions, and possessed a powerful spirit of critical sagacity in treating of historical characters. His writings therefore had a mischievous tendency in unsettling the minds of superficial inquirers. He moreover professed himself to be a follower of no sect in philosophy; but in thus preserving an independence in reasoning, it seemed only to be for the purpose of sneering at the opinions of all other men, and of indulging his humour in setting the various classes of thinkers at variance with each other. Bayle is described by Voltaire as being "the first of logicians and sceptics;" but this was said before Hume made his appearance in the philosophical world.

Condillac.

Stephen Bonnot de Condillac (born in 1715, died in 1780) was the founder of the sensual school of French philosophy. He taught that the basis, the principle of all that is developed in our mind, is sensation (*la faculté de sentir*). All ideas, knowledge, faculties, even reflection, actions, and customs, are successive transformations of this principle. In all his works he strongly argues this point; and the simplicity of his theory awakened the greatest interest. He was supported by Diderot, d'Alembert, and Helvetius, and the influence of his writings on society generally was most striking. The most difficult of all sciences, which requires the deepest study and the most persevering reflection, was brought within the reach of the multitude; every one could talk about metaphysics. But it was overlooked that this system did not lead men a step nearer to the solution of the highest and most important problems. The system was carried farther and farther, not always in accordance with the views of the author, but according to the direction given by him. Sensation (the lowest degree of intellectual action, and that in which we are most dependent upon the external world) being now considered the essential principle in all the operations of the mind, the distinction between sensation and perception, which Locke had made, being rejected, and man being regarded only as an animal of a somewhat finer organisation than the others, but moved only by sensual impulses (as in the system of Helvetius), the consequence was, that the material world was considered as the only form of existence, mind as only a connection of atoms, the basis of its actions egotism, and the end of these actions a refined sensuality; thence the belief in moral freedom, virtue, God, providence, and immortality, was looked upon as a folly unworthy of a reflecting mind, and a complete materialism became predominant. Since the time of Condillac, new theorists have arisen, among whom Victor Cousin is the more prominent. At present, France cannot be said to have any system of intellectual philosophy properly its own.

GERMAN PHILOSOPHY.

Leibnitz.

German philosophy is distinguished by an incessant striving for a systematic character, and the deduction of scientific conclusions from the simplest and most comprehensive principles. It must be considered to begin with Gottfried Wilhelm, Baron of Leibnitz (born at Leipsic 1646, died 1716), one of the most celebrated philosophers and scholars which Germany has ever produced. This eminent visionary, who was coeval with Locke and Newton, endeavoured to deduce philosophical truth from necessary and innate ideas of reason, by way of mathematical demonstration. The basis of his theory is, that there are in philosophy, as in mathematics, necessary truths, which cannot be learned from experience, but must be grounded in the soul itself, as they rest on principles, the proof of which is independent of the evidence of the senses. Such is the substructure of the rationalism of Leibnitz, whose singular line of reasoning on the nature and operations of the mind and senses it may be curious to follow. The principal characteristics of his rationalism are a peculiar theory of knowledge, the doctrine of monadology, and the theodicea, or doctrine of optimism. With regard to knowledge, according to this system—1. The necessary truths are innate to the soul, not indeed actually forming objects of knowledge, but capable of being called forth by circumstances. Whatever is derived from the senses is confused, and distinct knowledge is possessed only by the understanding. These views are opposed to the empiricism of Locke. In order to attain truth, it is necessary to use the rules of logic, as mathematicians also use them, by unfolding, analytically, the simple truths contained in a subject, until the fundamental truth is attained. The Cartesian criterion—clearness and distinctness—is not sufficient. "Our conclusions," says Leibnitz, "rest on two great principles—the principle of contradiction (according to which we deem that false which involves a contradiction, and that true which is opposed to falsehood), and the principle of the sufficient reason (which teaches that no assertion is true, if no sufficient reason can be given why it is true, rather than false), which leads to an absolute final reason, independent of accidental circumstances. But the final reason of the certainty of innate necessary truths is in God, as the source of all necessary and eternal truth. 2. Monadology forms the central point of the system, and Leibnitz believed that in this he had discovered the fundamental basis of actual knowledge. All experience teaches us that there are compound substances; consequently there must be simple ones. The senses give us only confused, the understanding distinct, knowledge; and the simple, which cannot be recognised by the senses, is the ground of the compound. These simple substances, from which the compound are formed, and each of which differs in its qualities from all others, since there are no two things exactly alike, Leibnitz calls *monads*, of which he assumes four sorts—pure monads (or living beings), the souls of beasts, the souls of men, and God, who, as the origin of all knowledge, of reality, and of the existence of things, the eternal, original Monad, he calls the *Monas monadum*. All created monads are united with bodies, or rather all finite beings are aggregates of monads, some having a central and governing monad. The different classes of monads conceive of the universe with different degrees of distinctness; God alone conceives it perfectly. There is no actual influence of one thing on another, but only an ideal connection; *i. e.* the internal changes of each monad are so arranged as to agree with the changes in the monads immediately connected with it. The cause of this agreement is the infinite wisdom and almighty power of the Deity. The divine understanding is the prototype of all truth, beauty, and absolute good, and by it all the interior changes in the monads were so predetermined, that there is a perfect harmony in their succession. This predetermination or established harmony was arranged by the Godhead when the plan of the world was formed. 3. The theodicea is the defence of the supreme wisdom of the Creator of the world, which had been impugned on account of the existence of evil. Such a theodicea Leibnitz attempted, particularly on account of the contrary views brought forward by Bayle. According to the Leibnitzian system, an infinite number of worlds are possible in the divine understanding; but, of all possible ones, God has chosen and formed the best. Every thing which really is, is best in connection, even if, by itself, it is imperfect. This system is therefore denominated optimism. Each being is intended to attain the highest degree of happiness of which it is capable, and is to contribute, as a part, to the perfection of the whole. We have not room to follow Leibnitz through his intricate theories regarding the existence of moral evil, the operation of finite spirits, &c. He obtained many followers, some of whom, by means of logic, carried his system to absurdity. The Leibnitzian school was followed by a period of eclectic philosophy, in which the scepticism of Hume, the examination of the understanding by Locke, the psychological investigations of Feder, Garve, and Mendelssohn, together with the sentimentality which reigned in poetry as well as in religion, prepared the way for the system of Immanuel Kant.

Kant.

This eminent German (born 1724, died 1804), who first published his theories of the human understanding in 1781, gave quite a new character to the philosophy of his country. Kant set out with an eager search after truth. He perceived that the idea of cause and effect is by no means the only one which the mind makes use of with the consciousness of its necessity, yet without having derived it from experience. This he found in his endeavours to ascertain what we can know, which led him to the fundamental laws of the mind. Having arrived at this conclusion, he strove to ascertain the exact number of these original or transcendental ideas or imperative forms—that is, such ideas as we do not derive from experience, but by which, on the contrary, we acquire experience. In the first rank of these are space and time. Kant shows that all our perceptions are submitted to these two forms; hence he concludes that they are within us, and not in the objects; they are necessary and pure intuitions of the internal sense. Truths acquired by experience never carry with them that absolute certainty—for instance, experience teaches us that the sun rises every day, that all men are mortal; yet we may imagine a day when the sun does not rise, and a man who does not die; but imagination itself cannot suppose any thing unconnected with space and time. This primitive intuition must have as its basis the primary laws of the understanding, without which we can comprehend nothing. As far as the transcendental ideas, or, as Kant calls them, categories, extend, so far extends the knowledge of the understanding *a priori*. Kant was at great pains in endeavouring to ascertain the number of these categories, and he found them to be all comprehended under the four classes of quantity, quality, relation, and modality. The categories themselves are twelve in number:—Under the first head are comprised, unity, multitude, totality; under the second, reality, negation, limitation; under the third, substance and accident, cause and effect, action and reaction; under the fourth, possibility, existence, necessity. These categories are necessary and indispensable for our understanding, as the forms of space and time were for our perceptions. We cannot figure to ourselves any thing without the relations of cause and effect, of possibility, quantity, &c.; which, with other words, is, we cannot perceive any thing except by those original, necessary, unchangeable forms of thought. Hence the demonstrative certainty of mathematics, the objects of which—space, time, quantity, &c.—lie in the necessity of the forms of thought, and not in the range of error to which experience is subject. To produce results, the categories are applied to exterior objects—objects of experience—in which application they are subject to error. The three original faculties, through the medium of which we acquire knowledge, are sense, understanding, reason. Sense, a passive and receptive faculty, has, as has been already stated, for its forms or conditions, space and time. Understanding is an active or spontaneous faculty, and consists in the power of forming conceptions, according to the categories already given, which categories are applied to objects of experience through the medium of the two forms of perception, space and time. Reason is the third or highest degree of mental spontaneity, and consists in the power of forming ideas.—Besides what are considered to be the merits of Kant in regard to intellectual philosophy, much is owing to him for his virtue and inflexible morality, which he anxiously endeavoured to place on their true elevated basis, after they had been referred exclusively to interest by Helvetius and others. His philosophy has been taught in all the German universities, excepting some Catholic ones.

We have now presented a sketch, which has been necessarily brief, of the principal leading philosophies in ancient and modern times; but it has been given more with the view of affording our readers an idea of what has been done in the way of exploring the hidden mysteries of mind, than with the hope that any benefit will be reaped from the perusal. The sketch, such as it is, exhibits a lamentable picture of misdirected ability—of valuable time spent in a search as vain as that after the "philosopher's stone." From the days of Zeno and Epicurus to those of Immanuel Kant, the world has been the theatre of successive systems of metaphysics, each of which, as we have seen, has met with followers of greater or less distinction, in schools and colleges, without having, either individually or collectively, been of any sensible benefit to the mass of the community. Logic, the design of which is to teach the right use of our reason, or intellectual and moral faculties, and the improvement of them in ourselves and others, has been actively employed in the endeavour to subvert the most obvious truths. Zeno demonstrated the impossibility of motion; Spinoza, that there was no God; Hobbes, that there was no difference between right and wrong; Hume, that belief was imaginary; Descartes, Mallebranche, and Locke, that mind was matter, or, in other words, that when we lose our consciousness of existence, we no longer preserve our identity. Well may the untaught reader inquire, What does all this mean? We may answer him in the words of Reid—"Poor untaught mortals believe undoubtedly that there is a sun, moon, and stars; an earth which we inhabit; country, friends, and relations, which we enjoy; land, houses, and moveables, which we possess. But philosophers, pitying the credulity of the vulgar, resolve to have no faith but what is founded on reason. They apply to philosophy to furnish them with reason for the belief of those things which all mankind have believed, without being able to give any reason for it. And surely one would expect that, in matters of such importance, the proof would not be difficult; but it is the most difficult thing in the world; for these three great men—Descartes, Mallebranche, and Locke—with the best good will, have not been able, from all the treasures of philosophy, to draw one argument that is fit to convince a man that can reason, of the existence of any one thing without him. Admired philosophy!—daughter of light!—parent of wisdom and knowledge!—if thou art she, surely thou hast not yet arisen upon the human mind, nor blessed us with more of thy rays than are sufficient to shed a 'darkness visible' upon the human faculties, and to disturb that repose and serenity which happier mortals enjoy, who never approached thine altar, nor felt thine influence! But if indeed thou hast not power to dispel those clouds and phantoms which thou hast discovered or created, withdraw this pernicious and malignant ray—I despise philosophy, and renounce its guidance; let my soul dwell with common sense." These are no doubt severe expressions of reproof from one of the most eminent inquirers into the nature of mind in modern times, but they are obviously no less severe than just. Professor Dugald Stewart has admitted with the Abbé de Bonald that "diversity of doctrine has increased from age to age, with the numbers of masters, and with the progress of knowledge; and Europe, which at present possesses libraries filled with philosophical works, and which reckons up almost as many philosophers as writers, poor in the midst of so much riches, and uncertain, with the aid of all its guides, which road it should follow—Europe, the centre and focus of all the lights of the world, has yet its PHILOSOPHY only in expectation."

While professors of moral philosophy have thus left the people in ignorance of the nature of mind, or presented them with disquisitions too abstruse for their comprehension, other authors, not connected with the schools, have come forward with the enlightened and philanthropic view of explaining the operation of the intellectual faculties, of cultivating the moral feelings, and subduing the animal propensities. Among the various writers who have thus endeavoured to benefit society, we may refer to Dr John Abercrombie, of Edinburgh, whose recent work, though scarcely systematic, abounds in valuable matter. We shall now notice the extraordinary exertions which for the last few years have been made by the phrenologists, whose system of mind, laying the question of its physiological origin and alleged foundation entirely aside, has perhaps better claims to notice than many who are repelled by the startling question as to that origin, may be aware of. Their system, at the hazard of appearing tautological, we shall term the

PHRENOLOGICAL PHILOSOPHY.

This new science of mind was first developed by Dr Gall, a German physician, who about the year 1791 attracted considerable attention to his anatomical and physiological inquiries respecting the brain and nerves. Gall had remarked at school, that some boys, who excelled him in spite of his efforts in committing words to memory, were distinguished by prominent eyes. Thence he inferred that the talent or the organ of verbal memory must reside in this part of the head. He afterwards became convinced that this and other talents actually depend on the formation of certain parts of the head. He collected skulls, carefully comparing the prominences common to all, and those which distinguish them from each other. He compared also the skulls of animals, studied the habits of beasts and men, the formation of their brain, and thus arrived by degrees to assign the particular localities of above twenty organs, or as many seats of the most prominent operations of the mind. This new system was called *Phrenology*, from two Greek words signifying the science of mind. Along with his friend

Dr Spurzheim, Gall subsequently delivered lectures in Germany and France, exhibiting his discoveries and views. Before his death, in 1828, phrenology had obtained many converts on the Continent, in Great Britain, and North America. The science, however, has not been more indebted to these philosophers for the advances which it has made, than to Mr George Combe, of Edinburgh, who embraced its doctrines about the year 1817, and has ever since exerted himself to extend the knowledge of them to others. Mr Combe not only equals his preceptors in reach and profundity of thought, exactness of observation, and the clearness and method with which he explains his views, but in these qualities has very few equals among the thinking men of the age. In a work which he published in 1828, under the title of "An Essay on the Constitution of Man, considered in relation of external objects," he gave a view of the phrenological scheme of mind apart from the question of its organological truth, and pointed out how it might be applied practically to the improvement of the condition of the human race.

This treatise has presented the science in a new aspect, and one under which it seems likely to make a far more rapid advance than formerly. Down to this period the great stumbling-block of phrenology evidently was its supposed pretensions to what appeared a kind of divination: it bore the appearance of one of those sciences which men have long considered false, from their not being founded in nature. As if disposed to compensate the credulity which their ancestors displayed respecting alchemy and astrology, the public have been perhaps too eager to condemn a science which, though at first sight one of the same order, never yet has made any pretensions that were not based on observation of facts patent to the senses. So much we can say in a spirit of fairness, without having ourselves so much acquaintance with the organological part of the science as to say whether it is to be believed or not. Since the publication of Mr Combe's Essay, which has been understood and practically applied by multitudes without regard to particular localities in the brain, the case has evidently been much altered. Phrenology may now be taken into consideration, not as a means of vaticinating upon the characters of men by an inspection of their heads, but as a scheme of the mental constitution; in short, a system of metaphysics, and, consequently, of morals. Considered in this light, it appears to us to have, in the first place, the important quality of intelligibility, which no other system altogether has. It seems for the first time to make plain the perplexing mixture of tendencies, feelings, and powers, which has heretofore rendered men such a riddle to himself. This it does by rigidly tracing the powers of mind to their *primitive* functions, and reducing them to a kind of democratic level, allowing each an agency independent of the rest, but which may be exerted in company with others, and dividing the whole into three great classes—propensities, moral sentiments, and intellectual faculties. While Mr Combe has treated these with a regard to the general improvement of the race, they have more recently been described by Mr James Simpson, in his eloquent and convincing work on education, to which that author thinks them eminently applicable, as analysing the being to be educated. As they are detailed in the latter work with the author's characteristic liveliness and point, and with the advantage of some additional observations made since the appearance of Mr Combe's treatise, we shall prefer taking our account of them from that source. The frequent allusions to the treatment of particular faculties in education made by Mr Simpson will incidentally serve to show that the science is practical as well as intelligible:—

"It is plain, that until an approximation shall be made to something like a practical analysis of the mind of man, until the faculties to be improved by education are known, education must continue to be vague, misdirected, and inefficient, as it has hitherto been. If, as is evident, we can make no practical use of a great part of the catalogue of faculties which we studied at college, may we not meet upon some admitted common ground? May we not adopt those impulses or powers of mind which directly constitute the view of man taken by necessity, although very unsystematically, in the common affairs of life; but by philosophers rejected, and therefore never reduced to any thing like system, and, above all, never resorted to in education. Let any one think what are the tendencies or characteristics in his fellow-men to which he traces their actions, and upon which he relies with the utmost confidence for certain expected results. Let us turn to our most successful portrayers of *nature*, a Shakspeare and a Scott, and observe what are their constituent characteristics of that nature, to which the same faculties in ourselves echo with such delighted sympathy. Assuredly these will not be found in the catalogues of the metaphysicians. I should be safe in conditioning, that I shall not need to claim for human nature any one impulse not recognised and dealt with—practically though not systematically—by Shakspeare and Scott. These are capable, we think, of a much more satisfactory analysis than might be supposed; an analysis which I only require to be granted to me, even for argument's sake, to obtain a basis for education which would advance its efficiency to a degree almost beyond our calculation. I feel so confident that all my postulates as to human powers, impulses, instincts, or faculties—for we need not dispute about names—will be conceded to me, from the impossibility, as I humbly view it, of refusing the concession, that I am content to peril the whole argument upon the admission by every educated person—First, that the impulses now to be enumerated form constituent parts of man; and, secondly, that, as is true of the physical structure and organic functions, each is related to some object or objects in nature, moral or physical, external to itself, but directly pointing to it, upon which it is exercised. I wish it, however, to be distinctly understood that I do not found upon physiological evidence of the truth of the analysis of faculties which I am humbly to offer, because that evidence is not generally admitted; I do not require to trace each faculty to a disputed cerebral origin; the faculties shall be merely metaphysically submitted *seriatim* to the reader's judgment, and his own experience appealed to; and any one which he does not recognise in man, I am quite contented that he shall reject. If, too, he does not think the relative object correctly added to each faculty as we advance, that, too, he is at perfect liberty to disallow.

1st, I do not fear denial, when I claim for man AN APPETITE FOR FOOD, an instinct which directs him, even when new-born, to remove the pain of hunger, the only pain then removeable by an act of his own. Forming a variety or mode of the instinct of food, which last includes hunger and thirst, is the desire of the stimulus of alcohol in wine or some other shape. The abuses of these appetites are gluttony and drunkenness. That this instinct is primitive, is demonstrated by its often existing in a state of disease; the insatiable craving of hunger, even when the stomach is full, is a common lunatic symptom; while the temptations of wine and ardent spirits often become altogether beyond the control of the will. The relative objects of that instinct are edible animal and vegetable matter; while the juice of the grape, and other extracts capable of being fermented and distilled, gratify the taste for alcohol alluded to.

2d, For the preservation of his species, man is endowed with AN INSTINCT OF SEX. As the abuse of this impulse leads to much evil and suffering, individual and social, it requires much more educational watching and regulation than it ever receives. The consequences to body and mind of this neglect are often horrible. Its derangement is known in lunatic asylums, and detailed in works on insanity. Its object, relatively, is the other sex.

3d, Man has an IMPULSE TO CHERISH HIS OFFSPRING. There are cases in which this propensity has been morbidly excited. Its relative object is the helplessness and innocence of childhood; the feeling and the object were intended for each other.

4th, A PROPENSITY OF ATTACHMENT to his fellow-men, in the alliances of society and friendship, is a part of man's constitution. This feeling is so strong that solitude has often produced mental alienation, as has the unmitigated silence of some penitentiaries. Man's fellows exist in manifest relation to this social tendency.

5th, No impulse requires more the restraining hand of education than the PROPENSITY TO CONTEND AND FIGHT. We are made most aware of its being part of man, by seeing it in the various forms of its abuse, contentiousness, contradiction, violence, assault, and war. But as no instinct or faculty was given for the purposes of abuse, we shall find the use of this propensity in self-defence, courage, enterprise, and general activity. This impulse has a marked relation to external objects; it was given to man that he may repel the dangers which often assail him from other animals, and the passions of his fellow-men.

6th, It is not enough that man shall contend and fight; it is often imperative upon him to destroy. Besides killing for food, he must, in self-defence, kill dangerous animals, and more dangerous men, that assail him; and to fit him for this, he has AN INSTINCT TO DESTROY. The feelings which prompt this extreme, with regard to his own species at least, are resentment, anger, and rage; these are often abuses, and certainly so is a cruel delight in giving pain, and even depriving of life. In disease, it is the most dangerous form of madness; it produces murder without motive, appetite for blood, ungovernable violence, and indiscriminate destruction of every thing within its reach. Much short of disease, it is a troublesome propensity; cruelty to animals, and the tendency to deface and destroy, are its manifestations; while the irascible tempers which disquiet the domestic circle are its most ordinary form of abuse. It requires for its regulation, if not its repression, the firmest and the gentlest educational management. The impulse is widely spread in the animal creation; it is the instinct of prey; and teeth, tusks, beaks, and claws, are its instruments. It prompts man, too, to arm himself with *destructive* weapons, from the rude club to the battery of cannon. Lastly, it constitutes the impulse to punish, to inflict pain, torture, and death.

7th, In nothing will the observant instructor of youth perceive more diversity among individuals than in the characteristics of reserve or openness. Some individuals are so close, that nothing can be extracted from them; others apparently conceal nothing. The truth is, that all conceal much more than they declare, and an IMPULSE TO CONCEAL is a constituent part of man, for the wise end of preventing that constant exposure of thought and purpose, which would not only render society intolerable, but would remove a material guard against the evils which, by their selfish passions, men are inclined to inflict upon each other. The right use of the impulse to conceal is a prudent reserve; its abuse is cunning, duplicity, and deceit. Those who are conversant with the insane are too well aware how often a morbid habitual cunning calls for increased vigilance. The related objects of the faculty are the other faculties whose outward manifestations it restrains: the perfection of what is called *acting*, in both a favourable and unfavourable sense, depends partly on the energy of this power: some children are consummate actors, and thereby greatly perplex their teachers, who are ignorant of the spring and origin of that deceptive character.

8th, Man has A DESIRE TO POSSESS the material things that contribute to his well-being, and loves to accumulate them in exclusive property. When the advantages to society of this accumulation are reflected upon, it is evident that what is called *capital* is an institution of nature, confined to man as to indefinite accumulation, though observed in bees, beavers, and some other animals, as to annual store. It is only necessary to think what would be the condition of social man if he lived, like most animals, on the chance of each day, to be convinced of the connection between accumulation and social power and enjoyment. The use of the faculty to each individual is the attainment of the means of regular subsistence for a family, and the benefit of inheritance: its abuse is avarice; its grosser abuse theft: its disease every one has heard of or witnessed in an impulse, not created by necessity, but beyond the control of the will, to appropriate things of value, and, in the worst cases, whether of value or not. The related objects of the propensity are material things which afford enjoyment in some way to the faculties, and money their sign and convertible value. The regulation of the propensity ought to be an important object of attention in education.

9th, Independently of his reason, man has an IMPULSE TO CONSTRUCT, to change the forms and combinations of matter into instruments and accommodations. Franklin called him a 'tool-making animal.' The faculty is often possessed in uncommon power by cretins and other idiots without an atom of intellect to guide it. Reason and imagination greatly aid the faculty in man, as is evident when we compare the wigwam with the palace. Individuals differ greatly in this primitive power; some can make whatever they see, others cannot fold a letter neatly. The relative objects of the impulse are manifest in the material world. This power the judicious instructor will recognise and call forth in his pupil.

It must have occurred to the reader, that in the inferior animals are found *all* the nine propensities now described, for they are well nigh essential to animal existence. On this ground I ask leave to distinguish them as a class, and refer to them in the sequel, by the name of the ANIMAL PROPENSITIES. Before leaving this class of faculties, it seems the best time to appeal to the reader's experience if it be not truth, and press the fact on the attention of the educationist, that vice and crime, in all their phases and varieties, are but other terms for the abuse of one or more of these specified impulses. The enumeration of a few will sufficiently illustrate this; every one can apply each instance to the impulse abused, for they are set down in the order adopted—namely, gluttony, drunkenness, incontinence, contention, violence, cruelty, murder, robbery, fraud, theft, &c.

10th, Scarcely anticipating the possibility of the rejection of any of the nine impulses already submitted, I would next, with not less confidence, claim for the man we are compounding, a sentiment of SELF-LOVE, in which is included as well self-elevation as self-preference. In due and beneficial endowment, it is a legitimate attention to our own well-being; it is self-respect, independence, and confidence in our own powers and capacities. In abuse, it is pride, self-sufficiency, disdain, insolence, love of power, tyranny, and general selfishness. It is a great exciting cause of the activity of the impulse to resentment and rage, and then it takes the deeper colour of revenge; and, when combined with the impulse to appropriate, it renders that propensity yet more steady, grasping, and exclusive. It is the special faculty of quarrels and duels, and forms the ingredient of turbulence and tyranny, which is a nuisance in public, and a curse in private, life. No faculty of man is more apt to run into abuse, and half the moral evils of man's lot spring from that abuse. The guide of youth cannot therefore too early begin to watch and repress its unamiable manifestations, and regulate its legitimate exercise. Under the present system of education, this important part of man is left to its own guidance. Need it be added, that it is often manifested in a form of insanity not to be mistaken; morbid self-exaltation accounts for the straw crowns and wooden sceptres of Bedlam. The related objects of the feeling are obviously self and its concerns.

11th, Another sentiment, often but improperly confounded with self-love, exercises a mighty influence over man, and furnishes the key to much of the pursuit of his life; and that is, DESIRE OF ESTIMATION. By the one, a man esteems himself; by the other, he courts the esteem of others. They are best distinguished in their abuse. The one is pride, the other vanity: the one assumes, the other begs; hence it is truly remarked, that an individual is too proud to be vain. The use of the sentiment now considered, as intended by the All-Wise who endowed man with it, is a proper regard to character, the feeling of shame, and, under proper regulation, the incitement to worthy conduct in the love of praise. The feeling shrinks from reproach, censure, ridicule, and exposure. It leads to a careful concealment of vices, follies, and weaknesses, and, better yet, often to their cure. The laws which enact disgraceful punishments, as the pillory, address it directly. It is essentially the love of glory, and, in combination with self-exaltation, it constitutes ambition. Finally, it often runs into disease, of which any one who has visited a large lunatic asylum must have been rather annoyingly made aware, by the eager competition of the vain patients to detail and display to him their merits, each at the same time pitying his neighbour for his vain-glory. What, it may be asked, has education ever done to regulate this and the previous powerful and all-pervading feeling? The answer is—Nothing! On the contrary, it has carefully *instituted* the means of aggravating the evils of both, by all the competitions, prizes, preferences, and 'honours' of our schools and colleges. The related object of this feeling is found in the tendency of mankind to observe and judge each other.

12th, That a SENTIMENT OF FEAR is a part of man, no one will deny, and least of all the teacher of the old school, whose ever-brandished rod and cane make a personal appeal to the feeling. The sentiment is given as a self-protector from dangers, physical and moral, with which we are surrounded. Its abuse is cowardice, terror, and panic. Punishment, for example's sake, implies our belief of its power as a motive. Its external objects are danger and evil in general. When diseased, it occasions the groundless fears and horrors of hypochondria, and is essentially that insane melancholy which furnishes the impulse to suicide, by sufferings far more intense than man is ever visited with in what is erroneously distinguished as reality.

The last and two preceding sentiments of self-love, and desire of estimation, evidently regard *self*, and, therefore, although very important constituent faculties in man, and intended, in their proper use, for the wisest ends, have nothing in them amiable or exalted. They are as self-seeking as any of the nine animal propensities, and therefore may conveniently be classed with these, under the general denomination of the INFERIOR FEELINGS. The whole twelve instincts make up and constitute the Scriptural entity of the 'law in the members warring against the law in the mind.'

13th, That there *is* a law in the mind, is beautifully implied in the very distinction of Scripture alluded to; and it is the object of education, while it represses and regulates the law in the members, to strengthen and confirm the law in the mind. The first element of the law in the mind is BENEVOLENCE—the benign parent of a catalogue of graces, in kindness, desire of the good of others, generosity, compassion, mercy, and all the sympathies of brotherly love. It is the charity which 'suffereth long and is kind,' which 'is gentle and easy to be entreated,' and which, in its expansiveness and sincerity, 'is without partiality and without hypocrisy.' It is impossible to conceive a description of benevolence more just, as well as beautiful, than the Scriptural. Sentient beings, generally, are the related objects of this exalted sentiment, and their happiness is its scope and delight. It is an error to suppose its function confined to compassion and relief to distress and misery. It goes much beyond this: it is a well-spring of good-will to men, and reaps positive delight from the increase and extension of human happiness. Its manifestations appear to the selfish to be mere sentimental enthusiasm, or weak sacrifice of substance and ease; yet *their* most exclusive joys are vapid, in comparison with the delights of benevolence. Truly, the field of benevolence is boundless, for it embraces all that can aid or advance human happiness, physical and moral. It desires to see man free, enlightened, morally and religiously elevated, and placed in physical comfort and safety. It descends also to kindness to the lower animals. Even this high sentiment is capable of abuse. This appears in facility, indiscriminate alms-giving, and profusion. In disease, it is beyond the power of the will of the individual, to whom, therefore, the law appoints a guardian.

14th, A sentiment of JUSTICE or conscientiousness belongs to man; it respects the rights of others, and is also manifested in truth and candour. Its deficiency is a great defect of character, unamended even by benevolence. The individual so endowed is apt to be generous before he is just, according to an everyday expression. It is a mistake to recognise a defective conscientiousness in that palpable dishonesty only which calls for the interference of the law. It is a wide-spreading evil in society, far short of that degree of its manifestation. It shows itself in a way and manner against which the law cannot make provision, in the great variety of modes in which men, for selfish ends, are *unfair* to each other, by taking advantages which they would not give; concealing the truth which ought to be told, or misleading with regard to it; disallowing others' claims, not capable of easy proof; shrouding others' merit; misstating or distorting others' argument; resenting fair competition; envying success; manifesting a selfish jealousy; indulging in evil-speaking and ridicule; and, in a thousand ways, 'doing to others that which we would *not* they should do to us.' The severest satire on mankind is really found in the distinction conceded to the fair, open, candid, and considerate character, to the Aristides of his circle, who is marked for his whiteness (the etymology of candour), in the midst of the various shades of discoloration in his fellows, with which he is surrounded. The disease of the feeling, for even conscientiousness may be over-excited, is observed in the melancholy self-accusatory ravings of some maniacs, especially in those too numerous cases in which religious terrors have driven reason from its seat. The related objects of the sentiment of justice are the rights and feelings of our fellow-men. It acknowledges the justice of God.

15th, The most superficial observer of man cannot have failed to feel in himself, and observe the signs in others, of a sentiment of VENERATION, a feeling of deference, submission, and reverence. Signs of these are shown by almost all in their converse with those they feel to be their superiors in intellect or conventional rank, as something that is their due; and the whole strength of the feeling can be testified by those whom it has deprived of utterance when suddenly brought into the presence of majesty.

But there is a higher related object of this feeling than earthly kings. The King of kings is its great end and object: it is then veneration, and constitutes the chief ingredient in the adoration of religious worship. A large natural endowment of the sentiment often carries mere external sanctity to excess, and, mistaking it for religion, claims, and often receives, consideration and homage for it, to the inconvenient crowding of the calendar.

The three feelings of *benevolence*, *justice*, and *veneration*, predominating over the inferior and selfish propensities, present us at once with an intelligible system of ethics. This is that supremacy of the moral sentiments which is partially admitted by ethical writers, from Butler to Chalmers; the latter in his Bridgewater Treatise constitutes conscience the sole ruler; but benevolence is not less offended by vice and crime than justice; while veneration is shocked with the daring disobedience to God's will which these aberrations involve. The three sentiments of justice, benevolence, and veneration, are powerfully combined in that preceptive keystone of Christianity, 'to do justly, to love mercy, and walk humbly with your God.' The humility so beautifully glanced at is that repression of self-exaltation (the tenth impulse I have treated of) which the instructor should never lose sight of; remembering that 'pride was not made for man;' self-love was intended for him, but not its abuse, 'which bringeth a snare.' The energy of these three feelings, acting as they always do in combination, constitutes the moral impossibility of committing crime; for a man in whom they are supreme is restrained from criminal acts more effectually than if fetters of triple brass were on his hands. If there be means—and it will appear in the sequel that there are beautifully simple and effectual means—of increasing the power of these invaluable sentiments, by the exercise of practical moral training, does it not vitally concern society to apply them? I shall offer a few words more on the supremacy of the higher feelings, after treating of the Intellect.

16th, I claim no more for man than almost all metaphysicians do, and all the non-metaphysical world, in attributing to him a sentiment of HOPE, the source of much worldly happiness, and the *natural* foundation of our prospects of a life to come. Hope is a chief ingredient in religious feeling; while, in common life, it is not confined to expectations and anticipations of the future, but is a permanent gaiety, lightness of heart, and buoyancy of spirits, which is contented with the present, dreads no evil, and constitutes in itself real happiness. Children, as well as adults, differ widely in this character of mind; an enlightened teacher of youth will convert the feeling to useful purposes.

17th, The teacher will find his pupils to differ in another respect: he will meet with some of them pliant and obedient, and others obstinate and impracticable; there is, in different degrees, in man, a sentiment of FIRMNESS, the use of which is perseverance and fortitude, the abuse of which is obstinacy. It is of importance that this should be recognised in education as an innate feeling, by which much labour to the teacher, and suffering to the young, might be prevented, by avoiding vain contests with obstinacy, persevered in by the teacher in the expectation of curing the defect, while he is only strengthening the feeling and confirming the habit. The struggle with an obstinate child, who is further fortified by pride and self-sufficiency, may be compared to an attempt to extract a nail by striking it on the head; every stroke only drives it faster. The judicious teacher will take care never to bring the matter to that issue, but will address himself to other faculties, especially justice, benevolence, and reflection; keeping in mind the fable, that the storm could not induce the traveller to part with his cloak, which he only held the faster, but the sun was more successful.

18th, Man loves the wonderful. That the sentiment of WONDER is innate, will scarcely be doubted by any one who observes its power as a motive, and the fortunes that are made by appeals to it. Well does the charlatan know the effect produced by his cry of 'wonder!' It is evidently bestowed as a source of delight in contemplating the wonders of creation, and as an impulse to inquiry. With veneration and hope, it constitutes the religious combination of faculties; I mean what is called religious *feeling*, for conscience and reflection are the bases of religious *duty*. The joint operation, in due proportion, of the two sets of faculties, makes up the perfection, humanly speaking, of the religious character; while a separation of them is always more or less to be regretted. Take away or impair reflection, and the remaining feelings will be apt to run into enthusiasm, and even fanaticism; take away or diminish conscience, and we have the apparent anomaly of sanctity without honesty, of religious excitement with much unfairness, censoriousness, intolerance, and persecution. Wonder is met with in morbid activity; its madness sees visions, and dreams dreams, nay, attempts miracles; in combination with a high estimate of self, it constitutes the prophet of special revelation, and the angel of light admitted to the counsels of heaven. Of this we have not to go far for examples—the leaders and their followers are all over-excited *wonderers*. Education is called upon to watch this faculty; it will show itself in a child, in a tendency to exaggerate and embellish, a marked delight to surprise and occasion wonder, with often an utter sacrifice of truth to attain that end.

19th, I do not anticipate objection to a faculty for the sublime, the beautiful, the elegant, the perfect, the poetical, as a constituent of the mind of man. The imagination of the metaphysicians comes nearest this sentiment, but it does not fully express it. Imagination is considered as a power which produces ideal creations; the feeling in question is a mere sentiment or habit of mind which aspires to the beautiful and perfect, and communicates an elegant refinement to the whole character; it prompts other faculties to create, while itself merely feels, and views all nature with associations of beauty and of poetry. Its abuse is romantic enthusiasm, unguided by reflection. Its related objects are all that is beautiful and sublime in nature; it is one of the gifts of Divine Benevolence which points directly at high enjoyment; like music, it is something superadded to the necessary faculties. When it is absent or deficient, the individual is gross and unrefined. Infant education takes much care of this feeling, and in various ingenious ways calls it into exercise, with different success, according to the degree of natural endowment; for in nothing do individuals differ more from each other. With the explanation now given, shall call this faculty IMAGINATION.

20th, THE LOVE OF THE LUDICROUS requires a judicious educational management. Man is the only laughing animal, the only one gifted with a specific enjoyment from the contemplation of incongruity. It is greatly abused in satire, tricks, and mischief, and requires watching: it operates severely on the tempers of many who are made its butts, and often withers every purpose of exertion or improvement. Certainly it has been greatly neglected in education. Its relative objects are found in the exhaustless field of incongruity.

21st, IMITATION is a marked faculty in man, which shows itself even in the youngest children. Its purpose is manifestly to bring society to a convenient uniformity of manners, without which it would present a scene of inextricable contrariety, and to aid in educing the powers of the young, by the energy of an impulse to do what they see done by their seniors. It aids, as is most obvious, the imitative arts, and has for its related objects no narrower field than universal nature.

The reader is requested to glance back at the faculties just treated of, beginning with 13 and ending with 21, which, like the animal propensities, happen to be *nine* in number, and oblige the author, by recollecting that, whenever he speaks of the MORAL SENTIMENTS, he means these nine faculties. The reader will at once observe that Nos. 10, 11, and 12, viz. Self-Love, Desire of Estimation, and Fear, are not of dignity sufficient to be classed with the moral sentiments; but, being as selfish in their nature as the nine animal propensities, and being also plainly discernible in the inferior animals, they are classed with the propensities under the general name of the INFERIOR FEELINGS; it follows that the moral sentiments are meant, when the term superior or HIGHER FEELINGS is used. These last distinguish man on this earth from all the creatures of God.

But the 'Law in the Mind' would be an imperfect regulator of the 'Law in the Members,' if it consisted even of the moral sentiments alone. Sentiments are but feelings, and feelings, however virtuous, are blind, and depend upon intellect for their proper direction. For example, benevolence prompts us to succour poverty; but that feeling makes no inquiry into the cause of that poverty which it profusely relieves. It therefore requires to be itself directed by another class of faculties, namely, the intellectual, which, observing, perceiving, knowing, and reasoning, can ascertain, if so it be, that the poverty is the result of idle and profligate habits, that the poor man is perfectly able-bodied and fit for labour, and that therefore the benevolence is wasted, and worse, upon the encouragement of an unworthy object. Man is endowed with intellectual faculties, and these may be divided into the KNOWING and REFLECTING. It is undeniable that, intellectually, we *know* and we *reflect*. It is a common observation that knowledge is not wisdom, till it is compared and reasoned on by reflection. It is its combination with reflection which constitutes that knowledge which is power. The weakest reflecting powers often co-exist in the same individual, with a store of knowledge which excites our wonder.

The KNOWING POWERS cognise two classes of objects; namely, *existences* and *events*; in other words, things that *are*, and things that *happen*. Let any one reflect for a moment, and he will find that whatever he knows, must be either an existence or an event. The paper on which I write is an existence—a thing that *is*; if I drop it on the carpet, it is an event, a thing that *has happened*, a change has taken place; soldiers are existences, their battle is an event; the acid and the alkali are existences, their effervescence on mixture is an event. Natural history concerns existences, civil history records events. From observing that the power of perceiving and remembering these two classes of objects, respectively, varies in a marked degree in different individuals, we may consider them as distinct faculties, which will require in education a separate range of study and exercise, the one improving the faculty for existences, the other the faculty for events. I claim, then, for man—

22d, A POWER TO COGNISE AND REMEMBER EXISTENCES.

23d, A POWER TO COGNISE AND REMEMBER EVENTS.

There are other knowing faculties, of marked distinction in the different degrees of manifestation by different individuals, which aid in the acquisition of knowledge; such as a perceptive power for each quality of matter, as its form, size, colour, gravitation, sound, &c.; and on these the talents of drawing, painting, sculpture, mechanics, and music, depend. But these manifestations must be so obvious to the enlightened and judicious educationist, that I shall not occupy time and space with a detail of them.

The REFLECTING POWERS suffer a twofold division, like the knowing, and we find individuals manifesting these powers differently, according to that division. The reflecting make use of the materials stored by the knowing faculties, for the purpose of performing the operation of REASONING—that consists in comparing two existences or two events, and concluding that something else exists, existed, *or* will or may exist, or that something else happens, happened, or will or may happen, in consequence; in which range are comprehended all the TRUTHS of the physical and moral world.

24th, The process of reasoning, of conclusion drawing, is sometimes performed by a simple act of comparison, or perception of analogy; a vast majority of mankind reason in this way: such a truth follows from the resemblance of two truths which they have compared. The whole of the brilliant field of what a reasoning is called *illustration* is nothing more than his process of comparison; and as many writers and speakers manifest almost an exclusive preference for analogical and illustrative reasoning, I feel that I am warranted in distinguishing in man the reflecting faculty of COMPARISON.

25th, Some reasoners, but comparatively few, are more severe, and are contented with no conclusions which do not stand in the relation of *necessary consequence* to their premises. This is truth, they reason, because it is deducible necessarily from the consideration of these other known truths brought together. These are the logicians who distrust analogy and comparison. The faculty they use is the highest intellectual power, the percipient of the relation of cause and effect, which I beg to be indulged in designating by the name of THE FACULTY OF NECESSARY CONSEQUENCE.

It is a metaphysical error to distinguish *Memory* as a primitive faculty, seeing that the cognising and reasoning powers must necessarily be the remembering powers; remembrance being nothing else but the continued impression of cognition and reasoning, varying according to the energy of those powers. If memory were a distinctive power, it would, in each individual, be alike *strong*, and *regard all* subjects of recollection alike. But as this is not consistent with fact, as one individual remembers existences, and another forgets existences and remembers events, while a third recalls with ease a train of reasoning, another musical airs, and another the faces of persons he has seen, or the scenes he has surveyed, each perhaps weakly remembering something *else* of the matters now enumerated, we are forced to the conclusion that there is no general faculty called memory, but that each faculty has its own power of recalling its impressions. The instructor of youth should ponder this truth well, and he will save himself and his pupil much time and labour in the indefinite and desultory exercise of a supposed general faculty of memory, when in truth he will actually improve the memory of each faculty in the proper direct cultivation of the faculty itself.

The reader is, it is trusted, now in a condition to see the propriety of disallowing *Perception* as a primitive faculty. Both the knowing and reflective *percipient* powers have now been explained and distinguished: the faculty of existences perceives existences; that of events, events; that of comparison, resemblances; that of necessary consequence, cause and effect; so that a general faculty of perception is necessarily a nonentity.

Last of all, I claim for man, whose composition we have now finished, the man-distinguishing faculty of LANGUAGE, whereby he converts his thoughts into the conventional signs called words, and, in oral and written discourse, excites the faculties of his fellow-men in the boundless extent of social intercourse. Language is a mighty instrument, but great evil follows the error of mistaking it for more.

The whole faculties which have been described are now brought under the reader's eye in a table for the convenience of reference:—

INFERIOR FEELINGS.

Animal Propensities.

Propensity of	*Food.*	Propensity to	*Conceal.*
.. ..	*Sex.*	.. ..	*Acquire.*
.. ..	*Offspring.*	.. ..	*Construct.*
.. ..	*Attachment*	Sentiment of	*Self-Love.*
.. .. to	*Fight.*	.. ..	*Desire of Estimation.*
.. ..	*Destroy.*	.. ..	*Fear.*

HIGHER FEELINGS.

Moral Sentiments.

Sentiment of	*Benevolence.*	Sentiment of	*Wonder.*
.. ..	*Justice.*	.. ..	*Imagination.*
.. ..	*Veneration.*	.. ..	*The Ludicrous.*
.. ..	*Hope.*	.. ..	*Imitation.*
.. ..	*Firmness.*		

INTELLECT.

Knowing Faculties.	Reflecting Faculties.
Cognition of existences.	*Comparison.*
.. .. *events.*	*Necessary Consequence.*
Percipients of Form, Colour, Sound, &c.	LANGUAGE.

Several general points require a moment's attention. 1. All the faculties in the preceding table belong to every sane individual of the human race; the want of any of them would be the imperfection of partial idiocy. 2. They are possessed in very different degrees of endowment in different individuals. It is this difference which constitutes the endless varieties in the characters of men. Taking the faculties in groups, it is evident that individuals in whom the inferior feelings predominate, will be coarse, sensual, and animal; while those in whom the higher feelings are the strongest, will be moral and refined. In each individual, some faculty, or combination of faculties, is always so powerful as to mark the character; and observation and discussion of these characterising peculiarities, in each other, constitute half the subject of human intercourse.

3. It must occur to the reader, and he is requested to remember it as a fundamental truth, that these characteristics of individuals arise from *innate* faculties, which are *permanent*, and, however improveable, not liable to be eradicated. The faculties modify each other, but the *general* character is fixed. The irascible man of to-day was so twenty years ago; so was the selfish; though higher feelings cultivated render the *conduct* of the one milder and of the other more liberal.

4. Another point is to be kept in mind by the reader—namely, that the human faculties are capable of acting in *combination* with each other, at least of *simultaneous activity*; the effect of which will be an increased tendency to a common end when the faculties acting are in harmony; or a modification of power, so that the balance in favour of the strongest will be the remaining force, when they antagonise each other. This is the state of what is called mixed motives, which scarcely needs illustration. In a public subscription for a charity, for example, benevolence prompts to give, and often much more strongly does vanity; but their united operation manifestly strengthens the impulse; self-love and avarice would save the money. Now, it is perfectly obvious that it will be given or withheld, according as one combination or the other prevails. Other examples might be supplied, but they can be easily figured. It is plain that what is called individual character must essentially be the product of a sort of balance of power among all the faculties; the strongest will stand out most prominent, as 'the ruling passion,' modified by others, and therefore only presenting itself as a remainder. It must be manifest that education should address itself pointedly to these combinations.

5. The last general observation which requires to be made, is one which will at once be admitted—namely, that there are degrees of value and rank in the faculties of man. It is a law of our nature to look upon the moral sentiments with more respect than the animal propensities, while the profound powers of reflection and reasoning are more elevated than the acutest faculties of observation. When superiority involves control, it is called supremacy; this control is exercised by the moral faculties, guided by the intellect, and constitutes what we call ethics. I was pledged to return to this important subject when I had explained the intellect, for the control is properly called the SUPREMACY OF THE MORAL SENTIMENTS AND INTELLECT."

So far as we have acquainted ourselves with the views of the phrenologists, they seem to us to hold the following doctrines in reference to the above scheme:—Every human being possesses a greater or less development of each faculty; those who have the inferior in greatest strength are apt to be low and sensual characters, while those who are strongest in the higher sentiments will probably be good moral men, and those who possess the intellectual powers in largest proportion are likely to manifest the greatest degree of what is called talent. Individual character is the product of a sort of balance of power among all the faculties, liable, however, to be modified by education and other circumstances. The phrenologists hold that every faculty is good in itself—that is to say, it has some utility in reference to the affairs of human life, and the concerns of the external world; only it is necessary that the inferior be controlled by the higher, so as to be exercised in those degrees which are allowable and useful. The higher may also have their excess of manifestation: benevolence, for instance, may be carried to extravagance. Here some other faculty may be trained to act as a guard upon that which is running to such extremes: for instance, cautiousness or conscientiousness—a due regard to our own necessities, and the claims of those depending upon us—may check the improper manifestation of benevolence. In general, the moral and intellectual faculties are considered by the phrenologists as being superior to the others, and as possessing a regulating power over them. But the intellectual powers require to be cultivated, and the moral sentiments to be fostered and guided by education, in order to arrive at their full efficacy.

The faculties are held by this class of philosophers to bear an exact relation to the external world. Each has its objects, which, when presented to it, excite it to activity, and delight it with agreeable emotions. "Human happiness and misery," says Mr Combe, "are resolvable into the gratification or denial of one or more of our active faculties." This writer has devoted a large portion of his Essay to delineate the ways of the world, which in too many instances are a cultivation of the inferior faculties, forming the causes of much of the misery which we endure; while the cultivation of the higher feelings renders life a scene of comparative felicity. He then proceeds to demonstrate the application of his system to the laws of nature, which he distinguishes into the three classes of Physical, Organic, and Moral, and each of which he shows to work independently of the others. "For example," says Mr Simpson, "an individual who neglects or carelessly observes the corresponding *physical* law of nature, will be drowned, or burnt, or crushed, or fractured, or lacerated, and that inevitably, however strictly he may obey the moral laws, even to the extent of the utmost reach of human virtue. Again, if he obeys the organic laws, he will reap bodily health, which is the specific reward of *that* obedience, nor will any degree of moral turpitude (if he avoids sensual excess, which is a breach of the organic as well as the moral laws) materially diminish his health. But his moral defects will bring their own punishment; and from these his health of body will not protect him. This principle affords a key to much that appears inscrutable in the moral government of this world. Whatever man may be permitted to hope with regard to another, he must study and obey the laws which regulate this world, else no degree of piety and worth will save him from the evils which follow neglect of the physical and organic laws; while no compliance with these last will shield him from moral suffering, if he contemns the moral laws. Whenever we get the principle of the *independent operation* of the different departments of the natural laws, the apparent confusion of life is explained, and we see why the bad man often prospers *externally* in this world, and the good man is overwhelmed with misfortune;—I say externally, for the bad man cannot reap higher enjoyment than physical and organic, while at the same time he suffers all the penalties of a low morality. On the other hand, the good and pious man, however physically and organically afflicted, is compensated, even here, with the direct consolations of virtue and religion. But the *kind* of happiness enjoyed, or misery suffered, will be found invariably to result to each character directly and separately, and without the possibility of interference of any of the others, from the specific law or laws obeyed or contemned. This theory of the independent operation of the different classes of the laws of nature, which is itself sufficient, when practically applied to the affairs of man, to work a momentous change in his condition in the present world, is not, it is believed, to be found in any previous author, and therefore belongs to Mr Combe.

In order to perceive the wise relation of the natural laws to the human constitution in body and mind, *both* these related objects must be understood. On the one hand, the laws, physical, organic, and moral, must be observed, and their independent operation demonstrated; and on the other, the *mind* of man, as well as his body, must be known; yet that knowledge, according to Mr Stewart, was down to his time 'yet in expectation.' Mr Combe has adopted the faculties which have now been detailed, as primitive in man, and comparing *these* with external nature and nature's laws, he at once saw and made plain to his countrymen and the world, the perfect correspondence and harmony which was the eternal design of an omnipotent Creator.

The same gifted writer has shown, that while each natural law acts separately, there is a beautiful combination in their action, having for its object the cultivation of the moral and intellectual powers of man, and the establishment of their supremacy over the animal propensities; in other words, THAT THE WORLD IS ACTUALLY ARRANGED ON THE PRINCIPLE OF FAVOURING VIRTUE AND PUNISHING VICE, AND THAT IT IS, THOROUGHOUT ITS CONSTITUTION, FRAMED IN ADMIRABLE ADAPTATION TO THE FACULTIES OF MAN AS A MORAL, INTELLIGENT, AND RELIGIOUS BEING."

No. 46. PRICE 1½d.

COTTAGE ECONOMY.

COTTAGE ECONOMY is that species of management by which the out-of-door concerns of a country residence or cottage are regulated on the most approved principles, and applies in a particular manner to the keeping of cows; the preparation of dairy produce for the table and for market; the rearing of pigs and curing of bacon; the practice of keeping hens, ducks, turkeys, and geese; the cultivation of gardens; and other similar objects—all of which, when rightly followed, tend to make the cottager more wealthy and more comfortable in his circumstances. With our limited scope in a single sheet, we cannot pretend to illustrate the whole of this important subject, but we believe that the following brief view of Cottage Economy and the hints we are able to give, will be found useful in directing industrious housewives and their husbands in the best modes of managing their establishments.

Before saying one word in detail, we consider it absolutely necessary to state that the most essential requisites connected with the economy of a cottage, are orderliness and cleanliness. To the disgrace and serious loss of many individuals in the country, these matters meet with by far too little attention. It may frequently be noticed in travelling through the country, that the inhabitants of cottages *seem* to live as if they despised habits of orderliness and neatness, and consider that slovenliness and dirt are productive of comfort. We take this opportunity of recommending a very different practice. If any thing is expected to be made by cottage economy, things must be kept not only in proper repair by active exertion at spare hours, but rigorously clean in their condition. The utmost regard to this is certainly indispensable in the keeping of cows and pigs. Both these animals love to be kept dry and clean. The cow requires to be rubbed down or curried like a horse, for its skin contracts vermin, which, with the loose hairs, which should also be removed, give it great uneasiness. In the same manner, the hog, as is afterwards fully mentioned, must be kept clean, dry, and warm, otherwise it will not thrive or be of any great value. Nothing speaks so emphatically of the prosperity and good management of a farmer or cottager, as a sty full of sleek, thriving, contented pigs, who seem to enjoy existence, and whose good care and quiet demeanour speak eulogies of their keeper.

We need not say how clean and tidy all things ought to be in the interior of the cottage; but we may point out how commendable is the practice of clearing away all foul puddles and other impurities from before or near the dwelling, of trimming the paths which lead up to the doorways, and of whitewashing the walls, and decorating them with flowering shrubs. A certain degree of attention to all this demonstrates a well-regulated mind on the part of the cottager and his family, and even while "little is coming in," render his humble abode a kind of rural paradise, and the delight and admiration of every passer-by. In order the better to accomplish this desirable result, cottagers should act upon some well-organised plan of procedure. They should make arrangements to devote certain days and snatches of time to the cultivation of their gardens, the mending of their fences, and the preservation of neatness about their premises. They should likewise make a point of setting their youngsters early to work in giving them assistance; for this will confirm them in habits of industry, and will greatly benefit their bodily health and moral feelings. Not a few cottagers encourage, or at least allow, the keeping of useless dogs about their households, greatly to the annoyance of the neighbourhood and passing traveller. We consider that the many curs which are thus kept are a serious nuisance, and greatly encumber the cottage economy, unless when kept as watch or sheep dogs. The cottager should not by any means throw away his valuable time—for time is to him as good as money—in cultivating breeds of dogs or game cocks, which can only lead to loss in the end, but act, as we say, on a systematic plan of practical utility, setting a good example to the rising generation around him, and bestowing all that part of his time not directed to actual labour and harmless recreation on the storing of his mind with general knowledge suitable to his capacity or taste.

THE COW.

No subject is of greater importance to the cottager than a perfect knowledge of the management of cows, and an acquaintance with those breeds which in the end turn out most profitable. It has long been ascertained beyond a doubt, that certain breeds of cattle are more susceptible of increasing in bulk than others. The same quantity of food may be given to those which have a tendency to be lean, and to those which take on fat and muscle easily, and, consequently, the food given to the former is lost to the feeder.

The whole of the cow kind—of which there are about nine different species—are ranked among those quadrupeds which naturalists term *ruminating animals*, in consequence of their chewing the cud—an operation which they always perform to grind their food more thoroughly, for the purpose of fitting it for being converted into chyle, for the nourishment and support of their bodies. As animals of this kind are entirely confined to grain and herbage for food, it is necessary that they should receive a large quantity into the stomach, as well as to retain it a considerable time before it is reduced into proper chyle; for this purpose their intestines are remarkably long and capacious, and formed into a variety of foldings. They are provided with no less than four stomachs. The food, after being masticated or ground, is conveyed into the first stomach, where it remains for some time; after which it is forced up again into the mouth, and undergoes a second chewing; it is then sent directly into the second stomach, and gradually passes into the third and fourth; from whence it is transmitted through the convolutions of the intestines. By this conformation, ruminating animals are enabled to devour large quantities of vegetable food, to retain it long in their bowels, and consequently extract from it a quantity of nutritious matter, sufficient for their growth and support.

Being destitute of the upper fore-teeth, the cow prefers the high and rich grass in pastures, to the short and more delicate herbage generally selected by the horse. For this reason, in our British pastures where the grass is rather high and flourishing than succulent and nutritious, the cow thrives admirably; and there is no part of Europe in which this animal grazes longer, yields more milk, or fattens sooner. The age of the cow is known by its horns; at the age of three years, the animal scales off a very slight external shell or coating from them, and at four years a ring is formed at their roots. Every succeeding year, another ring is added. Thus, by allowing three years before their appearance, and then reckoning the number of rings, the creature's age may be exactly known. The quantity of milk given by cows is very various; some will yield about six quarts in one day, while others give from ten to fifteen, and sometimes even twenty. The richness of the pasture contributes not a little to its increase. There have been instances of cows giving upwards of thirty quarts of milk in one day. In such cases there is a necessity for milking them thrice. From the milk of some cows, fourteen pounds of butter are made in a week.

It is well known that the cow will yield her milk freely, and will continue to give it as long without the aid of a calf as if it were permitted to suck her constantly. This is not the case with the ass, which will soon grow dry if her foal be not permitted to suck part of her milk every day. Cows go with young about nine months, and seldom produce more than one at a time. For a week or so previous to calving, they ought to be kept in an outhouse, which may be the means of preventing many accidents that occur during this critical period to both cow and calf. But if the cow should happen to have been left out in a cold night when in this state, and catch cold, which not unfrequently happens—and which may be ascertained by a trembling in the joints and her refusing food—the sooner she is driven into a warm situation the better. She should be provided with warm draughts of ale and beer, and good hay given her; but upon no account to drink till she has recovered, which will generally be effected in a few days by careful treatment: but when this process is ineffectual, balls of aromatic cordial substances should be given.

Until modern times, the cows of Britain were lank and thin in comparison to those of Holland or the Low Countries, and a great improvement has been wrought in our breed by the introduction of the Holstein or Dutch breed. This breed continued for a number of years the prevailing stock in all the counties on the eastern coast of Britain. In good pastures cattle of this kind grew to a large size, and the cows yielded a greater abundance of milk than those of almost any other kind. The first general principle laid down and adhered to in the improvement of the several breeds of cattle, and which has been so successfully brought into practice, was the most obvious—that is, the beauty of form; a principle which has been in common applied to every species of domestic cattle, and, with great seeming propriety, was supposed to form the basis of every kind of improvement, under an idea that beauty of form and utility were inseparable. But at present a distinction is made, by men who have long been conversant in practice, between a useful sort and that which is merely handsome. Utility of form is therefore the next general principle, and may be considered as arising from a larger proportion of those parts which are the most useful; thus, for instance, all those parts which are deemed offal, or which bear an inferior price, should be small in proportion to the better parts. A third principle of improvement laid down by breeders consists in the fineness of the muscular fibre, or what is termed flesh. But the great object which occupies the attention of breeders at present, is the fattening quality, or a natural propensity in cattle to arrive at a state of fatness at an early age, and in a short space of time; and it appears from observation, that beauty and utility of form, the quality of the flesh and its propensity to fatness, are principles consistent with each other, and are frequently found united in the same individual, and hereditary in particular lines or families of cattle. In regard to the means of improvement, it has long been an established maxim, that to improve the breed it is necessary to cross it with others of an alien stock, under an opinion that continuing to breed from the same line weakens the stock and produces degeneracy.

Mr Aiton, in a paper on the Dairy Cattle of Ayrshire, in the Journal of Agriculture for March 1834, has made the following useful observations on the system pursued in regard to cows in that county:—"It is certainly best to breed from bulls of good shape, and of a size suited to the cows to which they are put, otherwise their offspring will have large coarse bones, and never will be strong and spirited, in proportion to their size. They will be in fact ill shaped, dull, unhealthy mongrels. The most skilful breeders of dairy-stock in Ayrshire prefer bulls that have least of a masculine shape, and which have the greatest resemblance to a cow. The shapes that are most approved of in the Ayrshire dairy-stock, are, head small, but rather long and narrow at the muzzle; the eye small, but quick and lively; the horns small, clear, bended, and their roots at a considerable distance from each other; neck long and slender, tapering towards the head, with little loose skin hanging below; shoulders thin; fore-quarters light and thin; hind-quarters large and capacious; back straight, broad behind, and the joints of the chine rather loose and open; carcass deep; pelvis capacious and wide over the hips, with fleshy buttocks; tail long and small; legs small and short, with firm joints; udder large, broad, and square, stretching forward, and neither fleshy, low hung, nor loose, with large and prominent milk-veins; teats short, pointing outwards, and at a considerable distance from each other; the skin thin and loose; hair soft and woolly; the head, horns, and parts of least value small, and the general figure compact and well proportioned. It is not to be understood that every dairy-cow, or that any one of them, has all these fine shapes. But these are given merely as the perfection of the breed, or the shapes most desired and sought after."

PRODUCE OF THE DAIRY.

Where people are of the humbler walks of life, and keep a single cow, the most obvious purpose of its milk is to use it in the first place as food. Where there are young children, it is of much utility, and furnishes the family with a very nourishing article of diet. Where but one cow is kept, and the family consists of from two to three children, besides supplying them sufficiently with skim-milk, a certain portion of butter may be made; and the butter-milk will afford an agreeable and wholesome variety as a liquid to bread or oatmeal porridge, and also as a drink. Where there is too much skim-milk to be consumed by the family, the rest may be employed in making bread, as a substitute for water. It greatly improves the bread, and keeps it longer moist than when baked with water. In very hot weather, however, bread made with milk is more liable to become sour. Another use to which it may be applied with great benefit is in feeding pigs, more especially some time before they are killed, as it not only assists in rendering their flesh whiter, but also has a tendency to firm it.

Milk is a delicate article, and requires, as well as the cows which yield it, very great nicety of management. A great mistake is often committed in keeping a cowhouse close and foul in its atmosphere. Whatever be the extent of the cowhouse, it ought to be at least ten or twelve feet high in the side-walls, with proper apertures, and have no lofts above, so that the cows may have that which is absolutely necessary for their health, a plentiful supply of pure air. Cows should be kept dry, but not warm; they ought to be well rubbed down daily; the dung should also be removed carefully, and the urine carried off in a paved channel to the dungheap, or into the cottage garden—not permitted to exhale, and therefore lost for purposes of agriculture. The best way to tie up a cow is to attach it by a moveable chain to an upright iron rod; but it must possess as much liberty as will allow it to lick itself. After the milk is procured from the cow and properly sieved—but not strained till nearly cool if in warm weather—it should be placed in vessels in a cool milkhouse, where there is a free atmosphere, and properly secluded from flies and other insects by means of gauze on the windows. The milk-pans or vessels should be large and broad, and it is said that, if made of a metal called zinc, the cream will be more effectually thrown up. The addition of a little hot water will also tend to produce cream in greater abundance. Intense care must be taken to clean the milk-vessels. If they be in the least degree soured, the sweet milk is undone. The milk should never be suffered to sour in sweet-milk pans, but skimmed and carried off within twenty-four hours if in summer. The same or still greater care should be taken in cleansing the churn from all milky particles after being used. It is inattention to these points that causes nine-tenths of all the bad butter and cheese in this country. All milk-vessels should be well rinsed with hot water, and exposed to the open air to dry.

In feeding cows which are kept within doors, the following has been the most effectual way for inducing a large supply of milk:—They are fed with a bushel of grains, mixed with about an ounce of salt, at three o'clock in the morning; they are afterwards milked about six o'clock, and a quantity of turnips given to them, and shortly afterwards a proportion of meadow hay, equal to a tenth part of a truss. The cows are then turned out into the open air in a yard or some such convenient place, where they remain till about twelve at noon, and supplied with the same quantity of grass as in the morning, and again milked about half-past one o'clock, after which they are again supplied with the same quantity of turnips as before, and in an hour thereafter with hay, equal in quantity to the former meal. This is the system pursued in feeding from September till May, while turnips are in season. In the summer months they are fed upon cabbages, tares, grains, and second-cut meadow hay; and where it suits the cowfeeder, they are turned out to grass, and kept both day and night in the field. The daily average of milk given by a London cow is estimated at nine quarts, or the great quantity of 3285 quarts annually: which is, however, never sold in its pure state, but generally plentifully mixed with water.

In Edinburgh, milch cows are generally of the Northumberland, Ayrshire, and Roxburgh breeds. These are seldom kept by the feeders for more than a single year, by which time they contrive to fatten them for sale. In London, on the contrary, they are retained from five to seven years. The feeders in Scotland find that the quickest and most effectual method of putting them in selling condition is to feed them on brewers' wash, and the residue of the grains, called draff, which has the quality not only of fattening quickly, but also producing a greater supply of milk. To these are added hay, shellings, and bran; and in the spring and summer, bundles of fresh-cut grass are given to them; and when the cowfeeders reside at a convenient distance from grass parks, they are sent to them, where they continue night and day during the summer months. When, however, cows are kept constantly in the house, the feeders, in giving them grass, take care always to place straw or hay beneath it, and this is constantly eaten by the cow after it has finished the grass. In Edinburgh, cows are usually milked twice a-day, namely, at half-past five in the morning and three in the afternoon, although it is sometimes necessary to do it three times. The produce may be averaged at twenty-four English pints daily, each cow. This quantity is obtained from cows of the best breeds, but those of a smaller kind give much less, varying from twelve to eighteen English pints a-day. These latter consume as much meat as cows of the largest kind; hence it is obvious that there is much more profit in keeping those of a superior breed, not only from giving a larger quantity of milk, but they besides feed faster, and consequently turn out to greater account in the end.

It must be obvious to those cottars and farm-servants who possess a single cow, that the more improved the breed, the better. It may be difficult at first to raise a sum sufficient to purchase a large cow; but it will be much their interest to accomplish this desirable object by the strictest economy; and having once obtained their object, they will thereby be certain to improve their means. In villages where there is a right of commonty, the keep of a cow will be trifling compared with the yield; for where the milk cannot be sold sweet (which is the most productive method of getting quit of it), it can either be made into butter or cheese. The former of these is the next best way of selling the produce, and that fresh if possible. If managed with prudence, there are few pursuits in a country way more profitable than cows. We knew a frugal housewife, in the county of Perth, whose mode of managing her domestic concerns is well worthy of imitation. It was this:—Her first ambition after marriage was to obtain a cow; and what cash her husband and she had after furnishing their house, with six months' after-saving, enabled her to purchase a small cow: and as she lived at some distance from a small town, she was obliged to churn the milk, and carry the butter to market. She sold as much of the butter-milk as she could, and with the rest she fed pigs; she also made cheese from the skim-milk. Her greatest difficulty was in obtaining bedding for her cow and pigs during the first year. This she overcame, by cutting rushes from the side of a stream, and the grass which grew in a fir plantation at a little distance from her residence. She made a determined resolution to lay aside every farthing of the cow's produce, for the purpose of obtaining a superior animal when her first one ceased to give milk. The first winter's meat was also heavy upon her. This she took care to provide for in the following summer. She had carefully accumulated all the manure of her cow-house and piggery; this she would not dispose of, but agreed with a neighbouring farmer for the use of as much ground as would supply her cow with winter turnips and potatoes, and manured and planted it. This not only served her own purpose, but also benefited the farmer; as it is well known that the best crops of wheat or oats are obtained after a green crop, and the ground is also cleaned in consequence of the mode of culture necessary for green crops. This so completely answered her expectations, that she had ample provisions for her cow, had as many potatoes as served her family, and with the small ones fed her cow and pigs. By determined economy, she soon was able to purchase an additional cow, and continued during a long life to pursue the same course, greatly to the benefit of her family.

If a cottager has forty rods of land, it should be dug or trenched in the spring, always keeping the top earth at the top. In April or May, it should be laid out in high and sharp ridges, about two feet apart. When the weeds appear, and have got about three inches high, if the weather is dry, the ridges should be turned into furrows, whereby the weeds are buried. This should be repeated again and again as the weeds appear, until about the 26th of August, at which time the ground must be dug anew, supplied with manure, and raked. One half of it is then to be sown with early York cabbage seed, and the other with sugar-loaf cabbage seed, in drills eight inches apart, taking care not to put the seed too thickly into the drills, but sufficiently so that there may be no blanks. The seed requires to be only a quarter of an inch below the surface. Rake it smooth, but do not tread the ground at this early season. Treading may be proper in light soils in summer, but in spring and autumn it is hurtful. When they have acquired six leaves, they should be hoed with care. In the course of a few days they ought to be thinned; those left to be two inches apart, and with those taken out another rod of ground ought to be planted—four thousand in each row, and eight inches apart, and three inches in the row—after having prepared it as above directed. The ground between them should be frequently hoed, not only to keep the weeds down, but also to encourage the growth of the plants; and they will thereby become straight and strong. The remaining thirty-six rods should be manured and turned over early in November; and then transplant the plants on the ridges, at fifteen inches apart, taking care to replace any of the plants which fail. These plants should be protected against the rigour of a hard winter by means of straw, ferns, litter, or rushes. These must be laid between the rows and the plants, taking care not to cover the leaves; and plants that die from the effects of frost must be replaced from the bed.

A great enemy to cabbages is the slug, and the utmost pains ought to be taken to destroy these wherever they appear. Many plans have been suggested for destroying these animals, but none is so effectual as to search for and destroy them. The evening is the time they generally crawl abroad, or after a shower, at any time of day. During winter, many of the outside leaves will turn black and decay; but whenever they begin to show a disposition to do so, they should be cut off and given to the cow, otherwise they will go to waste. It has been computed, and indeed experience has proved it, that the above number of cabbages should keep a cow for about two hundred days, supposing she is allowed eight pounds of these each day. This, it must be observed, is sufficient for a large cow; and a small one may be kept perfectly on from seventy to seventy-five pounds a-day. Care must be taken to use those which have not grown solid, in the first place, as they are most liable to decay. In the month of March, more early York cabbages should be sown, and also in April. The ground which has been cleared of plants must now be dug and thoroughly manured; and continue to do so as the cabbages are cut and well covered in. These spots should be planted with strong plants, which will bring a succession of cabbages fit for use at different times. In selecting the cabbage-plants for transplanting at this late season, strong ones only should be used. This need not be continued after the middle of August, as what has already been recommended will give food till November, by which time from three to four thousand turnips will have arrived at maturity. It is supposed that these turnips are full-sized, that is, averaging about from four pounds and three-quarters to five pounds each; consequently, at fifteen pounds a-day, this will serve a cow for six months, independently of the cabbage. During summer, the best kind of food for cows is of course grass pasture, but this may be greatly assisted by the industry of the cottager.

MAKING CHEESE.

In situations where sweet milk cannot be conveniently disposed of, the making of cheese is a most important method of converting the milk to the best advantage. The coagulation of milk is produced by several substances; but that in most general use is the preparation of the stomach of a sucking calf, properly cleaned and soaked in a brine of salt and water. The following is the method of preparing this by Mr Marshall, a celebrated agriculturist:—"Take a calf's bag, maw, or stomach, and having taken out the curd contained therein, wash it clean and salt it thoroughly, inside and out, leaving a white coat of salt over every part of it. Put it into an earthen jar or other vessel, and let it stand three or four days, in which time it will have formed the salt and its own natural juice into a pickle. Take it out of the jar, and hang it up for two or three days, to let the pickle drain from it; resalt it, place it again in a jar, cover it tight down with a paper pierced with a large pin, and in this state let it remain till it be wanted for use. In this state it ought to be kept twelve months: it may, however, in case of necessity, be used in a few days after it has received the second salting; but it will not be so strong as if kept a longer time. To prepare the rennet for use, take a handful of the leaves of sweet briar, the same quantity of the leaves of dogrose, and the like quantity of bramble leaves; boil them in a gallon of water, with three or four handfuls of salt, about a quarter of an hour; strain off the liquor, and having let it stand until perfectly cool, put it into an earthen vessel, and add to it the maw prepared as above. To this is added a sound good lemon, stuck round with about a quarter of an ounce of cloves, which gives the rennet an agreeable flavour. The longer the bag remains in the liquor, the stronger of course will be the rennet. The quantity, therefore, requisite to turn a given quantity of milk, can only be ascertained by daily use and observation." In Gloucestershire, a third of a pint is used to coagulate fifty gallons of milk; but as a general average, it is perhaps safer to take something less than half an English pint; much, however, depends upon the strength of the rennet. To make milk coagulate properly, it should be heated to from eighty-five to ninety degrees; and after the rennet is applied, it ought to stand two hours, during which time it should be covered, so as to allow about five degrees of its original heat to escape. But the season of the year, the heat of the weather, and the kind of pasture, all tend to make the necessary length of time differ.

Considerable caution is necessary in separating the whey from the curd. If the milk be much heated when put to coagulate, and the curd be broken, and the whey quickly and strongly pressed out, the cheese will be very poor, as much of the rich part of the milk is pressed out. The whey ought therefore to be cautiously removed, and a gentle pressure used; then the cheese will be good. The quality of cheese is extremely variable, and the goodness of its quality depends greatly on the manner in which it has been made; such as, whether it has been made of milk of one meal, of two meals, or skimmed milk. The method of milking also affects it, as well as the season of the year; the preparation of the rennet, the manner in which it has been coagulated, the gathering of the curd, the salting, and its management in the press. We shall endeavour to give some hints on these particulars.

Milking.—The cows should be milked in summer at four o'clock in the morning and four in the afternoon. Every drop of the milk should be taken away, as the last drawn is by far the richest in quality. The utmost regularity must be kept as to the hour of milking; and the cows should never be allowed to run about, as this materially affects the milk. In Gloucestershire, all the best cheeses are made from one meal of milk.

Temperature of the Curd.—It is found that milk which has been produced on poor clay soils requires to be coagulated at a higher temperature than that which is the produce of rich pastures; ninety degrees being what is considered the best for the latter kind of soils; for those of the former the heat may be ninety-five degrees.

Gathering the Curd.—Whenever the process of coagulation has been completed, the curd is broken and gathered. A cheese-knife is taken, and with it the curd is cut in various directions. It is then allowed to stand for a minute or two, when the operation is renewed, and the curd cut into smaller pieces, which is again and again repeated till the curd is reduced into very small portions. In this operation about forty minutes are usually expended. The cheese-tub is then covered with a cloth, and allowed to remain undisturbed for forty minutes or half an hour. When the curd has subsided, the whey is skimmed off with a wooden skimming-ladle or dish, and the curd well pressed by the bottom of the ladle, assisted by the hands, or a semicircular board made nearly to fit the tub. The curd is again cut with the cheese-knife, to allow the whey fairly to escape, and pressure is again employed till the whey is entirely drained off. The curd is now put into one or more vessels, and broken with the hands as small as possible. During this process salt is thrown over the curd, and thoroughly mixed with it. The proportion of salt is not well ascertained, but it must be guessed by estimation and tasting the curd. It is then put into a vat or mould, usually made of elm, adapted to the form of the intended cheese, and perforated with very small holes in the bottom for the escape of the whey. The vat must be filled at least an inch above the brim; this is to prevent the curd from shrinking below its sides when the whey is squeezed out; because, if the curd should be thus shrunk, the pressure would be on the brim of the vat, and the necessary weight prevented from reaching the cheese, which would render it open and spongy. Before the curds are put into the vat, a cheese-cloth is spread over it, sufficiently large when turned up to cover the whole cheese. A smooth circular board is then placed on the top of the vat, and the whole are placed in the cheese-press and allowed to remain two hours. The cheese, after being taken out and a dry cloth substituted, is turned upside down in the vat, and again put in the press, where it is allowed to remain for eight hours, when it is again taken out, rubbed with salt, a clean cloth again applied, and then put into the press a third time, and allowed to remain for twelve or fourteen hours. When it is taken out, if any of the curd has forced its way beyond the shape of the vat, it is pared off. The cheese is then placed upon a shelf, and regularly turned every day till sufficiently dry.

Skewering.—In the process of forming very large cheeses, it becomes necessary to have perforations in the sides of the vat, for the reception of iron skewers, which must be thrust through them in all directions to facilitate the escape of the whey. This must be repeatedly done during the first day's pressing, because it is quite necessary that every drop of the whey should be expelled, otherwise the cheese will not keep.

Cheese-Press.—There are now many very well-contrived cheese-presses. Perhaps one of the most convenient and cheapest is that manufactured at the Shotts Ironworks, Scotland. It costs only three pounds five shillings. In this machine the pressure is produced by the combination of a rack-wheel and pinions, with a lever and weight. By this the pressure can be regulated to the greatest nicety. It has also great powers, and is capable of communicating pressure of from a ton and a half to two tons and a half, which is sufficient for much larger cheeses than are made in Britain.

Gloucester Cheese.—In this county the best cheeses are always made of a single meal of milk. These go by the name of one-meal cheeses. Cheeses are made of two sizes, the double and the single; the one thin and the other thick; the former having eight to the hundredweight, and the thick four. Single cheeses are made from April till November, but the thick are made only in May, June, and the early part of July. Good cheese can, however, be made all winter, although not equal in quality to that made during the summer months. The inferior qualities of cheese made in this county are produced with half new milk and half skim-milk. Gloucester cheese is coloured with Spanish arnotto. The red pulp which covers the seeds of that plant is suspended in vessels of hot water, and is allowed to subside at the bottom of the vessel, and afterwards dried and formed into cakes or balls. To every hundredweight of cheese an ounce of this substance is used. A piece of this arnotto is rubbed upon a smooth stone, and it is mixed with the milk before the rennet is applied.

Cheshire Cheese.—The cheeses of this county are generally made of a very large size, weighing from sixty to one hundred pounds. They are usually made from the milk of two meals; and in the winter, sometimes five or six meals are employed in making curd. The cream is withdrawn from the evening's milk, and again added in the morning; others do not add the cream at all. There are various opinions respecting the propriety of this proceeding, which are still undecided. When two meals of milk are made use of, a part of the creamed milk of the former meal, to the proportion of a half, a third, or only some four or six gallons, are kept, and made scalding hot over a fire. Half of this is then poured into the cheese-tub among the cold milk, and the remainder into the vessel in which the cream of this milk had been placed. All these are thrown into the cheese-tub together, and to them is added the fresh milk which has just come from the cow. They term this process melting the cream, and is considered the best method of uniting different meals of milk. The rennet is now added.

Arnotto is also used in Cheshire as a colouring matter; this is added by tying up a sufficient quantity in a linen rag, and placing it in half a pint of warm water, in which it is allowed to remain during the night. The water, after the rag has been well squeezed into it, is now added to the milk in the cheese-tub. The same method of breaking the curd is pursued as we have above noticed. They make a practice of shifting the cheese very often when in the press; frequently not allowing it to remain more than half an hour at a time for the first half day; after which it is taken out of its cloth, and placed in a tub of hot whey or water, and permitted to remain from an hour and a half to two hours; this is to give tenacity to the skin, and to prevent blistering; it is then dried, and, being covered with a dry cloth, is again placed in the vat, and put into the press. It is sometimes pricked all over to allow the escape of air, which might blister it. For two days thereafter, it is removed twice a-day, and rolled in a dry cloth; after which it is taken out and placed on the drying shelf. In the operation of the two last turnings, finer cloths are employed, to prevent any coarse marks from the threads being seen on the surface. Some are so particular as to place the cheese for some hours in the vat without a cloth, so as to efface all the thread-marks. In Cheshire they have two methods of salting cheese, very different from that pursued in Gloucestershire: the first of which is to place the cheese in the vat, in a cloth which has been immersed in brine, and then allow it to remain for several days, turning it at least once a-day; another method is to cover the upper surface of the cheese with salt every time it is turned, for three days; during which time the cloth must be twice changed. Both of these processes are completed by afterwards placing the cheese upon a salting bench, and then rubbing the whole external surface with salt for eight or ten days successively. It is then washed with warm whey or water, and placed on the drying shelf, where it remains for three weeks in summer, and a month or five weeks in winter. Three pounds of salt are required for a cheese of sixty pounds. The next operation is to smear the whole surface of the cheese with butter; they are placed on shelves, and firmly rubbed, and again smeared daily for fifteen days. However long the farmer keeps his cheese, the turning daily is constantly kept up, and rubbing employed thrice a-week in summer, and twice in winter.

Stilton Cheese.—The evening's meal of milk is allowed to stand; it is creamed next morning, and added to the morning's meal along with the rennet. When it has coagulated, the curd is not broken in the ordinary way, but is taken out whole, and placed in a sieve to drain gradually. During this process, a gentle pressure is applied; and when it is divested of all the whey, it is placed in the vat, and kept on a dry board. Stilton cheeses generally weigh from six to twelve pounds; they require two years to ripen sufficiently for sale, and are never considered to be so till they are blue inside. To hasten ripeness, some farmers add wine to the curd. These cheeses are sometimes made in a net, which gives them the form of a melon, and these are reversed daily in the process of drying. They are the most valuable of all the British cheeses.

Lincolnshire Cheese.—An excellent cream cheese is made in this county, by retaining the cream of a former meal of milk, and adding to that which is immediately from the cow. This cheese is only pressed two or three times, and, when only a few days old, is sold to be eaten with salads, such as lettuces and radishes.

Dunlop Cheese.—This cheese took its name from the parish of Dunlop, in Ayrshire, Scotland, where it was originally manufactured; but cheese equal in quality, and made on the same principles, is produced in various parts of Scotland. It is said that cheese from unskimmed milk was not made in Scotland till after the revolution. Tradition says that it was first made by a woman named Barbara Gilmour, who, having fled Scotland from religious persecution, and taken refuge in Ireland, returned from thence to her native parish Dunlop, in Ayrshire, and introduced the making of this cheese. How she acquired a knowledge of this in Ireland at so early a period, we cannot conjecture, as at the present day it is a notorious fact that good cheese is seldom produced in that country, which is remarkable in an eminent degree for the richness of its pasture, and, consequently, the superior quality of its butter.

In this district of Ayrshire the cows are of the small improved breed, the average living weight varying from thirty to forty stone. They are kept constantly in the fields from May till October, which may have a tendency to give a richness to their milk, as they enjoy the best health and vigour from this continual exposure to the free air. They produce from nine to ten English gallons of milk daily, and are milked twice a day, namely, at six in the morning, and the same hour in the evening. The best quality of cheese is made by those who have such a number of cows as can produce as much milk as to enable them to make cheese daily. About a dozen will effect this. This is made by mixing the evening's milk with the new morning's milk, or *vice versa*; that is, they never mix two meals together of more than twelve hours' standing. The milk is brought to its natural heat, and the rennet applied; and as soon as it has coagulated, which seldom requires more than fifteen minutes, the curd is stirred gently with a roller, and then pressed softly by the skimming dish, and the whey removed as it gathers, until the curd assumes a solid appearance. To complete the process of removing the whey, it is sometimes put into a drainer, and pressure applied above to force all the whey out. The curd is then returned into the cheese-tub, and cut into very small portions by means of a four-bladed knife; indeed, some individuals use one with six blades. A sufficient proportion of salt is then added, and well mixed with the hands. As this is generally done by guess, there must of course be considerable variety in the saltness of the cheese; which perhaps is as well, as there is much variety of taste in this respect. After these operations, it is put into the vat or cheese-mould, which is called a cheesit, chessel, or chesser, in Scotland. The curd is not put in in lumps, but rubbed as small as possible between the hands. It is then put into a press, and afterwards frequently removed, and the cloth changed, and replaced by a dry one. This process is usually continued for from two to three days, and the cheese is then taken out and placed on a shelf, turned and rubbed carefully with a coarse cloth daily. Dunlop cheese has always been made without any colouring, but of late years the practice of colouring has been introduced by many of our Scottish farmers; but the true lover of Dunlop cheese prefers them in their unsophisticated and unadorned state; for however colour may please the eye, it adds nothing to the pleasure of the palate. Dunlop cheeses are made of various sizes, from twenty to sixty pounds; and it has been calculated that a dozen cows will produce upwards of a ton and a half in a season. The cheese-press which has been long used in Ayrshire is of a simple construction. It consists of a large cubical stone, from half a ton to a ton in weight, placed in a framework of wood, and raised and depressed by means of a screw; and cottagers content themselves with a large flat stone, which is lifted off and on the vat with the hands.

Mr Robison, secretary of the Royal Society of Edinburgh, has discovered a mode of speedily rendering any cheese blue, which is by perforating it with an instrument, and introducing a little of the blue of another cheese into it, which has the effect of inoculating even the newest cheese.

Wiltshire Green Cheese.—This is a fanciful kind of cheese, which is produced by steeping in a given quantity of milk, one part of marigold leaves, with two parts of sage leaves, allowing them to remain one night; to this are added a few parsley leaves. This decoction is then coagulated, and afterwards mixed with a certain quantity of curd made in the usual manner. The cheese is then formed in the ordinary way. We have seen a cheese of this kind in France, which was said to have been made in Switzerland, which had, besides the above ingredients, the flavour of wild thyme and rosemary. But we confess it needs an acquired taste to relish these.

Ewe-milk Cheese.—This cheese is made by a mixture of ewe-milk and cow-milk, in the proportion of two parts of the former to one of the latter. The process of coagulation and formation of the cheese is in the ordinary manner. It is generally made salter than cow-milk cheese, and has a strong and pungent taste. An imitation of Parmesan or Italian cheese has been made from ewe-milk, in the same manner as the true cheese of that name is made.

MAKING AND CURING BUTTER.

Churning.—There are various methods practised in this operation. Some persons put the new milk directly into the churn, and permit it to stand until the cream is thrown up on its surface, and then churn the whole together; others put the milk into large flat dishes, and permit it to stand from seven to eight hours (some permit it to stand twelve hours), till the cream has risen, and then skim it off, and churn it alone, which is reckoned the best mode of conducting the process. In creaming, the cream should if possible be lifted off the dish all in one unbroken mass. This may be accomplished by loosing it all round with the creaming-spoon, and drawing it to one side of the dish, when it may be easily lifted. Cream may be kept from three to seven days before being churned, depending upon the state of the weather. It requires more labour and time to make butter from the milk and cream churned together, but it has been found that a greater quantity of butter is produced from this practice. Great steadiness in the motion of the stick, or driving of the handle in barrel-churns, is required. Want of attention in this respect has been known entirely to spoil the butter. In summer, butter should be churned early in the morning. If the common upright churn is used, it should be placed in a tub of cold water, which ought to extend for a foot up its sides, and be kept in this situation during the whole operation of churning. By using this precaution, the butter will be firmer, and will more easily separate from the milk. In winter, on the contrary, heat is necessary for the accomplishment of churning more easily; the kitchen fireside is a very proper place for the purpose; while care must be taken to prevent the one side of the churn from getting heated, as this would have a tendency to render the butter rancid and ill tasted. When the butter has fully come, it is taken out of the churn with the skimming-dish, and put into a wooden or crockery vessel; if the former, it should be previously well rubbed with salt, to prevent it sticking to the sides. The milk is now carefully pressed out of the butter; to effect which, it requires considerable pressure; for if any of the milk remains, the butter will soon spoil. Some are in the habit of washing the butter with cold water, but this is an unnecessary practice.

Making up.—The butter is now made up into rolls or small prints cast from flat moulds of wood, on which are relieved figures of some kind. If the butter is soft, it may be placed in wooden or other vessels, and there allowed to swim in cold water, but it is considered bad to allow the butter itself to come in contact with water.

Curing or Salting Butter.—Wooden vessels are the best for preserving butter when salted. These should be internally rubbed firmly with salt, and the cavity round the margin of the bottom should be filled up with melted butter which has been salted. The best preparation for preserving butter is one part of sugar, one part of nitre, and two parts of salt. These are all finely pounded together, and to every pound of butter an ounce of this composition is used, and completely mixed with the butter as soon as it is made; it is then placed in the kit or firkin, and closely pressed down, and rendered quite even on the surface, and carefully covered with a cloth which has been smeared with melted butter, to prevent the air from affecting it. Some use parchment for this purpose. This operation should be repeated till the vessel is completely filled, when it must be covered with a double piece of cloth, over which has been poured melted butter, and all the cavities completely filled up with the same, and some salt sprinkled over the surface. The firkin should then have a wooden lid or covering, which must fit it as tightly as possible, so as totally to exclude the air, for it is this element which destroys the butter by coming in contact with it. Every time, therefore, that butter is taken out of the firkin, it should be closely covered up. The more effectually to guard against rancidity when curing salt butter, a strong brine of salt is poured over its surface. Winter-made butter is always very pale; to give it a richer appearance, a dye is frequently added. The best and safest are the leaves of marigold and carrot juice, which are placed in a cloth, and squeezed amongst the cream when put into the churn.

REARING CATTLE.

Although this department of our subject more properly belongs to farming and grazing than to Cottage Economy, we shall give a few of the leading points to be attended to.

Calves should be allowed to suck their dams for some time, at least two or three weeks; but in lieu of this, milk may be given to them to drink from a pail. After the first fortnight, half or even the whole may be skimmed milk, and in many parts even this is mixed with water; and no other food is given them till they are able to graze. In Cheshire they are suckled for three weeks, and afterwards fed on whey, buttermilk, or skimmed milk, mixed with flour, pea or bean meal, or oatmeal. Sometimes they get a mixture of all these, and at other times separately; but this depends upon the fancy of the feeder. Many persons think calves should never be allowed to suck their dam at all, but at once be taught to drink from a pail, by which means they are not liable to fall off or suffer by weaning. The quantity allowed to a calf is about two gallons of milk daily at first; this, however, must be increased as they advance in age, and farinaceous substances, as above recommended, added to it. The best winter feeding for calves is hay, and clover hay is decidedly the fittest for the purpose. It has been found sometimes that feeding very young calves on old milk has the effect of scouring them for some time, but it will soon go off. The following is the Duke of Northumberland's method of feeding calves:—Take one gallon of skimmed milk, and to about half a pint of it add half an ounce of treacle, and mix them thoroughly; then take one ounce of linseed oilcake, finely pounded, and sprinkle it into the milk, while it is stirred all the time with a spoon. When properly incorporated, mix the whole together, and place it on the fire till it is about the warmth of new milk. This must then be given to the calf. The quantity of powdered oilcake may be increased as occasion requires.

Spring has long been found to be the best time for rearing calves, but this will depend much upon the time the animals are calved. It has been noticed that those which have been weaned late in the autumn or in the winter seldom thrive well. When a calf is weaned from the teat in spring, it should be turned out during the day into an inclosure where it will be free from harm, and where it can have tolerably good grass to nibble at. If there are more than one calf, it is found they sooner become reconciled to their privation in being separated from their dams. For this purpose, also, they ought to be at some distance from where the dams are fed, so that they may not hear each other's lowing; and there ought to be neither ponds nor ditches where the young animals may injure themselves. They should be provided with milk porridge at their feeding hours, and for the first six months they should be removed under cover during the night, after which they may be left out night and day. Their pasture should be frequently changed, and finally removed into a yard at Michaelmas. After this they may be fed in the same manner as cows and other cattle. By the following summer they will, having been properly fed, have acquired strength and substance, and, by way of economy, may be fed on the coarser pastures which may be in possession or within reach of the owner. It has been found of great benefit to feed young cattle on turnips for three months during winter, for the first two or three years.

DISEASES OF COWS.

There are many diseases to which horned cattle are liable, and some of these are of a dangerous kind. These are

Field Fever.—The cure for this is bleeding, and in their drink half an ounce of nitre is given twice a-day. In warm weather they need not be housed.

Inflammatory Fever is often induced by over-driving and other causes: it prevails most in young animals. Bleeding and purgatives, with fever-powder as a drink, are the cures. It has been found that four drachms of muriatic acid, with a decoction of three pints of oak bark, have proved salutary as a drink in this complaint.

Epidemic Influenza.—This is a disorder to which cattle are very liable, and has long been known as a scourge of these animals. It is caused by very stormy weather, and frequent changes of temperature. This disease at first commences by itching of the ears, shaking of the head, and difficulty in swallowing, staggering in their walk, great weakness, and a constant desire to lie down; with a discharge from the eyes and nostrils, a strong and frequent cough, and an almost constant discharge of thin green fæces. Bleeding for the first two days is recommended; clean litter given frequently, and the animal kept in a situation where there is a free circulation of air; and fumigating the place often; green boughs burnt with pitch have been efficacious. The body should be washed with aromatic herbs in water, or, what is still better, vinegar. Saline purgatives in the early stages have frequently been found beneficial; these may consist of from ten to twenty ounces of Epsom salts. When, however, the disease assumes an alarming appearance, a farrier must be applied to, as it is unsafe for unskilful persons to attempt a cure.

Inflammation of the lungs and of the stomach, frenzy fever, and the hove or blown (an inflammation of the paunch, ending in ruptures), are also common; but to discriminate these, requires much judgment, and it is safer to apply to those skilled in the diseases and cure of cattle. Indeed, to give a satisfactory account of these, and to mark such treatment as is requisite in all the maladies of cattle, would require a pretty large volume.

The principal disease of calves is a kind of convulsions, occasioned either by worms or cold. The best specific for worms are doses of turpentine of half an ounce at night, and the same quantity next morning. Sometimes a simple dose of aloes will dislodge the worms. When the convulsions proceed from cold, the calf should be rolled in a warm blanket, and a dose of a drachm of laudanum in ale given. When they are attacked with diarrhœa, the following prescription may be administered in the shape of a drink, which may consist of beer, or brewer's wash, and draff:—Glauber salts, dissolved, two ounces; castor oil, four ounces; powdered rhubarb, half a drachm; powdered opium, four grains; gruel, one pint. If they will take the above without any other liquid, so much the better.

BREEDING AND FEEDING PIGS.

Animals of the hog kind possess a middle nature between those that live upon grass and such as are carnivorous, and unite in themselves most of those distinctions which are peculiar to each class. Like the one, they will feed on animal substances, and do not ruminate; like the other, they are cloven-hoofed, live chiefly on vegetables, and seldom seek after animal food, except when urged by necessity. The most numerous breed of hogs in Great Britain is that generally known by the name of the Berkshire pigs, now spread through almost every part of England and many parts of Scotland. They are in general of a reddish-brown colour, spotted with black; have large hanging ears, nearly covering their eyes; are short-legged, small-boned, and easily made fat. Some of these have been fed to an almost incredible size.

In country situations, where woods are extensive, and the grass of them of no value to the farmer, the feeding and breeding of pigs will be found very profitable to the cottager; for where they have a wide range, they will require but little food, save what they find for themselves in grazing upon the coarse grass, and in digging in the ground for worms and roots of various kinds, for which their long and curiously formed snout peculiarly fits them; and it is only in the fattening that any particular attention requires to be devoted to the mode of feeding them. If there happens to be a mill near at hand, the dust, shellings, and bran, will be procured easily and cheaply. We cannot give a better instance of the profit of a good breed of pigs than one which occurred near Drogheda in Ireland, in 1813. It was of a sow which was fed for nine months. The following was its produce:—

July 1813, it produced a litter of eleven, seven of which were sold at 30s. each,	L.10	10	0
July 1814, a litter of eleven; nine sold at 40s. . . .	18	0	0
March, three of first litter sold in market at	31	0	0
April, sow sold fat at . .	20	5	5
	L.79	15	5

And a breeding sow was kept, valued at L.20.

The domestic pig generally brings forth twice a-year, and produces from ten to twenty at a litter; she goes with young four months, and farrows early in the fifth. At that time she must be carefully watched, to prevent her from devouring her young; still greater attention is necessary to keep off the male, as he would devour the whole litter. The flesh of the hog is a wholesome food for those who take much exercise, but not for such as lead a sedentary life. It is of great importance to this country as a mercantile nation; for it takes on salt better than any other kind of flesh, and consequently is capable of being preserved longer; it is therefore in great use in ships, and makes a principal part of the provisions of the British navy.

By a mixture of the Chinese black swine with others of the larger British breed, a kind has been produced which possesses many qualities superior to either of the original stocks. They are very prolific, are sooner made fat than the larger kinds, upon less provisions, and are cut up, when killed, into more useful and convenient portions. Arthur Mowbray, Esq. of Sherburn, in the county of Durham, had a pig of this breed which littered within ten months three times, producing in all fifty pigs; the last litter consisted of nineteen. The Chinese or black breed is now very common in Britain. They are smaller, have shorter legs, and their flesh is whiter and sweeter than the common kind. A kind similar to this were those found in New Guinea, which proved so seasonable a relief to our circumnavigators when that country was first visited by them. An unceasing attention to improvement has produced or new-modelled the Chinese breed in this country, to what is deemed to be nearer perfection. The delicacy of appearance, the thin transparent ears, small head, short legs, and even the colour of the hair, are all considered as requisite qualities, which ought to be attended to in this kind. They are seldom fed for the same purposes as the larger breeds of swine, being considered too small to be dried into bacon, but they are preferred as the best and most delicate for pork and roasting pigs.

Although swine are found to succeed in all countries, and their constitutions have been accommodated to every climate, yet they are found to degenerate and not thrive well either in the extremes of heat or cold. In a native state we find them, when inhabiting countries towards either extreme, seeking situations most adapted to their constitution. Swine, in a domesticated state, require to be kept very dry and warm, otherwise they will never thrive. It will be noticed that in cold weather they invariably bury themselves among the straw and litter with which they are supplied as bedding, thus pointing out their natural desire for heat. The piggery should therefore be in some well-sheltered spot, and if possible with a south or west exposure. If kept in small sties, there should be a small aperture at each end of them, so as to permit the free passage of air through them for ventilation. These may be kept open constantly during the summer months, but only allowed to be open for air once every second day in winter, and that in the forenoon, while they must be carefully shut up in the evening. Pigs will be found to grow notwithstanding the neglect of all these precautions, but we know from experience that they will grow much faster and will be more healthy with them. We cannot too strongly impress the necessity of cleanliness in the management and rearing of pigs. There is not a more mistaken idea than that a pig is naturally a filthy animal. If they are dirty in their habits, it is from the education which they receive from those who are careless in keeping their piggeries clean. The floor of the sty in which they sleep ought to be some inches above the level of the small enclosure in front, for feeding and exercise; and as much room as possible should be afforded for the latter purpose. When pigs are not kept very clean, they are liable to a disease in the skin, something like itch or mange. This can only be averted by what we have above recommended.

Cottagers should purchase their young pigs either in April or the month of January; and if four months old at any of these periods when bought, he will be a year old by the time that pigs are generally killed—namely, commencing at Christmas. No pig should be killed sooner; and even if eighteen months old, so much the better, as the flesh is more solid at that age. During the summer, the pig may be fed on all kinds of refuse from a garden; and if allowed to go at liberty, he will find plenty of food for himself, either in woods, road-sides, or lanes. If cottagers brew their own beer, the grains which are the refuse of it will greatly assist in rearing them. When the season approaches for feeding, which ought to be about the beginning of November, something more nourishing must be given. But care must be taken not to commence with feeding too rapidly, otherwise surfeit may be produced. The best materials for feeding are barley and peas meal; and if milk, either skimmed or churned, can be given at same time, it will greatly facilitate the feeding, and improve the quality of the flesh. Many persons feed their pigs on potatoes, but in that case the flesh is never so solid and good, and the fat is loose and flabby. Soft meat may do very well as a meal for pigs when they are growing, but upon no account should it be given when they are to be fed for killing. Those who feed pigs for their own use generally give them a feed or two of corn daily for fourteen days before they are killed, and give them nothing else but churned or skimmed milk to drink; and for a day before killing, the pig should not get any food. Where people's circumstances will not permit any of the modes of feeding for killing which we have above pointed out, a good substitute will be found in boiled potatoes, mixed with a handful or two of oatmeal. Indeed we have seen good pork in Ireland which had been fed entirely on potatoes; and although it was not very fat, the texture of the flesh was fine, solid, and well tasted, and more palatable to a stomach unaccustomed to strong food than that which is fatter.

Fattening for Bacon.—The pigs selected for this purpose should never be less than from eighteen months to two years of age. Although bacon may be cured from animals which are not more than a year old, yet it wants that solidity which gives a zest to this excellent food; and, besides, it does not keep so long when young. Three to four months' feeding is necessary. Where persons are near a distillery or brewery, the refuse grains and wash will be found an excellent thing to begin with, and the process is finished with hard food, as we have above pointed out. For even one of the largest sized pigs, Mr Henderson, a late writer on this subject, thinks, that, in the process of feeding, not more than six Winchester bushels of oats made into meal should be consumed. It ought to be shelled before grinding, but not sifted.

Fattening Sucking Pigs.—The sow ought to be well fed, and kept in a warm comfortable situation. When pigs which have been weaned are fattened for killing, they should be constantly fed on skimmed or butter milk, mixed with peas, barley, or oat meal. Pigs at six months old are fit for killing as pork, and may be eaten either fresh or pickled. It cannot, however, be long kept at so early an age.

In all cases there are general rules which ought to be strictly attended to. These are, to keep the feeding-troughs at all times clean and sweet, and the food should be given in small quantities, and frequently. It should be occasionally changed, as they feed better on variety; and salt should at all times be added to their food. Swedish turnips and carrots are excellent food for pigs, both of which are eaten by them with great avidity. Some persons are in the habit of boiling these roots before giving them to pigs.

Curing Pork and Bacon.—A brine is made of salt and water, so strong that an egg will swim in it. It is then boiled and poured upon the pork when cold. The meat should be entirely covered with this brine, otherwise it will require to be turned every day. In curing bacon, when the animal has been properly cut up into its various divisions, it is placed in a tub and strewed with pounded saltpetre, and afterwards plentifully covered with salt. It should lie in that state for about a week, when those parts which were undermost should be brought to the top, and those that have been above put beneath, at the same time giving them another plentiful supply of salt. They are permitted to lie for three weeks longer, and then taken out and hung up to dry. The side of a kitchen chimney, where it is not too hot, will be found the best place for this purpose; or if bacon is cured to a great extent, a smoking-house must be constructed for this purpose. Should it not be convenient to hang them up at the time above pointed out, they may be turned over and kept in the tub for a couple of months longer, without suffering any injury.

Breeding Swine.—The boar should never be less than twelve months, and the sow ten months old. For a cottager's purpose, the smaller or Berkshire breed will be found the best. The sow ought to have an ample abdomen, but not a tendency to much fat. At the same time, a sow ought to be in good condition when she is breeding, otherwise little good can be expected of her progeny. Many persons labour under the mistaken notion that swine while breeding should be kept lean, but nothing can be more erroneous; for, after farrowing, great part of those juices which would be converted into milk, were she in good condition, will naturally go towards nourishing her system. The time of gestation being four months, care should be taken that her time of farrowing shall be in September and March. The first of the litter will be two months old before very cold weather sets in, and the second will have the advantage of all the summer months, and will make much greater progress in their growth than during the winter months. Pigs brought forth in winter seldom do much good, unless kept in houses where there is a constant fire.

Before farrowing, the sow should be provided with very short straw or hay, as the pigs are apt to conceal themselves beneath the litter, and not being seen by the sow, are frequently smothered by her. When pigs are weaned, great care is necessary to prevent them falling off; and they ought therefore to be fed with the richest milk, mixed with either barley, peas, or oat meal. Much of the after progress in feeding depends upon the care that is taken of pigs at weaning. If starved at this period, they seldom fairly recover it. Where the cottager has not the means of giving milk, the next best thing is meal and water, and that should not be too thin, and repeated six or eight times a-day. Swine are subject to a variety of diseases, but these cannot be treated of to any advantage here; they must be studied from books written expressly for the purpose. The dung of the hog, owing to the nature of its food and other circumstances, forms the richest of the animal manures, and will prove of great value to the cottager's garden if carefully attended to.

THE GOAT.

Where cottagers have not the means of keeping a cow, a goat will be found a very useful animal; it is easily fed, and generally pastures on such grasses as are rejected by the cow and the sheep. To those peasants who live in the neighbourhood of high mountainous countries, the trouble and expense of keeping a couple of goats will be nothing, as they will find sufficient nourishment in the most heathy and barren grounds. Heaths, also, which are unfit for any kind of pasture, will afford this animal an ample supply of food; and it requires no care or attention, easily providing for itself proper and sufficient food. In mountainous countries goats render considerable service to mankind, the flesh of the old ones being salted as winter provision, and the milk is used in many places for the making of cheese. The flesh of the kid is highly palatable, being equal, if not superior, in flavour to the most delicate lamb.

In Britain the goat produces generally two young at a time, sometimes three, rarely four. In warmer climates it is more prolific, and produces four or five at once, though the breed is found to degenerate. The time of gestation is five months. The male is capable of propagating at one year old, and the female at seven months, but the fruits of a generation so premature are generally weak and defective; their best time is at the age of two years, or eighteen months at soonest. A goat is old at six years, although the life of this genus extends to fifteen years.

If goats are properly trained, they will return to their owners twice a-day to be milked, and prefer sleeping under a roof when accustomed to it. The milk of the goat is sweet, nourishing, and medicinal; not so apt to curdle upon the stomach as that of the cow, and therefore preferable to those whose digestion is but weak. The peculiarity of this animal's food gives the milk a flavour different from that either of the cow or the sheep; for as it generally feeds upon shrubby pastures and heathy mountains, there is an agreeable mildness in the taste, very pleasing to such as are fond of that aliment. The quantity of milk produced daily by a goat is from three half pints to a quart, which yields rich and excellent cream. If properly attended to, a goat will yield milk for eleven months in the year. In several parts of Ireland and the Highlands of Scotland, the goat is the chief possession of the inhabitants. On those mountains where no other useful animal could find subsistence, the goat continues to glean sufficient living, and supplies the hardy natives with what they consider a varied luxury. They lie upon beds made of their skins, which are soft, clean, and wholesome; they live upon their milk, with oatbread; they convert a part of it into butter, and some into cheese; and the flesh furnishes an excellent food, if killed in the proper season and salted. They are fattened in the same manner as sheep; but taking every precaution, their flesh is never so good or so sweet in our climate as that of mutton. It is otherwise between the tropics. The sheep there becomes flabby and lean, while the flesh of the goat rather seems to improve, and in some places is cultivated in preference to that of the sheep. The cream of goat's milk coagulates as easily as that of cow's, and yields a larger proportion of curd. The cheese is of an excellent quality, and high flavoured; and although in appearance it looks poor, it has a very delicate relish, and strongly resembles Parmezan cheese. Some farmers have been in the practice of adding a little goat's milk to that of cows, which materially improves the flavour. In winter, when native food becomes scarce, the goat will feed upon turnip-peelings, potato-peelings, cabbage-leaves, and other refuse of a house.

THE RABBIT.

In a wild state, the rabbit lives in holes in the earth, where it brings forth its young, and retires on the approach of danger. Its fecundity is truly astonishing. It breeds seven times in the year, and generally produces eight young at a time; from which it is calculated that one pair may increase, in the course of four years, to the amazing number of *one million two hundred and seventy-four thousand eight hundred and forty*. The rabbit produces at the age of five or six months · the female goes with young about thirty days. Previous to her bringing forth, she makes a bed with down, which she pulls off her own coat. She never leaves her young but when pressed with hunger, and returns as soon as that is allayed, which she effects with surprising quickness. During the time she suckles her young, she carefully conceals them from the male lest he should devour them, and frequently covers up the mouth of the hole that her retreat may not be discovered. The rabbit lives to the age of eight or nine years, and prefers warm and temperate climates.

Such is the account of the rabbit in a wild state, and the same will apply in all respects to that in a domesticated condition, which, however, grows to a much larger size than the wild rabbit, from which it originally sprung. The domestic rabbit is of various colours, such as fawn-colour, black, white, brown, and frequently variegated. The skin of the rabbit is of value for making hats, and a ready market can in consequence be found for them at all times. In country situations the breeding of rabbits may be cultivated to much advantage; they will eat a great many wild plants, which can be easily procured as food, such as dandelion, sour docks, colewort blades, grass, clover, strawberry leaves, cabbage blades, turnips, carrots, the leaves of turnips and greens, and other succulent plants. The hog-weed is also a favourite food with them, as they will eat root, stem, and leaves; it is a tall plant, which grows abundantly in hedgerows and coppices in many counties of England; its flower and seed are exactly like those of the parsnip. Previous to fattening rabbits for food, they should be fed on hay, and afterwards on shallings and oats, when the flesh will be more delicate in flavour than even that of the wild rabbit. We knew a family in the country which had a small garden surrounded by a wall; part of this was separated by the tenant (a labouring man) from the rest by a railing, and trenched to the base of the foundation of the wall, and laid with slabs. In the corner was erected a small wooden house, well thatched, for the rabbits to live in; and on this spot, with the assistance of his children, he fed a great many rabbits annually, which served them for flesh, and he sold the skins. The usual annual number which he killed was about twenty dozen. During the time the doe has young ones, she will require a plentiful supply of green meat, and that of the most succulent kind, and should besides get a few oats once a-day. The houses in which rabbits are kept should be well aired every day if possible, and all rotten vegetable substances swept carefully away, as the effluvia from these produce diseases in the young ones.

FOWLS.

They must be considered careless cottagers who do not contrive to keep a few domestic fowls; even one good laying hen is a treasure to a humble family. The ordinary fecundity of this useful bird is truly astonishing, as it usually lays, in the course of a year, two hundred eggs, provided it be allowed to go at liberty, is well fed, and has a plentiful supply of water. Many instances have been known of hens laying three hundred in a year. This is a singular provision in nature, and it would appear to have been intended peculiarly for the use of man, as the hen usually incubates only once in a year, although she will occasionally bring out two broods. Few hens are capable of hatching more than from twelve to fifteen eggs; so that, allowing they were all to sit twice a-year, and bring out fifteen at a time, there would still be at least one hundred and seventy spare eggs for the use of man. It is therefore evident, that in situations where hens can pick up their food, they must prove very profitable; for, supposing that the eggs of one fowl during the year were sold, without any of them being hatched, they would bring on an average ninepence per dozen, or fourteen shillings, and the hen herself would be worth two shillings at least. As the number of eggs which are annually brought out by a hen bear no proportion to the number which she lays, schemes have been imagined to hatch all the eggs of a hen, and thus turn her produce to the greatest advantage; so that, in place of twelve or fourteen chickens, upwards of two hundred may be produced.

The hen's nest is made without any care, if left to herself; a hole scratched in the ground among a few bushes is the only preparation she makes for the season of incubation. Nature, almost exhausted by its own fecundity, seems to inform her of the proper time for hatching, which she herself testifies by a clucking note, and by discontinuing to lay. The good housewives, who often get more by their hens laying than by their chickens, artificially protract this clucking season, and sometimes entirely remove it. As soon as their hen begins to cluck, they stint her in her provisions; and if that fails, they plunge her into cold water; this for the time effectually puts back the desire for incubating, but then it often kills the poor bird, who takes cold, and dies under the operation.

General Management of Poultry.—On the general management of poultry, Mr Main gives the following interesting particulars, resulting from his own experience:—"Every kind of poultry should be kept in a separate house, different kinds being exceedingly pugnacious towards one another. The individuals of every species are also pugnacious among themselves; and on this account the number of cock birds is always limited. One cock to seven hens, one gander to six geese, one drake to six ducks, are the general proportions with regard to the commoner kinds of fowls; and one turkey-cock, and one peacock, are considered quite enough, on a moderately sized farm, for breeding purposes. The turkey, guinea-hen, and pea-hen, are very fastidious in the choice of nests, and therefore require watching. If the latter fix on some secluded spot in the wood or hedges, she must not be removed; and, while sitting, she will come home, call for food, and fly back to her nest. In such places they are in danger of being killed by the fox; but if a circle of peeled rods be placed archwise on the ground, at some distance round the nest, it will scare the marauder. Pea-fowls seldom roost in houses, preferring the tops of buildings or the branches of trees. Every farm should have a place for fattening poultry, containing coops. Fowls are usually fattened with barleymeal and milk or water; and if this is made thin enough, they need no drink. Geese are fattened with oats, given them in shallow earthen pans of water. Turkeys are best fattened with barleymeal and milk; but with professional feeders, many rich and unnatural ingredients are mixed with their food, and forced down the throats of the helpless birds. Ducks are fattened like fowls, but must be allowed plenty of water. The flesh of poultry acquires flavour according to the quality of the food on which they have been fed. Musty or otherwise damaged grain is sure to be tasted in the fowl, goose, turkey, or duck, that has been fed on it, however dressed; on the other hand, general cleanliness and sweet food improve the flavour of the flesh. Rotten or musty litter will taint the birds as well as their eggs. In fact, no poultry of any kind will thrive if not kept perfectly clean; and even with the utmost care, a place where poultry have been long kept becomes what the housewives call tainted, and where they will thrive no longer. The surface of the ground becomes saturated with their exuviæ, and is therefore no longer healthy. To avoid this effect, some poulterers in the country frequently change the sites of their poultry-houses, to obtain fresh ground; and to guard against the same misfortune, farmers who cannot change their henhouses and yards, purify the houses by fumigations of blazing pitch, by washing with hot lime-water, and by strewing large quantities of pure sand both within and without the poultry-houses. Washing the floor of the house every week is necessary; for which purpose it is also necessary that it be paved either with stones, bricks, or tiles."

But as these three modes are expensive, we would recommend to the cottager an equally good flooring, which is much cheaper: that is, by making a composition composed of lime and smithy-ashes, together with the riddlings of common kitchen ashes; and these having been all finely broken, must be mixed together with water, and put on the floor with a mason's trowel, and nicely smoothed on the surface. If this is put on a floor which is in a tolerably dry situation, and allowed to harden before being used, it will become nearly as solid and compact as stone, and is almost as durable. The floors of such houses should be washed out with a mop, which is much more easily done than with a washing-cloth. The inside of the laying-boxes requires frequent washing with hot lime-water to free them from vermin, which greatly torment the sitting hens. For the same purpose, poultry should always have a heap of dry sand laid under some covered place, or thick tree, near their yard, for them to dust themselves in; this being their resource for getting rid of the vermin with which they are annoyed. Geese may hatch eleven or thirteen eggs; ducks the same; fowls thirteen; turkeys, guinea-hens, and peafowls, choose their own number. Turkey chicks cannot be reared if hatched after the end of September. Chickens are subject to a disease called the roop or croup, which seizes them when about three weeks old, or just as the feathers appear on the head. It is caused by small worms breeding in the windpipe in such numbers as to stop respiration, and which, if they cannot cough them up, soon kill them. An infusion of yellow toad-flax, a nauseous and bitter weed, is given as a preventive, but is seldom successful. The disease mentioned by Mr Main is also called the gapes. The worm by which it is produced has a round body, which is acuminated at the posterior end, the lower aperture projecting on a long stalk or arm, that extends rather beyond the anterior end of the body where the other aperture is placed, and is about half the size of that part; these openings spread a little, or are somewhat funnel-shaped, by which the animal adheres to the trachea, from which it cannot be removed without considerable difficulty. It is of a deep blood-red colour, and about an inch in length. The cause of this malady has not yet been ascertained, and it obtains in high as well as in low situations; but whether the nature of the soil or that of the water is productive of it, remains yet to be discovered. We have seen it in all situations. The place of the throat to which these worms adhere becomes much inflamed, which also produces inflammation in the lungs, although none of the worms themselves have been found so low down. But as this disease is confined to the trachea, we consider that no specifics can reach it. We have, however, cured chickens by thrusting a feather stript to within a little of the point down their throat, and turning it quickly round several times, which has had the effect of removing the worm, and in several instances it has been brought out on the feather. Care must be taken not to put the feather lower down than the bottom of the trachea, otherwise, by entering the lungs, it may cause immediate death. This operation is a very painful one to the poor chicken, but it is less than the pain it endures from the worm. The turkey in America, while in a young state, is also subject to this distemper.

There is no species of live stock so suitable to a farm-labourer or cottager as poultry. It has frequently been remarked, "that none but Scotch Highlanders or Irish cottagers have the luxury of fresh eggs in winter, or very early chickens in spring: and as their poultry are of the common breeds, the cause of their continuing to lay eggs when others stop can only be, that they roost in the same rooms with their owners, enjoy some little warmth, and probably live partly on cooked food. On the other hand, the poultry which are lodged in places fitted up for them in farm buildings, or other outhouses, are forced to endure a much lower temperature during winter than is suitable for their laying at that season, and to live almost entirely on uncooked food." Another powerful reason is, that the poultry which live in the same apartments with their owners enjoy a superior degree of cleanliness, even more so than those which are kept in the best conducted poultry-houses.

When a cottager desires to have his hens to lay all winter, he must take care to place his poultry-house somewhere near the fireplace, so that the hens may derive heat from it. This may be accomplished in several ways, both in cottages which are already built, and in those which are yet to construct. The fireplace in almost all cottages is placed either in the exterior or in one of the interior walls. When it is in the outer wall, a poultry-house can be constructed so as to lean against it on the outside of the house, immediately opposite to the fireplace; and if the wall of the house be too thick to admit of the heat passing through, so as to warm the henhouse, then a part of the wall may be taken out, and a fire-brick or stone partition placed in the aperture, which will allow sufficient heat to pass through. But what is still better, a cast-iron plate, being a more effective conductor of heat, will answer a great deal better. Take care to have the walls of the poultry-house so thick that they will retain the heat, and the roof ought also to be well and effectually closed, so as to prevent the escape of heat or the entrance of cold air. A very effectual method is to have the space between the slates or ceiling filled with hay or straw, which is a plan universally pursued in Holland. It would be well also to hang the walls and door round with straw mats. The Dutch thatch the whole roof and sides of the fowlhouse during winter.

Where the fireplace is in the interior wall of the house, the best method for warming the poultry-house is to have a small pit dug in the bottom of the floor, over which is placed a stone or plate of iron, and this pit should be filled with hot embers, of which a supply once a-day will effectually warm the apartments. Another method is to communicate heat to a cistern of water under the floor of the poultry-house, by means of pipes passing from the kitchen fire; but this, although comparatively simple, is too much out of the common way to be adopted by labouring people. Poultry-houses may be made of any form or size; but let them be invariably in warm and dry situations, for even ducks, geese, and other aquatic birds, thrive best when kept dry and warm. All fowls of the gallinaceous kinds roost in elevated situations, and perches should therefore be made for them at a distance from the ground. The rods or rails should be roundish, and of such a diameter that they can grasp them with their feet; it is not, however, necessary that they should be either perfectly round or smooth. Geese and ducks, on the contrary, prefer sitting low; and as their feet are flat and webbed, and consequently incapable of grasping round surfaces, the flatter the place on which they sit the better.

During incubation, fowls should be kept very quiet and retired, and in a dark situation if possible. It is also essential, while fowls are under the process of fattening, that they be kept solitary, and also in a dark situation. All kinds of poultry, when young, are possessed of great activity, and hence require a considerable range to preserve them in health and vigour; consequently, it will be found that they grow faster, larger, and stronger, in situations where they are not confined within the limits of a poultry-yard. They also require the use of salt, sand, and small pebbles, to promote digestion; and their food should consist of green vegetable substances as well as grain, meal, &c. A complete poultry-yard should have a variety of ground, such as dry soil for fowls, turkeys, and guinea-hens, and a damp low situation, with a pond or running stream, for geese and ducks. The poultry-yard should also have a shed for the birds sheltering under, both in the heat of the day and during rain, as much heat is injurious to fowls; and even geese and ducks cannot stand much rain without being injured, although the oily nature of the feathers will protect them from being wet through much longer than those of fowls.

In general, far too little care is taken of poultry. They are often suffered to live "any way," and to eat any thing that hunger compels them to have recourse to. In some parts of Surrey the fowls are admirably managed; and it may be safely asserted that the Scotch are a hundred years behind their neighbours in this profitable branch of cottage economy. At least one-half of the fowls brought to the Edinburgh market would be considered uneatable in London. To improve the breed ought to be a primary object in different parts of the country; and this might be done by procuring eggs from Dorking, in Surrey. Besides this, a better system of feeding on more nutritious aliment should be adopted. Hens are particularly fond of shred particles of flesh meat, the refuse of the table; and if such nutriment be given to them after moulting in the autumn, they will immediately commence laying. Chickens ought to be in a good condition for market when twelve months old. If too little attention is paid to poultry, less is given to the proper preservation of eggs, which often come to market with a strong flavour of rank straw, if not absolutely rotten. As eggs easily contract a bad flavour, they ought to be carefully put aside in some clean place after being taken from the nest. Bran is a good material to lay them amongst for a certain length of time before sending them to market.

GEESE.

Our common tame goose is the wild species domesticated, known to naturalists by the name of the fen or stubble goose. Where people have a right of common, or live in the vicinity of marshy heaths, the breeding and rearing of geese will prove very profitable, for in such situations they are kept at a very trifling expense; they are very hardy, and live to a great age. If properly kept and fed regularly, although sparingly, they will lay upwards of a hundred eggs yearly. If these are set under large hens, each having half a dozen, with the assistance of the goose herself, they may be nearly all hatched. For the first three or four days they must be kept warm and dry, and fed on barleymeal or oatmeal mixed with milk, if it is easily procured; if not, let these ingredients be mixed with water. They will begin to grow in about a week. For a week or two the goslings should not be turned out till late in the morning, and taken in early in the evening. In Ireland the tenantry depend much on the breeding of these birds and turkeys to pay their rent; and with those who are industrious and favourably situated for rearing geese, they even do more in many instances. In the early part of the year they are allowed to feed on grass, on heaths, meadows, and commons; and as most of the peasantry have small bits of corn land of their own, the geese are turned out on the stubble to pluck what grass is left; and they also fatten upon it, and improve the flavour of their flesh.

Although water be the natural element of geese, yet it is a curious fact that they feed much faster in situations remote from rivers and streams. To fatten geese it is necessary to give them a little corn daily, with the addition of some raw Swedish turnips, carrots, mangel-wurzel leaves, lucerne, tares, cabbage leaves, and lettuces. They should not be allowed to run at large when they are fattening, as they do not acquire flesh nearly so fast when allowed to take much exercise. Therefore, those who can only afford to bring up a goose or two, should confine them in a crib or some such place about the beginning of July, and feed them upon the ingredients above recommended, with a daily supply of clean water for drink. If, on the contrary, from a dozen to twenty are kept, a large pen of from fifteen to twenty feet square must be made, and well covered with straw in the bottom, and a covered house in a corner for protection against the sun and rain when required, because exposure to either of these is not good. It will be observed that about noon, if geese are at liberty, they will seek some shady spot to avoid the influence of the sun; and when confined in small places, they have not sufficient room to flap their wings and dry themselves after being wetted; nor have they room to move about so as to keep themselves warm. There should be three troughs in the pen, one for dry oats, another for vegetables—which ought always to be cut down—and a third for clean water, of which they must always have a plentiful supply. It must be remembered that the riper the cabbages and lettuces which they are supplied with, the better. In the neighbourhood of large towns, the most profitable way of disposing of geese is in a dead state; as nearly the same sum can be obtained for them as if they were alive, and then you have the feathers, which are valuable, and may be sold to much advantage by themselves when you have collected a stone weight or more.

Geese are kept in vast quantities in the fens of Lincolnshire, several persons there having as many as a thousand breeders. They are bred for the sake of their quills and feathers, for which they are stripped while alive, once in the year for their quills, and no less than five times for their feathers. The first plucking commences about Ladyday, for both, and the other four are between that time and Michaelmas. It is said that in general the birds do not suffer very much from the operation, except when cold weather sets in, which then kills great numbers of them. The old geese submit quietly to the operation, but the young ones are very noisy and unruly. The possessors, except in this cruel practice, treat their birds with great kindness, lodging them very often in the same room with themselves.

These geese breed in general only once a-year, but, if well kept, they sometimes hatch twice in a season. The best method for promoting this is to feed them with corn, barley, malt, fresh grains, and, as a stimulant, they should get a mixture of pollard and ale. During their sitting, each bird has a space allotted to it, in rows of wicker pens placed one above another, and the gooseherd who has the care of them drives the whole flock to water thrice a-day, and, bringing them back to their habitation, places every bird (without missing one) in its own nest. One gander is generally put to five geese. The time of incubation varies from twenty-seven to thirty days. The goose begins to lay in March, but the time of the month depends upon the state of the atmosphere. When goslings are first allowed to go at large with their dam, every plant of hemlock which grows within the extent of their range should be pulled up, as they are very apt to eat it, which generally proves fatal to them. Nightshade is also equally pernicious to them, and they have been known to be poisoned by eating sprigs of yew-tree.

TURKEYS.

This is certainly one of the most valuable fowls which have been naturalised in this country, but it very difficult to rear. The turkey-hen lays from fifteen to twenty eggs, and then sits upon them. She will bring out two broods in a year. The eggs are of a pale yellowish-white colour, finely streaked and spotted with reddish-yellow. They are a most delicious food, much more delicate in their flavour than those of the common hen. In England or Scotland, however, the eggs are seldom to be met with for sale, being deemed too valuable to be used as food. In Ireland they are to be got in the markets in great abundance, especially in the midland counties, where we have bought them at ninepence per dozen. In that country, when the turkey-hen has laid about half a dozen eggs, they afterwards take away one daily, by which means the hens are induced to produce a greater number of eggs than otherwise. This they assist by means of stimulating food, such as hemp-seed and buck-wheat. There is an interval of a day between the laying of each egg. It is said that the first two eggs which she lays are unfruitful. A turkey-hen can seldom hatch more than from sixteen to eighteen eggs. The time of incubation varies from twenty-seven to twenty-eight days, at which time the young begin to pierce their shelly prison, and emerge from it. When they first come forth, they are extremely weak, and much assiduous care is necessary to rear them. The first thing to be attended to, is to remove them to a situation where they are not exposed to the sun's rays, which at first are too powerful for them. A woody place is the most suitable to their natural habits. Nothing is so destructive to them as rain, from which they must be protected.

When young turkeys accidentally get wet, they should be brought into a house, carefully dried by applying soft towels to them, and then placed near a fire, and fed upon bread which has been mixed with a small proportion of ground pepper or ginger. It should be made up in the form of small peas. If the bread is too dry for this purpose, it may be moistened with a little sweet milk. Should the turkey-pouts refuse to eat it, a few of these pellets may be forced down their throats. Even heavy dews prove destructive to them, and frost is no less injurious in its effects. These must therefore be most carefully guarded against, when the hens incubate in March or early in April. Dry and sandy situations are most congenial for breeding turkeys, and especially elevated situations where large woods are contiguous. A single male turkey is sufficient for twelve or sixteen females, although the former number is probably the safest, to prevent sterility in the eggs, which is frequently the case with those of turkeys. Eggs should never be entrusted to the care of a female until she is at least two years of age, and they may be kept for the purpose of incubation till they reach their fifth year. The largest and strongest hens should always be kept for this purpose. During the time the hen is sitting, it becomes necessary to place food near her, as otherwise, from her assiduity, she may be starved to death, as turkey-hens seldom move from their nest during the whole time of incubation.

Where farmers rear turkeys in great numbers, they do not indulge the hen by allowing her to sit as soon as she has done laying, but keep them from her until all the other hens have ceased to lay, as it is of consequence that they should all be hatched about one time. When hens are unhappy during this interval, they may be indulged with hens' eggs. When all the females have ceased to lay, each of them is provided with a nest ranged close to the wall, in a barn or other convenient place, and each female is supplied with from sixteen to twenty of her own eggs. The windows and doors are then closed, and only opened once in the twenty-four hours for the admission of air, and for the purpose of feeding the hens. They are taken off their nests, fed and replaced, and again shut up. On the twenty-sixth day, the person who is entrusted with the management of the birds, examines all the eggs, and removes those that are addled; feeds the hens, and does not again disturb them till the pouts have emerged from their shells, and have become perfectly dry, from the heat of the parent bird, as to be subjected to cold at this time would certainly kill them. When the young birds are thoroughly dried, two of the broods are joined together, and the care of them entrusted to a single hen; and those which have been deprived of their offspring are again placed on hens' or ducks' eggs, and subjected a second time to the tedious operation of incubation, in which case it is not unusual for them to bring out thirty eggs. We cannot recommend this practice, in point of humanity; for the poor hens, when they have accomplished their second sitting, are literally reduced to skin and bone, and frequently so weak as hardly to be able to walk.

As before hinted at, great care should be taken of the young turkey-pouts; besides warmth, proper food, and shade, the nearer they are to a pure running stream, the better, as they drink a great deal, and nothing is of greater importance to their being successfully reared as fresh drink. They must be also carefully protected from strong gusts of wind, and on the slightest appearance of a thunder-storm, should be immediately taken into a house. They should get no food for twenty-four hours after they leave the egg. Their first food should be hard-boiled eggs finely chopped and mixed with crumbs of bread. Curds is also an excellent food for them. When they are about a week old, boiled peas and minced scallions are given to them. If eggs are continued, the shells should be minced down with their food, to assist digestion, or some very coarse sand, or minute pebbles. They should be fed thrice a-day; and as they get older, a mixture of lettuce-milk will be found beneficial, together with minced nettles. Barley boiled in milk is another excellent food at this period, and then oats boiled in milk. In short, the constitution of young turkeys requires at all ages every kind of stimulating food. When about three weeks old, their meat should consist of a mixture of minced lettuce, nettles, abelmoschus, curdled milk of burdocks, bran, and dried camomile; but when all these cannot be readily obtained, part of them must be used. Fennel and wild endive, with all plants which are of a tonic character, may be safely given to them. Too much lettuce, however, has been found to be injurious to them; and it is a curious fact, that both cultivated and wild vetches are a poison to young turkeys; the great blue-flowered digitalis, cicuta, and henbane, are also fatal to them; so that, wherever turkeys are kept, these should be carefully rooted out. When pouts are about a month old, they should be turned out, along with the parent bird, into the fields or plantations, where they will find sufficient food for themselves. Grass, worms, all kinds of insects and snails, are their favourite food, and nature dictates to them such vegetables as are conducive to their general health. As their feet are at first very tender, and subject to inflammation from the pricking of nettles and thistles, they ought to be rubbed with spirits, which has the effect of hardening the skin, and fortifying them against these plants.

The glandulous fleshy parts and barbles of their heads begin to develope when they are from six weeks to two months old. This is a critical period with the pouts, and unusual care must be bestowed on them, as they now become weak and often sickly. A little brine mixed with their food will be found very beneficial, or spirits much diluted with water. A paste made of fennel, pepper, hempseed, and parsley, has been found an excellent remedy when afflicted with an inflammation in the wattles, to which they are liable when growing. They are very subject to this if the weather happens to be broken and changeable at the time these tubercles are growing. These parts swell and grow very red, which frequently proves fatal to them. If, therefore, such be the state of the weather at this critical period, the paste above recommended should be given even although they are perfectly healthy, which will be found an excellent preventive. When the inflammation becomes very great, recourse is often had to bleeding in the axillary vein, which frequently recovers them.

Soon after the turkey-pouts have acquired their first feathers, they are liable to a disease which is very fatal to them, if not attended to. This distemper produces great debility, and the birds appear languid and drooping, and almost totally neglect their food. Their tail and wing-feathers assume a whitish appearance, and their plumage has a bristled aspect. This is occasioned by a disease in two or three of the rump-feathers. On examination, the tubes of these will be found filled with blood. The only remedy for this disease is to pluck them out, when the bird will speedily acquire its wonted health and spirits.

In fattening turkeys for the table, various methods are resorted to. Some feed them on barleymeal mixed with skim-milk, and confine them to a coop during this time; others merely confine them to a house; while a third class allow them to run quite at liberty; which latter practice, from the experience of those on whose judgment we can most rely, is by far the best method. Care should, however, be taken to feed them abundantly before they are allowed to range about in the morning, and a meal should also be prepared for them at mid-day, to which they will generally repair homewards of their own accord; they should be fed at night, before roosting, with oatmeal and skim-milk; and a day or two previous to their being killed, they should get oats exclusively. We ourselves have found from experience, that when turkeys are purchased for the table, and cooped up, they will never increase in bulk, however plentifully they may be supplied with food and fresh water, but, on the contrary, are very liable to lose flesh. When feeding them for use, a change of food will also be found beneficial. Boiled carrots and Swedish turnips, or potatoes mixed with a little barley or oat meal, will be greedily taken by them. A cruel method is practised by some to render turkeys very fat, which is termed cramming. This is done by forming a paste of crumbs of bread, flour, minced suet, and sweet milk, or even cream, into small balls the size of a marble, and, after the bird has made a meal in the ordinary way, these are forced down its throat.

DUCKS.

Ducks are a kind of fowl easily kept, particularly near ponds or streams of water. In keeping them in a domestic state, one drake is usually put to five ducks. The ducks begin to lay in February; their time of laying being either at night or early in the morning. They are extremely apt to deposit their eggs in some sequestered spot, and to conceal them with leaves or straw. From eleven to fifteen eggs is the number which a duck can properly cover. The time of incubation is about twenty-eight days. The place where they incubate should be as quiet and retired as possible; and if they have liberty, they will give no trouble whatever in feeding, as the duck, when she feels the call of hunger, covers her eggs carefully up, and seeks food for herself, either by going to the streams or ditches in her neighbourhood, or, if no such are at hand, she will come to the cottage and intimate her wants by her squalling. When the young are hatched, they should be left to the care of the duck, who will lead them forth in due time; and when she does so, prepare a coop for them, which should be placed on short grass, if the weather is mild; and if cold or stormy, they should be kept under cover. The future strength of the brood will depend much upon the care that is taken of them for the first three or four weeks after they have emerged from the shell. Ducklings will begin to wash themselves the first day after they are hatched, if they find water at hand. Therefore, a flat dish filled with that element should be always within their reach. Many persons are in the practice of clipping the tail, and the down from beneath it, in ducklings, if the weather is wet during the first weeks of their existence. This is to prevent them from draggling themselves, which has a tendency to produce intestinal diseases. From a fortnight to three weeks is all that is necessary to confine them to the coop.

The first thing on which ducklings are fed is a mixture of barley, peas, or oat meal, and water. They may afterwards be fed upon a mixture of buck-wheat and any of the above-named meals. The greatest attention must be paid to keeping their bed warm and dry, and with young ducks a frequent change of straw is absolutely necessary, as their beds soon get dirty and wet. It is a common practice to set ducks' eggs under a hen; but where water is at hand, and the ducklings are permitted to enjoy this element, so natural to them, the practice of giving them an adopted mother is not to be recommended.

In feeding ducks for use, peas and oat meal are to be preferred. It is said that barleymeal renders their flesh soft and insipid. Bruised oats should be given to them freely for some weeks before they are killed, which renders their flesh solid and well tasted; and the same general principles recommended in the feeding of geese should be kept in view. It has been found that the offals of butchers' shops feed ducks quickly, and that this does not impair the flavour of their flesh.

Those who have paid much attention to the management of domestic poultry assert that geese and ducks should be kept apart from other fowls. The former should have their houses ranged along the banks of a piece of water with a fence, and sufficiently extensive for walks in front, with doors for their access to the water, which can be closed at pleasure; for, as we have already observed, too much exercise on water is not conducive to their feeding quickly.

PIGEONS.

Pigeons are also very easily kept about a cottage, and occupy a space in the roof which is fit for no other purpose. They require little or no care; and as for food, they will generally seek that for themselves, although it will be necessary occasionally to give them a little. Care must be taken that the dovecot is not approachable by cats or vermin. When they are first begun to be kept, a pair or two ought to be got which have not flown, otherwise it is ten to one but they will leave their new domicile. They should be kept shut up in the place appropriated for keeping them, and well fed during this time. Of the domestic pigeon there are not fewer than twenty varieties, such as carriers, croppers, powters, fantails, tumblers, &c. Their principal food is grain; they drink much, and not at intervals like other birds, but by a continued draught like quadrupeds. The house-dove or common pigeon, as is well known, breeds every month. During breeding time, they associate in pairs, and pay court to each other with their bills; the female lays two eggs, and the young ones that are produced are for the most part a male and a female. When the eggs are laid, the female, in the space of fifteen days, not including the three days during which she is employed in laying, continues to hatch, relieved at intervals by the male. From three or four o'clock in the evening till nine the next day, the female continues to sit; she is then relieved by the male, who takes his place from ten till three, while his mate is feeding abroad. In this manner they sit alternately till the young come out. The cottager who keeps a few pigeons and rabbits can never be at a loss for a little palatable and nourishing food, and that consisting of two kinds.

BREWING ALE AND BEER.

Many cottagers have no accommodation or possess no means to brew their own beer; but others have both, and to these the following practical observations will be found useful:—One of the first and most essential things to be attended to in brewing is a proper knowledge of the quality of malt to be used for that purpose. When malt is good, it is full of flour, or, more properly speaking, that substance from which flour is made. If the skin of the grains is thin, and yields easily and freely when bitten asunder, it is a sure proof of the malt being of a good quality; but, on the other hand, if the skin is thick, hard, and brittle, it is sure to be bad. Besides the smaller quantity of nutritious matter in this last kind, it will be found not to malt so well as grain of a good quality; that is, it will be longer of shooting out the roots and exhibiting signs of vegetation, and even some of the roots will not appear at all; so that all that does not shoot is lost, as it remains simply barley; and thus that portion of it has not benefited the beer in any degree. When malt is not home-made, but purchased from a maltster, it is sometimes found to be adulterated with barley. To detect this, take a cupful of the unground malt, and put it into a basin of cold water; mix it with the water so that all the grains have been fairly wet; all that are malted will swim, and the barley which has been added, or that which is but imperfectly malted, will sink to the bottom.

The specific gravity or weight of barley is much greater than that of malt, and the better the quality of the barley, the heavier it is; consequently the heavier the malt is, when opposed to light malt, the better it is also, as not only producing stronger but better beer. Some persons are in the practice of mixing barley with the malt in making beer, but experience has most satisfactorily proved that the beer is neither so good nor so strong, neither is it so wholesome; so that the best, though dearest at first, is cheaper in the end.

Hops.—There is also considerable variety in the quality of hops, which can only be detected by experience. So different indeed are they, that they vary in price from one to five shillings a pound. The use of hops in making beer is to preserve it. The coarser kind, at one shilling per pound, may have as much of the bitter principle as the finer qualities, and, consequently, is as effectual a preservative; but then they will be coarse, and harsh in the flavour, imparting a disagreeable taste to the beer. Hops are the seed-pods or husks of a species of vine called the hop-vine. These are subject to great variety, depending on soil, cultivation, and other circumstances. Good hops have a pleasant and fresh smell, and will keep for any length of time. Indeed, they have been known to be perfectly fresh after the lapse of twenty years. The quantity of hops used in beer will depend upon their quality and the length of time which the beer is intended to be kept—if they are good, a pound to the bushel of malt, providing the beer is made in the cool season of the year, and not to be too long kept; but if the weather is warm, and the beer wished to be preserved for a length of time, then it will be necessary to use one pound two ounces to a pound and a quarter of hops.

Water.—The more pure the water used for brewing, the better, and hard water is at all times to be avoided, as, from the great quantity of mineral salts and other substances which it contains, the beer which is made from it is generally flat and ill tasted. The best water is rain water, and next is that from a pure spring, and, last of all, river water.

Utensils.—The size of the utensils will of course depend upon the quantity required. We shall suppose that a family will brew at one time eighteen gallons of ale and thirty-six of small beer. It will be easy, from the dimensions which we point out for these quantities, to calculate what sizes of utensils will be requisite for larger or smaller quantities. 1. A copper boiler capable of containing forty-two gallons. 2. A mashing-tub of such dimensions as will contain sixty gallons, to be broader at top than bottom, its depth and width being nearly equal. In the centre of the bottom there is a hole for draining off the wort. Into this perforation is fitted a stick tapered at the point for the space of six inches, so as to answer the purpose of a cock for stopping the hole above mentioned. This stick must be a foot or eighteen inches longer than the depth of the mashing-tub. 3. An underbuck or shallow tub, which is placed under the mash-tub for the purpose of catching the wort which runs from the grains. 4. A tun-tub capable of containing thirty gallons. 5. Two coolers. These are shallow tubs about a foot or fourteen inches deep. Some use from three to four, so as to cool the liquor more quickly. A simple substitute for these are the heads of wine-butts or pipes.

Process to be pursued.—The copper boiler must be filled with water, and brought to the boiling point. An adequate quantity of water is added to the malt in the mashing-tub, so as to let it be freely stirred and separated; the water must be heated to one hundred and seventy degrees by the thermometer; but when the cottager has not this instrument in his possession, let the malt be added as soon as, by looking into the tub, the face can be distinctly seen as in a mirror. Let it be well stirred with a broomstick for a quarter of an hour; fill the copper, and bring it to the boiling point; about forty gallons of water must be added, as the grains will absorb about ten gallons. The mashing-tub should be covered over with sacks, and allowed to stand for two hours; the wort is then drawn off; in this operation the tub should be raised on two stools, so that the underbuck may be placed beneath it for the reception of the wort, which ought to be run off very slowly, to prevent the sediment from following. It is then removed to the tun-tub. Empty the copper, and put the wort into it, with a pound and a half of hops, which ought to be previously well rubbed and separated. Bring it to the boiling point, and allow it to boil briskly, with the lid off, for an hour at least. The liquor is now taken off the fire, and put through a strainer to keep back the hops; wickerwork baskets will answer this purpose. The liquor must be put into various coolers, and distributed into such quantities that they will all be cool about one time. The liquor which has been set to cool is now brought to the heat of seventy degrees, when it is put into the tun-tub, and half a pint of yeast added to it. A gallon of the liquor should first be taken out, and the yeast well mixed with it, together with a handful of wheat or rye flour, and poured into the tun-tub. The whole liquor is then agitated till completely mixed. The tun-tub should be in a situation where it will neither become too warm nor too cold, but of the temperature of fifty-five degrees. Should the working of the beer be in cold weather, the tub ought to be covered with sacks, to prevent the air from destroying the fermentation. To work effectually, it will require to stand forty-eight or fifty hours; but this will depend upon the state of the air. The first yeast which rises on the top must be removed in twenty-four hours, and the second quantity in twelve hours more, and continue this at intervals until it has done working, and no more yeast rises to the top. It is now ready for casking, but must first be perfectly cold, otherwise the liquor will be spoiled. From one to two bushels of malt may be used in making the above quantity, and this will depend on the strength which it is wished to be. From the sediment and grains of the ale which have been left, small beer can be made. Take the hops which were used before, with an additional pound of fresh hops, and these must be placed in the boiler, with thirty-six to forty gallons of water. When it has boiled an hour, it must be taken off, and proceeded with in the same manner as the ale; and to it must be added a pint and a half of yeast. When put into the cask, however, it must not be quite cold, as it requires to work in the barrel, and not in the tub, as in the case of ale. It should be bottled when a fortnight old, as it will be too weak to keep without souring, unless drunk quickly.

COTTAGE GARDENS.

The cottage which has not a garden attached is destitute of not only a great conveniency, but without one of its greatest ornaments. Every cottager ought to possess a garden, however small. Its cultivation occupies many hours which would otherwise be spent in frivolous pursuits. The labourer who occupies a tolerably good-sized garden, and takes a pride and pleasure in its improvement, is seldom found in ale-houses, or among disorderly company of any sort. His happiness is centered in his home, and he sets a good example for his children to follow, in his industrious domesticated habits. The principal object in keeping a cottage garden should be to produce vegetables for the kitchen, which can be accomplished at extremely little expense or trouble; and besides having nearly always some kind of fresh pot-herbs, there will generally be a quantity of refuse, which may be given to a cow or pig. Profit may also sometimes be derived from fruit, and in favourable situations bees may be kept with advantage. A cottage garden ought to be managed on a simple plan, while at the same time some variety of productions is desirable. Much must depend on the occupant being supplied with good seeds; for five shillings per annum, laid out in the purchase of seeds, properly selected, and sown in due season, would render his garden doubly valuable. The fittest articles for cultivation in a cottage garden are summer cabbage, winter kail or savoys, potatoes, carrots, peas, beans, leeks, and onions. French beans are recommended as being very productive and profitable. Useful herbs, such as balm, mint, camomile, and rhubarb, should not be neglected. We need hardly say how useful are a few gooseberry bushes. Strawberries require a great deal of care. The produce of the garden must greatly depend on the care taken of it, and the careful collection of every thing that can be converted into manure. To the mine of dung of the pigsty, if there be one, add the leaves of the vegetables, the soot and ashes from the chimney and fire, and every other article which will make manure; and this kind of compost will form an excellent enricher of the soil of the garden, or small potato patch. Cottagers are often so ignorant as to allow the fluid which runs from their cowhouse and piggery to go to utter waste in stagnant puddles. This fluid is the best of all manures; it abounds in those gases from which vegetation derives its chief subsistence, and ought to be carefully managed and directed to the irrigation of gardens and fields. In some parts of England, the gardens of labourers, and the entrance to their cottages, are adorned by flowering creepers, shrubs, and plants, which, though not attended with any profit, yet indicate a greater attention to neatness, and an enjoyment of more comfort, than the occupiers of the miserable unadorned huts in other countries can possess. The sight of such *superfluities* is a gratifying voucher that *necessaries* are not wanting.

The following are the seasons usually appropriated to the sowing and planting of vegetables in the cottage or kitchen garden:—In January, delve up the soil to meliorate with the weather. About the middle of February, sow the principal crops of early peas, beans, and radishes, and make plantations of strawberry, gooseberry, and currant plants; continue also to delve and clear the garden of winter refuse. In March and April, sow yellow turnips, the larger sorts of peas to succeed those sown last month; also full crops of onions, leeks, and carrots; and plant early cabbages, greens, &c. In May, sow cabbages and cauliflowers for a late crop; also all kinds of flower seeds. In June, clear the garden, water those plants requiring such attention; sow red beet for pickling, transplant leeks, &c., and stake the peas and beans. In July, sow spinach, turnips, small salading, lettuce. In August, sow onions, cabbage, lettuces; also cauliflower to stand the winter. September is a good month for transplanting all kinds of greens. In October and the three following months, dig and trench all vacant ground. This rough outline will suggest the course of general culture in the garden; and we may add, that as the weather and climate change, so must much be left to the good sense of the cottager in arranging the periods of sowing, planting, and trenching his garden. It is of the utmost consequence to have the fences of gardens secure and complete, and this matter alone ought at all times to meet with due attention.

HINTS ABOUT BEES.

It is not every cottage garden that lies so commodiously to the sun, or is in so secluded a situation, as to render it available for bees; but where such is the case, and where the labourer has a little leisure, it is extremely advantageous in many instances to keep one or two hives. Often has the poor but industrious cottager been relieved from embarrassed circumstances by the toil of a swarm of bees. Nature having supplied this useful insect with food, it puts its owner to little or no expense for that article. That which it chiefly requires is a comfortable and quiet abode. There have been many improvements of late in bee-hives, or *skeps*, as they are called in the north; but the good old-fashioned rustic straw hive is still reckoned among the best. It should be situated in a nice sunny sheltered spot at the end of the garden, and will be all the better for having flowers and shrubs in its immediate vicinity, on which the bees may at times settle. It ought to be placed upon a roundish board, supported on three or more feet which cannot be climbed up by vermin. The best time for establishing a hive is just before the taking-up season, which is generally about the end of August. In examining a hive for purchase, turn it gently up some cool evening, and observe if the combs are crowded with bees, and the combs worked down to the floor. If white or of a light yellow colour, it denotes their being of the present year's produce, and fit for the purpose; but if they are of a deep yellow or brown, they are of the last season, and not so proper. If the cottager has to protect his hive from wet, he may place a coping of straw upon it; but this thatch ought to be removed as soon as it begins to rot, for insects will lodge in it, and the effects of its rank smell will endanger the health of the bees. There is as great danger of hives proving too hot in summer as cold in winter, and both must if possible be prevented by proper shades and protectives.

The most difficult part in the economy of these insects is the management of them during swarming. Their swarming consists in a portion of the bees in the hive flying off to seek new quarters in consequence of the growing want of room in the hive for the young bees. When the swarm flies off, it will light on a bush or any likely place for clustering, in which case, if the cottager be clever, he may secure this new colony by holding over them an empty hive. The bees may be shaken from the bush into a linen cloth, and the skep then held above them. All swarms, if the weather be fair, will begin to work almost as soon as hived. Swarms at the latter end of May or beginning of June are said to prosper better than those which remove earlier. Hitherto, in order to get at the combs of honey, it has been a general practice to fumigate hives with brimstone. But this cruel mode, which kills the bees, may be avoided by following a new plan, which has been found available, and consists in stupifying the bees with the fumes of a narcotic. After subjecting them to this process, they recover, and again take up their quarters in the hive, provided honey be left for their subsistence during the winter. This narcotic is the *Fungus maximus*, or large mushroom. After being gathered, it is squeezed in a piece of paper, and baked in an oven till it be dry. A piece of this being cut off, is fixed on the end of a wire or stick, and set fire to under a hive. On the fumes rising, they stupify the bees, which drop into the vessel held beneath, and remain dormant till their hive is robbed. The smoke must be prevented from escaping by the aid of a cloth. This narcotic may be purchased in London, at Butler's Herbalist, Covent Garden. Cottagers entirely ignorant of the habits of bees ought to procure a manual for their direction. Among other books of this kind, we recommend a recent publication, entitled "The Management of Bees, by Samuel Bagster, junior."

ARCHITECTURE.

HISTORY OF ARCHITECTURE.

ARCHITECTURE appears to have been among the earliest inventions, and its works have been commonly regulated by some principle of hereditary imitation. Whatever rude structure the climate and materials of any country have obliged its early inhabitants to adopt for their temporary shelter, the same structure, with all its prominent features, has been afterwards kept up by their refined and opulent posterity. Thus, the Egyptian style of building has its origin in the cavern and mound; the Chinese architecture is moulded from the tent; the Grecian is derived from the wooden cabin; and the Gothic from the bower of trees. The first habitations of men were such as nature afforded, with but little labour on the part of the occupant, and sufficient to supply his simple wants—huts, grottoes, and tents. But as soon as men rose above the state of nature, and became acquainted with some of the arts, they began to build more durable and more commodious habitations. After they had learned to build houses, they commenced the erection of temples to their gods, and these they made still more splendid than private dwellings. Thus, architecture became a fine art, which was first displayed on the temples, afterwards on the habitations of princes, and public buildings, and at last became an universal want in society.

Traces of these eras of advancement in the art of erecting buildings, are found in various quarters of the globe, especially in eastern countries, where the remains of edifices are discovered, of which fable and poetry can alone give any account. The most remarkable of these vestiges of a primitive architecture, are certain pieces of masonry in the island of Sicily, as well as in some other places, called the works of the Cyclops, an ancient and fabulous race of giants, mentioned by Homer in his Odyssey. The walls they erected were composed of huge stones, laid in this manner:—

According to Vitruvius, a celebrated Roman writer of the first century, mankind at first erected forked stakes for walls, and disposed twigs between the interstices, covering the whole with loam; others, he says, piled up dry clods of clay, binding them together with wood; and to avoid rain and heat, they made a covering with reeds and boughs; but finding that this roof could not resist the winter rains, they made it sloping and pointed at the top, plastering it over with clay, and by that means discharged the rain water. That this was the original mode of erecting dwellings, may be concluded from observing that to this day some nations construct their habitations of the same kind of materials. The erection of houses chiefly of timber, and thatching the same with straw, is still a common practice in the country parts of England and Normandy; and we need not travel beyond Ireland and the rude parts of Scotland to see dwelling-houses or huts formed principally of mud and turf. Not a few instances could be produced, however, wherein these humble and frail "clay biggings" have been the birthplaces of men of as great genius as ever first drew breath in the dwellings of princes.

The originally rude style of house architecture was first improved in Italy, from whence a superior taste spread over Europe; yet even till a comparatively recent era, the chief towns of England and Scotland were erected in an exceedingly mean style. We find that in the twelfth century the style of domestic building which obtained in the better order of Scottish burghs was just one advance beyond the primitive cottages which gave shelter to the peasantry. From a specimen in the town of Perth, which was only destroyed in the last age, and which is known to have been erected in the thirteenth century, it would appear that a good house, such as might be occupied by one of the better order of merchants, consisted of one strongly built ground-flat, with a more flimsy superstructure of wood, having an open gallery or balcony in front. Specimens of such buildings exist to this day in the meaner parts of Edinburgh, with apparently little alteration from their original condition, except what consists in the substitution of slate for thatch. The following is a sketch of one of the most ancient of these structures, situated between houses of modern erection.

The repeated occurrence of fires, and the progress of a better taste, as well as the great diffusion of wealth by means of trade, have at length concurred to establish all over Britain a prodigiously improved system of city architecture, whether of brick or stone; and in the present day we find the dwellings of persons not only in the higher, but the inferior ranks, inhabiting mansions, which, in architectural decoration, emulate the most splendid temples and palaces of ancient times. When we consider what these magnificent edifices were more than a thousand years ago, it seems marvellous how such a length of time should elapse before a good style of architecture was applied to domestic erections; but a satisfactory reason is given for this in the circumstance of the exceedingly slow advancement of a middle class in society, and the ages of superstition and barbarous warfare, which for many hundreds of years interrupted the cultivation of the human intellect, and, consequently, the establishment of comfortable usages. Architecture has been so little considered as a science affecting domestic structures, that its history refers almost exclusively to the erection of temples; and as it is mainly from this species of buildings that all modern architectural decoration has sprung, it will be necessary to go back with our account to the times when these temples were erected.

The most ancient nations known to us, among whom architecture had made some progress, were the Babylonians, whose most celebrated buildings were the temple of Belus, the palace and the hanging gardens of Semiramis; the Assyrians, whose capital, Nineveh, was rich in splendid buildings; the Phœnicians, whose cities, Sidon, Tyre, Aradus, and Sarepta, were adorned with equal magnificence; the Israelites, whose temple was considered as a wonder of architecture; the Syrians and the Philistines. No architectural monument of these nations has, however, been transmitted to us; but we find subterraneous temples of the Hindus, hewn out of the solid rock, upon the islands Elephanta and Salsetta. Of the Persian architecture, the ruins of Persepolis still remain; of the Egyptian obelisks, pyramids, temples, palaces, sepulchres; of the Etruscan, some sepulchres and portions of city-walls. The character of this elder architecture was immoveable firmness, gigantic height, prodigal splendour, which excited admiration and astonishment, but comparatively little pleasure. The Greeks were the first who passed from the rough and gigantic to a noble simplicity and dignity. The Doric order of columns characterises this first period. The greatest masters, Phidias, Ictinus, Callicrates, and others, encouraged and supported by Pericles, emulated each other, as soon as peace at home and abroad was restored. The beautiful temple of Minerva was erected upon the Acropolis of Athens, also the Propylæum, the Odeum, and other splendid buildings. An equal taste for the arts arose in the Peloponnesus and in Asia Minor. A high degree of simplicity was united with majestic grandeur and elegance of form. The beauties of architecture were displayed not only in temples, but also in theatres, odeums, colonnades, market-places, and gymnasia. The Ionic and Corinthian columns were added to the Doric. At the end of the Peloponnesian war, the perfection of architecture was gone. A noble simplicity had given place to excess of ornament. This was the character of the art at the time of Alexander, who founded a number of new cities. But a strict regularity hitherto prevailed in the midst of this overcharged decoration. After the death of Alexander, 323 B. C., the increasing love of gaudy splendour hastened the decline of the art more and more. In Greece, it was afterwards but little cultivated, and, in the edifices of the Seleucidæ in Asia, and of the Ptolemies in Egypt, an impure taste prevailed. The Romans had no temples, or similar public edifices, equal to the Grecian masterpieces, although they had early applied their industry to other objects of architecture, viz., to aqueducts and sewers. The capitol and the temple of the capitoline Jupiter were erected by Etruscan architects. But soon after the second Punic war, 200 B. C., they became acquainted with the Greeks.

Sylla was the first who introduced the Grecian architecture to Rome; and he, as also Marius and Cæsar, erected large temples in this and in other cities. But under Augustus the art first rose to the perfection of which it was capable at that time. He encouraged the Greek artists, who had exchanged their country for Rome, and erected, partly from policy, many splendid works of architecture. Agrippa built temples (the Pantheon), aqueducts, and theatres. Private habitations were adorned with columns and marble. Splendid villas were built, of which the rich Romans often possessed several. The interior was adorned with works of art obtained from Greece. The walls were covered with thin marble plates, or were painted, and divided into panes, in the middle of which were represented mythological or historical subjects. They were also surrounded with the most elegant borders. These borders were what we call grotesques. Almost all the successors of Augustus embellished the city more or less, erected splendid palaces and temples, and adorned, like Adrian, even the conquered countries with them. Constantine the Great transferred the imperial residence from Rome to Constantinople, so that nothing more was done for the embellishment of Rome.

But at the time when the Romans received the art from the Greeks, it had already lost, among the latter, its perfection and purity. In Rome, it rose indeed in a short time to its former height, but soon degenerated, with the continually increasing magnificence of the emperors, into extravagance of ornament. About this time, the Roman or Composite column originated, which was employed in temples and splendid buildings. In the time of Nero, whose golden palace is celebrated, the exterior and interior of the buildings were profusely adorned. Adrian, who encouraged artists as much as possible, was not able to restore a noble and simple taste in architecture. Instead of imitating the beautiful models already existing, the endeavour, in his time, was to invent new styles, and to embellish the beautiful more and more. Now originated the many curved and twisted ornaments, the high pedestal under the columns, the numerous bas-reliefs on the exterior of buildings, the flutings of the columns, the reduction of the same according to a curved line, the coupled columns, the reduced pilasters behind the columns, the small columns between larger ones, the round and cut pediments, and the concave friezes.

Thus the art was practised from the time of Vespasian to the reign of the Antonines. Works were produced in this period which may still be considered as masterpieces, but which want the great and noble style of the Greeks. In the provinces taste became still more corrupt. Architecture declined continually after the Antonines; more ornaments were continually added, which is proved particularly by the Arch of the Goldsmiths, so called in Rome. Alexander Severus, indeed, himself a connoisseur, did something for its improvement; but it rapidly declined under his successors. The buildings of this time are either overcharged with mean and trifling ornaments, as those of Palmyra, erected about 260 A.D., or they border on the rude, like those of Rome, erected under Constantine. Little was done under the following emperors for the embellishment of the cities, on account of the continually disturbed state of the empire. Justinian, however, built much. His principal edifice was the church of St Sophia, at Constantinople. The beautiful works of ancient architecture were almost entirely destroyed by the Goths, Vandals, and other barbarians, in Italy, Spain, Greece, Asia, and Africa; and whatever escaped destruction remained in neglect. Theodoric, king of the Ostrogoths, a friend of the arts, endeavoured to preserve and restore the ancient buildings, and even erected several new ones, the ruins of which are still to be seen in Ravenna and Verona.

We may consider this period as the era of the origin of modern art. We see a new style taking place of the ancient classical architecture, and eventually extending as far as the conquests of the Goths, through Italy, France, Spain, Portugal, a part of Germany, and even to England, whither, however, the Goths did not penetrate. Whether this modern architecture, which is called Gothic, originated from the Germans, is not decided. We find, in the buildings erected under Theodoric, nothing attempted but simplicity, strength, and the display of national taste in their exterior (the interior is unknown to us). But the buildings erected during the Lombard dominion in Italy (from 568), and all the monastic architecture of that time, have been erroneously called Gothic. Since the error was perceived, it has been distinguished by the name of the old Gothic, from the proper Gothic, which is called the modern Gothic.

The Lombards entertained no respect for antiquities, and neither spared nor preserved them. Whatever they built was tasteless and faulty. On the exterior of their churches they placed small semicircular columns, and small pillars in a row along the cornice of the pediments; in the interior, coarse pillars united by semicircular arches; the small windows and doors were finished with semicircles; the columns, capitals, and arches, were often overlaid with incongruous sculpture; the roofs of the naves covered with beams and boards, which were afterwards changed into arches, and on this account often required arched buttresses on the outside. This Lombard style in architecture clearly proves the decline of science and art. It was employed in the seventeenth century in Pavia, the chief city of the Lombard kingdom, in the erection of the churches of St John and St Michael; at Parma, in the church of St John; at Bergamo, in the church of St Julia; in the chapel of Altenötting, in Bavaria; in the castle of Nuremberg; in the Scottish church at Ratisbon, &c.

The architects driven from Constantinople (Byzantium) were the first who combined with it the use of the Ionic pedestals and columns, provided with capitals formed according to their own taste, among which were twisted ones. In this Lombard-Byzantine style were erected the cathedrals of Bamberg, Worms, and Mentz; also the church Miniato al Monte, near Florence, and the most ancient part of the minster of Strasburg. Cupolas were afterwards added, as used in the East; and these, as well as the tasteless capitals, and the many slender pillars and minarets, of which we often see two rows, one on another, indicate the proper Byzantine or Oriental style of architecture. In this style were erected, besides the church of St Sophia in Constantinople and others, the church of St Mark, in Venice, the Baptisterium and the cathedral of Pisa, and the church of St Vitalis, in Ravenna.

The Normans who had settled in Sicily built the cathedral of Messina upon the foundation of an old temple—a huge but tasteless edifice, in which, by means of the changes made in different centuries, we may observe, at the same time, the rise and fall of the art. The Vandals, Alans, Suevi, and Visigoths, had penetrated into Spain and Portugal; the Arabs and Moors expelled them in the eighth century, and destroyed the kingdom of the Goths. The Mussulman conquerors had at that time almost exclusive possession of the arts and sciences. Saracen architects rose in Greece, Italy, Sicily, and other countries; after some time, many Christians, particularly Greeks, joined them, and formed together a fraternity, who kept secret the rules of their art, and whose members recognised one another by particular signs.

At this period, three different styles of architecture prevailed—the Arabian, a peculiar style, formed after Greek models; the Moorish, which originated in Spain out of the remains of Roman edifices; and the modern Gothic, which originated in the kingdom of the Visigoths, in Spain, through the mixture of the Arabian and Moorish architecture, and flourished from the eleventh until the fifteenth century. The two first styles differ but little from each other: the Moorish style is principally distinguished from the Arabian by arches in the form of a horse-shoe. But the Gothic, or old German, is very different. Swinburne mentions the following marks of distinction:—The Gothic arches are pointed; the Arabian circular; the Gothic churches have pointed and straight towers; the mosques terminate in globes, and have here and there minarets, covered with a ball or a cone: the Arabian walls are adorned with Mosaic and stucco, which we find in no ancient church in the Gothic style.

The entrance of a Gothic church is a deep arch, diminishing towards the interior of the building, and adorned on the side walls with statues, columns, niches, and other ornaments; but those of the mosques, and of other Arabian and even Moorish buildings, are shallow, and made in the same manner as doors are at present. Besides, Swinburne observes, that, among the different Arabian capitals which he saw, he found none resembling, in design and arrangement, those which we find in the Gothic churches of England and France.

The Moorish architecture appears in all its splendour in the ancient palace of the Mahommedan monarchs at Granada, which is called the Alhambra, or Red-house, and which resembles more a fairy palace than a work of human hands. The character of the Arabian architecture was lightness and splendour. Rich ornaments and lightness in the single parts render it agreeable to the eye. The modern Gothic architecture, which originated in the attempts of Byzantine artists to cover the coarseness and heaviness of the old Gothic by an appearance of lightness, excites the imagination by its richly adorned arches, its distant perspective, and its religious dimness, produced by its painted windows. It retained, from the old Gothic architecture, the high bold arches, the firm and strong walls; but it disguised them under volutes, flowers, niches, little pierced towers, so that the stairs appear hanging in the air; they gave to the windows an extraordinary height, and adorned the building itself with statues. This style, in which many churches, convents, and abbeys, were erected, was formed in Spain, and thence extended over France, England, and Germany.

The Germans were unacquainted with architecture until the time of Charlemagne. He introduced from Italy to Germany the Byzantine style, then common. Afterwards the Arabian architecture had some influence upon that of the western nations; for the German art shows its characteristics in the pointed arches and the buttresses, &c. This was united with the Byzantine style, to which in general they still adhered, and thus originated a mixed style, which maintained itself until the middle of the thirteenth century. Then began the modern Gothic or German style, which we may also call the romantic, since it was formed by the romantic spirit of the middle ages. Growing up in Germany, it obtained its perfection in the towers of the minster of Strasburg, in the cathedral of Cologne, in the church of St Stephen in Vienna, the cathedral of Erfurt, the church of St Sebaldus in Nuremberg, the church of St Elizabeth in Marburg, &c., and extended itself from thence to France, England, Spain, and Italy. The German architecture shows also the influences of climate and religion, particularly in the churches. The slender columns, always united in groups, rise to a lofty height, resembling the giants of the grove, in whose dark shade the ancient Teuton used to build his altar. In the *chiaro oscuro* of the dome, the soul, divested of earthly thoughts, must collect itself, and rise like the dome to its Maker. The decorations of the ancient Christian churches are by no means an accidental ornament. They speak a figurative religious language; and at the tabernacle, or ciborium, over the altar, where the pyx is kept, the whole temple is presented in miniature to the view of the beholder. In these edifices, every one must admire the accurate proportions, the bold yet regular construction, the unwearied industry, the grandeur of the bold masses on the exterior, and the severe dignity in the interior, which excites feelings of devotion in every spectator. We must therefore ascribe to the German architecture more symbolical than hieroglyphic eloquence and dignity.

The Italians disengaged themselves by little and little from the Byzantine taste. Even in the eleventh century, Byzantine architects built the cathedral of Pisa and the church of St Mark in Venice. But in the twelfth century, a German architect, named William (Guglielmo), and, in the thirteenth, Jacob, with the surname Capo, who died in 1262, and his pupil or son Arnolf, are mentioned as having built churches and convents in Florence. The modern Gothic style passed from the churches and abbeys to the castles, palaces, bridges, and city gates, many of which were built in this manner; for instance, in Milan, sixteen city gates of marble, and several new palaces; in Padua, seven bridges and three new palaces; in Genoa, two docks and a splendid aqueduct; and the town of Asti, in 1280, almost entirely. Architecture was continually improving in Italy, particularly in the fourteenth century. Galeazzo Visconti finished the great bridge at Pavia, and built a palace which had not then its equal. About the same time, the famous cathedral of Milan was erected. The Marquises of Este erected handsome edifices at Ferrara, and Albert the splendid palace at Belsiore. In Bologna, the great church of St Petronius was begun, and in Florence the famous tower of the cathedral. The fifteenth century, in which the study of ancient architecture was revived, was greatly distinguished. The Dukes of Ferrara, Borso, and Ercole of Este, were active patrons of architecture. Duke Francesco embellished Milan with the ducal palace, the castle Porta di Giove, the hospital, and other edifices. Ludovico Sforza erected the buildings of the university at Pavia and the hospital of Milan. The Popes adorned Rome, and Lorenzo de Medici, Florence, with splendid buildings. The artists returned to the monuments of antiquity, and studied their beautiful forms and just proportions.

The most illustrious architects of this time were Filippo Brunelleschi, who built at Florence the dome of the cathedral, the church S. Spirito, and the palace Pitti, besides many edifices at Milan, Pisa, Pesaro, and Mantua; Battista Alberti, who wrote at the same time, on architecture; Michelozzi Bramante, who commenced the building of St Peter's; Michael Angelo Buonarotti, who erected its magnificent dome; and Giocondo, who built much in France, and afterwards directed, with Raphael, the building of the church of St Peter's. These were followed by others, who proceeded in their spirit—Palladio, Scamozzi, Serlio, Barozzio, known by the name of Vignola. They are the founders of the existing taste in architecture. That, however, they studied their art in those works of antiquity which had already deviated from the early purity and elevated grandeur, is evident in their buildings, from the many curved and twisted ornaments, the circular, irregular, and cut pediments, the coupled columns, high pedestals, and other things, which were unknown to architecture at the time of Pericles. Thus a new period in architecture had begun in Italy. Italian masters, and young artists sent to Italy, introduced the Roman taste into foreign countries, which gradually supplanted the Gothic. Since that time, architecture has experienced different destinies in different countries. It has risen and declined at different periods; yet laudable attempts have been made in recent times to advance it to its true perfection, though we cannot affirm that they have succeeded every where.

ELEMENTARY PARTS OF BUILDINGS.

The essential elementary parts of a building are those which contribute to its support, enclosure, and covering. Of these, the most important are the foundation, the column, the wall, the lintel, the arch, the vault, the dome, and the roof. In laying the foundation of any building, it is necessary to dig to a certain depth in the earth, to secure a solid basis, below the reach of frost and common accidents. The most solid basis is rock, or gravel which has not been moved. Next to these are clay and sand, provided no other excavations have been made in the immediate neighbourhood. From this basis a stone wall is carried up to the surface of the ground, and constitutes the foundation. Where it is intended that the superstructure shall press unequally, as at its piers, chimney, or columns, it is sometimes of use to occupy the space between the points of pressure by an inverted arch. This distributes the pressure equally, and prevents the foundation from springing between the different points. In loose or muddy situations, it is always unsafe to build, unless we can reach the solid bottom below. In salt marshes and flats, this is done by depositing timbers, or driving wooden piles into the earth, and raising walls upon them. The preservative quality of the salt will keep these timbers unimpaired for a great length of time, and makes the foundation equally secure with one of brick or stone.

The simplest member in any building, though by no means an essential one to all, is the column or pillar. This is a perpendicular part, commonly of equal breadth and thickness, not intended for the purpose of enclosure, but simply for the support of some part of the superstructure. The principal force which a column has to resist is that of perpendicular pressure. In its shape, the shaft of a column should not be exactly cylindrical, but, since the lower part must support the weight of the superior part, in addition to the weight which presses equally on the whole column, the thickness should gradually decrease from bottom to top. The outline of columns should be a little curved, so as to represent a portion of a very long spheroid, or paraboloid, rather than of a cone. This figure is the joint result of two calculations, independent of beauty of appearance. One of these is, that the form best adapted for stability of base is that of a cone; the other is, that the figure, which would be of equal strength throughout for supporting a superincumbent weight, would be generated by the revolution of two parabolas round the axis of the column, the vertices of the curves being at its extremities.

The swell of the shafts of columns was called the entasis by the ancients. It has been lately found that the columns of the Parthenon at Athens, which have been commonly supposed straight, deviate about an inch from a straight line, and that their greatest swell is at about one-third of their height. Columns in the antique orders are usually made to diminish one-sixth or one-seventh of their diameter, and sometimes even one fourth. The Gothic pillar is commonly of equal thickness throughout.

The wall, another elementary part of a building, may be considered as the lateral continuation of a column, answering the purpose both of enclosure and support. A wall must diminish as it rises, for the same reasons, and in the same proportion as the column. It must diminish still more rapidly if it extends through several stories, supporting weights at different heights. A wall, to possess the greatest strength, must also consist of pieces, the upper and lower surfaces of which are horizontal and regular, not rounded nor oblique. The walls of most of the ancient structures which have stood to the present time, are constructed in this manner, and frequently have their stones bound together with bolts and cramps of iron. The same method is adopted in such modern structures as are intended to possess great strength and durability, and in some cases the stones are even dovetailed together, as in the lighthouses at Eddystone and Bell Rock. But many of our modern stone walls, for the sake of cheapness, have only one face of the stones squared, the inner half of the wall being completed with brick, so that they can in reality be considered only as brick walls faced with stone. Such walls are said to be liable to become convex outwardly, from the difference in the shrinking of the cement. Rubble walls are made of rough irregular stones laid in mortar. The stones should be broken, if possible, so as to produce horizontal surfaces. The coffer walls of the ancient Romans were made by enclosing successive portions of the intended wall in a box, and filling it with stones, sand, and mortar, promiscuously. This kind of structure must have been extremely insecure. The Pantheon, and various other Roman buildings, are surrounded with a double brick wall, having its vacancy filled up with loose bricks and cement. The whole has gradually consolidated into a mass of great firmness. The reticulated walls of the Romans, having bricks with oblique surfaces, would at the present day be thought highly unphilosophical. Indeed, they could not long have stood, had it not been for the great strength of their cement. Modern brick walls are laid with great precision, and depend for firmness more upon their position than upon the strength of their cement. The bricks being laid in horizontal courses, and continually overlaying each other, or breaking joints, the whole mass is strongly interwoven and bound together. Wooden walls, composed of timbers covered with boards, are a common but more perishable kind. They require to be constantly covered with a coating of a foreign substance, as paint or plaster, to preserve them from spontaneous decomposition. In some parts of France and elsewhere, a kind of wall is made of earth, rendered compact by ramming it in moulds or cases. This method is called building in *pisé*, and is much more durable than the nature of the material would lead us to suppose. Walls of all kinds are greatly strengthened by angles and curves, also by projections, such as pilasters, chimneys, and buttresses. These projections serve to increase the breadth of the foundation, and are always to be made use of in large buildings, and in walls of considerable length.

The lintel, or beam, extends in a right line over a vacant space, from one column or wall to another. The strength of the lintel will be greater in proportion as its transverse vertical diameter exceeds the horizontal, the strength being always as the square of the depth. The floor is the lateral continuation or connection of beams by means of a covering of boards.

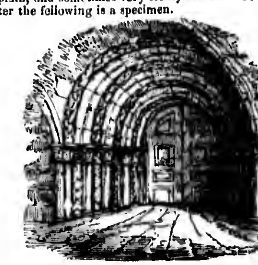
Arches.

The arch is a transverse member of a building, answering the same purpose as the lintel, but vastly exceeding it in strength. The arch, unlike the lintel, may consist of any number of constituent pieces, without impairing its strength. It is, however, necessary that all the pieces should possess a uniform shape—the shape of a portion of a wedge—and that the joints formed by the contact of their surfaces should point towards a common centre. In this case, no one portion of the arch can be displaced or forced inward; and the arch cannot be broken by any force which is not sufficient to crush the materials of which it is made. In arches made of common bricks, the sides of which are parallel, any one of the bricks might be forced inward, were it not for the adhesion of the cement. Any two of the bricks, however, constitute a wedge by the disposition of their mortar, and cannot collectively be forced inward. An arch of the proper form, when complete, is rendered stronger, instead of weaker, by the pressure of a considerable weight, provided this pressure be uniform. While building, however, it requires to be supported by a centring of the shape of its internal surface, until it is complete. The upper stone of an arch is called the keystone, but is not more essential than any other. In regard to the shape of the arch, its most simple form is that of the semicircle. It is, however, very frequently, a smaller arc of a circle, and, still more frequently, a portion of an ellipse.

The simplest theory of an arch supporting itself only, is that of Dr Hooke. The arch, when it has only its own weight to bear, may be considered as the inversion of a chain, suspended at each end. The chain hangs in such a form that the weight of each link or portion is held in equilibrium by the result of two forces acting at its extremities; and these forces, or tensions, are produced, the one by the weight of the portion of the chain below the link, the other by the same weight increased by that of the link itself, both of them acting originally in a vertical direction. Now, supposing the chain inverted, so as to constitute an arch of the same form and weight, the relative situations of the forces will be the same, only they will act in contrary directions, so that they are compounded in a similar manner, and balance each other on the same conditions. The arch thus formed is denominated a catenary arch. In common cases, it differs but little from a circular arch of the extent of about one-third of a whole circle, and rising from the abutments with an obliquity of about thirty degrees from a perpendicular. But though the catenary arch is the best form for supporting its own weight, and also all additional weight which presses in a vertical direction, it is not the best form to resist lateral pressure, or pressure like that of fluids, acting equally in all directions. Thus the arches of bridges and similar structures, when covered with loose stones and earth, are pressed sideways, as well as vertically, in the same manner as if they supported a weight of fluid. In this case it is necessary that the arch should arise more perpendicularly from the abutment, and that its general figure should be that of the longitudinal segment of an ellipse. In small arches, in common buildings, where the disturbing force is not great, it is of little consequence what is the shape of the curve. The outlines may even be perfectly straight, as in the tier of bricks which we frequently see over a window. This is, strictly speaking, a real arch, provided the surfaces of the bricks tend towards a common centre. It is the weakest kind of arch, and a part of it is necessarily superfluous, since no greater portion can act in supporting a weight above it, than can be included between two curved or arched lines.

Besides the arches already mentioned, various others are in use. The acute or lancet arch, much used in Gothic architecture, is described usually from two centres outside the arch. It is a strong arch for supporting vertical pressure. The rampant arch is one in which the two ends spring from unequal heights.

About the eighth century, the Anglo-Saxons in England began to erect churches on plans partly borrowed from the remains of Roman edifices in this country. They in particular introduced the circular or rounded arch; and a few very beautiful examples of this kind of building still remain in different parts of the country. It is called Saxon or Norman, from its having prevailed during the reign of the Saxon and Norman kings in England. It commenced at the establishment of Christianity among the Saxons, in the sixth century, and continued till about the year 1135, in the reign of King Stephen. The entrance to the Temple Church, London; the Abbey Gate, Bristol; and the Church of Romsey in Hampshire, are in this style of architecture. The doors in this style are sometimes quite plain, and sometimes very richly carved. Of the latter the following is a specimen.



Between the reign of Stephen and that of Henry III., the circular arch began to disappear, and before the death of the latter monarch, gave way to the pointed arch. At first the two arches were intermixed, and the style was then called semi or half Norman. Some suppose that the pointed arch was introduced from the Saracens by the Crusaders to the Holy Land, and from this circumstance they call it the Saracenic arch; but the greater number of persons imagine it to have arisen from the accidental intersection of several rounded arches with each other. That this will produce pointed arches of different widths and heights, according to the points of intersection, may easily be shown by placing two hoops or rings across each other, allowing one point of the hoops or rings to rest upon a floor or table. The crossings of the boughs of trees in an avenue also afford a familiar illustration of the same fact. In the Temple Church the two arches may be found united, and other specimens may be seen in the Church of St Cross near Winchester; the ruins of Buildwas Abbey, Shropshire; Fountains Abbey, Rievaulx Abbey, and Roche Abbey, in Yorkshire.

When the circular arch totally disappeared in 1220, the early English style commenced. The windows of this style were at first very narrow in comparison with their height; they were called lancet-shaped, and were considered very elegant; two or three were frequently seen together, connected by dripstones. In a short time, however, the windows became wider, and divisions and ornaments were introduced. Sometimes the same window was divided into several lights, and frequently finished at the top by a light in the form of a lozenge, circle, trefoil, or other ornament. A specimen of this kind may be seen in the beautiful church of St Saviour's, Southwark, which has lately been thrown open to view by the improvements connected with the erection of the New London Bridge, and another and a very beautiful example in the "Lady Chapel," near London Bridge, on the Surrey side of the Thames. With reference to the formation of this arch, it is curious to examine the extreme accuracy with which the masonry is connected at the springing of the arch. It is in this respect much superior to that of a later period. The door of St Mary's, Lincoln, is also in this style, of which we subjoin an example.

About the year 1300, the architecture became more ornamental, and from this circumstance received the name of the decorated English style, which is considered the most beautiful for ecclesiastical buildings. The windows of this style are very easily distinguished; they are large and wide, and are divided into several lights by mullions, which are upright or perpendicular narrow columns, branching out at the top into tracery of various forms, such as trefoils, circles, and other figures. York Cathedral affords a fine specimen of this sort of architecture, and there is a beautiful window of the same style in the south transept of Chichester Cathedral. The west front of that of Exeter is another specimen, and the doorway of Lincoln Cathedral is in the same style.

The transition from the decorated to the florid or perpendicular style was very gradual. Ornament after ornament was added, till simplicity disappeared beneath the extravagant additions; and about the year 1380, the architecture became so overloaded and profuse, that it obtained the title of florid, which by some persons is called the perpendicular, because the lines of division run in upright or perpendicular lines from top to bottom, which is not the case in any other style. King's College Chapel, Cambridge, begun in the reign of Henry VI., though not finished till some time after; Gloucester Cathedral; Henry VII.'s Chapel at Westminster; St George's Chapel at Windsor; Wrexham Church, Denbighshire; and the Chapel on the Bridge at Wakefield, Yorkshire, are all of this character. Many small country churches are built in this style; and their size not admitting of much ornament, they are distinguished from structures of a later date by mouldings running round their arches, and generally by a square head over the obtuse-pointed arch of the door. A peculiar ornament of this style is a flower of four leaves, called from the family reigning at that period the Tudor flower.

In describing arches, the upper surface is denominated the extrados, and the inner surface the intrados. The springing lines are those where the intrados meets the abutments or supporting walls. The span is the distance from one springing line to the other. The wedge-shaped stones which form an arch are sometimes called voussoirs, the uppermost being the keystone. The part of a pier from which an arch springs is called the impost, and the curve formed by the upper side of the voussoirs the archivolt. It is necessary that the walls, abutments, and piers, on which arches are supported, should be so firm as to resist the lateral thrust as well as vertical pressure of the arch. It will at once be seen that the lateral or sideway pressure of an arch is very considerable, when we recollect that every stone or portion of the arch is a wedge, a part of whose force acts to separate the abutments. For want of attention to this circumstance, important mistakes have been committed, the strength of buildings materially impaired, and their ruin accelerated. In some cases, the want of lateral firmness in the walls is compensated by a bar of iron stretched across the span of the arch, and connecting the abutments, like the tie-beam of a roof. This is the case in the cathedral of Milan, and some other Gothic buildings.

Arcades.

In an arcade, or continuation of arches, it is only necessary that the outer supports of the terminal arches should be strong enough to resist horizontal pressure. In the intermediate arches, the lateral force of each arch is counteracted by the opposing lateral force of the one contiguous to it. In bridges, however, where individual arches are liable to be destroyed by accident, it is desirable that each of the piers should possess sufficient horizontal strength to resist the lateral pressure of the adjoining arches. The vault is the lateral continuation of an arch, serving to cover an area or passage, and bearing the same relation to the arch that the wall does to the column. A simple vault is constructed on the principles of the arch, and distributes its pressure equally along the walls or abutments. A complex or groined vault is made by two vaults intersecting each other, in which case the pressure is thrown upon springing points, and is greatly increased at those points. The groined vault is common in Gothic architecture.

Domes.

The dome, sometimes called cupola, is a concave covering to a building, or part of it, and may be either a segment of a sphere, of a spheroid, or of any similar figure. When built of stone, it is a very strong kind of structure, even more so than the arch, since the tendency of each part to fall is counteracted, not only by those above and below it, but also by those on each side. It is only necessary that the constituent pieces should have a common form, and that this form should be somewhat like the frustum of a pyramid, so that, when placed in its situation, its four angles may point towards the centre or axis of the dome. During the erection of a dome, it is not necessary that it should be supported by a centring until complete, as is done in the arch. Each circle of stones when laid is capable of supporting itself without aid from those above it. It follows that the dome may be left open at top without a keystone, and yet be perfectly secure in this respect, being the reverse of the arch. The dome of the Pantheon at Rome has been always open at top, and yet has stood unimpaired for nearly two thousand years. The upper circle of stones, though apparently the weakest, is nevertheless often made to support the additional weight of a lantern or tower above it. In several of the largest cathedrals there are two domes, one within the other, which contribute their joint support to the lantern, which rests upon the top. In these buildings, the dome rests upon a circular wall, which is supported in its turn by arches upon massive pillars or piers. This construction is called building upon pendentives, and gives open space and room for passage beneath the dome. The remarks which have been made in regard to the abutments of the arch apply equally to the walls immediately supporting a dome. They must be of sufficient thickness and solidity to resist the lateral pressure of the dome, which is very great. The walls of the Roman Pantheon are of great depth and solidity. In order that a dome in itself should be perfectly secure, its lower parts must not be too nearly vertical, since in this case they partake of the nature of perpendicular walls, and are acted upon by the spreading force of the parts above them. The dome of St Paul's Church in London, and some others of similar construction, are bound with chains or hoops of iron, to prevent them from spreading at bottom. Domes which are made of wood depend in part for their strength on their internal carpentry. The Halle du Bled, in Paris, had originally a wooden dome more than two hundred feet in diameter, and only one foot in thickness. This has since been replaced by a dome of iron.

Roofs.

The roof is the most common and cheap method of covering buildings, to protect them from rain and other effects of the weather. It is sometimes flat, but more frequently oblique, in its shape. The flat or platform-roof is the least advantageous for shedding rain, and is seldom used in northern countries. The pent roof, consisting of two oblique sides meeting at top, is the most common form. These roofs are made steepest in cold climates, where they are liable to be loaded with snow. Where the four sides of the roof are all oblique, it is denominated a hipped roof, and where there are two portions to the roof of different obliquity, it is a curb or mansard roof. In modern times, roofs are made almost exclusively of wood, though frequently covered with incombustible materials. The internal structure or carpentry of roofs is a subject of considerable mechanical contrivance. The roof is supported by rafters, which abut on the walls on each side, like the extremities of an arch. If no other timbers existed except the rafters, they would exert a strong lateral pressure on the walls, tending to separate and overthrow them. To counteract this lateral force, a tie-beam, as it is called, extends across, receiving the ends of the rafters, and protecting the wall from their horizontal thrust. To prevent the tie-beam from sagging, or bending downward with its own weight, a king-post is erected from this beam to the upper angle of the rafters, serving to connect the whole, and to suspend the weight of the beam. This is called trussing. Queen-posts are sometimes added, parallel to the king-post, in large roofs; also various other connecting timbers. In Gothic buildings, where the vaults do not admit of the use of a tie-beam, the rafters are prevented from spreading, as in an arch, by the strength of the buttresses. In comparing the lateral pressure of a high roof with that of a low one, the length of the tie-beam being the same, it will be seen that a high roof, from its containing most materials, may produce the greatest pressure, as far as weight is concerned. On the other hand, if the weight of both be equal, then the low roof will exert the greater pressure; and this will increase in proportion to the distance of the point at which perpendiculars drawn from the end of each rafter would meet. In roofs, as well as in wooden domes and bridges, the materials are subjected to an internal strain, to resist which, the cohesive strength of the material is relied on. On this account beams should, when possible, be of one piece. Where this cannot be effected, two or more beams are connected together by splicing. Spliced beams are never so strong as whole ones, yet they may be made to approach the same strength by affixing lateral pieces, or by making the ends overlay each other, and connecting them with bolts and straps of iron. The tendency to separate is also resisted, by letting the two pieces into each other, by the process called scarfing. Mortises intended to truss or suspend one piece by another, should be formed upon similar principles.

STYLES OF BUILDING.

The architecture of different countries has been generally characterised by peculiarities in external form, and in modes of construction. These peculiarities among ancient nations were so distinct, that their structures may be identified even in the state of ruins, and the origin and era of each may be conjectured with tolerable accuracy. Before we proceed to describe architectural objects, it is necessary to explain certain terms which are used to denote their different constituent portions. The architectural orders will be spoken of under the head of the Grecian and Roman styles, but their component parts ought previously to be understood.

The front or façade of a building, made after the ancient models, or any portion of it, may present three parts, occupying different heights:—The pedestal is the lower part, usually supporting a column; the single pedestal is wanting in most antique structures, and its place supplied by a stylobate; the stylobate is either a platform with steps, or a continuous pedestal, supporting a row of columns. The lower part of a finished pedestal is called the plinth; the middle part is the die, and the upper part the cornice of the pedestal, or surbase. The column is the middle part, situated upon the pedestal or stylobate. It is commonly detached from the wall, but is sometimes buried in it for half its diameter, and is then said to be engaged. Pilasters are square or flat columns attached to walls. The lower part of a column, when distinct, is called the base; the middle, or longest part, is the shaft; and the upper, or ornamented part, is the capital. The height of columns is measured in diameters of the column itself, taken always at the base. The entablature is the horizontal continuous portion which rests upon the top of a row of columns. The lower part of the entablature is called the architrave, or epistylium. The middle part is the frieze, which, from its usually containing sculpture, was called zophorus by the ancients. The upper or projecting part is the cornice. A pediment is the triangular face produced by the extremity of a roof. The middle or flat portion enclosed by the cornice of the pediment is called the tympanum. Pedestals for statues, erected on the summit and extremities of a pediment are called acroteria. An attic is an upper part of a building, terminated at top by a horizontal line instead of a pediment. The different mouldings in architecture are described from their sections, or from the profile which they present when cut across. Of these, the torus is a convex moulding, the section of which is a semicircle, or nearly so; the astragal is like the torus, but smaller; the ovolo is convex, but its outline is only the quarter of a circle; the echinus resembles the ovolo, but its outline is spiral, not circular; the scotia is a deep concave moulding; the cavetto is also a concave, and occupying but a quarter of a circle; the cymatium is an undulated moulding, of which the upper part is concave and the lower convex; the ogee or talon is an inverted cymatium; the fillet is a small square or flat moulding. In architectural measurement, a diameter means the width of a column at the base. A module is half a diameter. A minute is a sixtieth part of a diameter. In representing edifices by drawings, architects make use of the plan, elevation, section, and perspective. The plan is a map or design of a horizontal surface, showing the ichnographic projection, or groundwork, with the relative position of walls, columns, doors, &c. The elevation is the orthographic projection of a front, or vertical surface; this being represented, not as it is actually seen in perspective, but as it would appear if seen from an infinite distance. The section shows the interior of a building, supposing the part in front of an intersecting plane to be removed. The perspective shows the building as it actually appears to the eye, subject to the laws of scenographic perspective. The three former are used by architects for purposes of admeasurement; the latter is used also by painters, and is capable of bringing more than one side into the same view, as the eye actually perceives them. As the most approved features in modern architecture are derived from buildings which are more or less ancient, and as many of these buildings are now in too dilapidated a state to be easily copied, recourse is had to such imitative restorations, in drawings and models, as can be made out from the fragments and ruins which remain. In consequence of the known simplicity and regularity of most antique edifices, the task of restoration is less difficult than might be supposed. The groundwork, which is commonly extant, shows the length and breadth of the building, with the position of its walls, doors, and columns. A single column, whether standing or fallen, and a fragment of the entablature, furnish data from which the remainder of the colonnade, and the height of the main body, can be made out. A single stone from the cornice of the pediment is often sufficient to give the angle of inclination, and, consequently, the height of the roof. In this way, beautiful restorations are obtained of structures, when in so ruinous a state as scarcely to have left one stone upon another. We come now to the different styles of architecture.

Egyptian style.—In ancient Egypt, a style of building prevailed, more massive and substantial than any which has succeeded it. The elementary features of Egyptian architecture were chiefly as follow:—1. Their walls were of great thickness, and sloping on the outside. This feature is supposed to have been derived from the mud walls, mounds, and caverns of their ancestors. 2. The roofs and covered ways were flat, or without pediments, and composed of blocks of stone, reaching from one wall or column to another. The principle of the arch, although known to them, was seldom if ever employed by them. 3. Their columns were numerous, close, short, and very large, being sometimes ten or twelve feet in diameter. They were generally without bases, and had a great variety of capitals, from a simple square block, ornamented with hieroglyphics or faces, to an elaborate composition of palm-leaves, not unlike the Corinthian capital. 4. They used a sort of concave entablature, or cornice, composed of vertical flutings, or leaves, and a winged globe in the centre. 5. Pyramids, well known for their prodigious size, and obelisks, composed of a single stone, often exceeding seventy feet in height, are structures peculiarly Egyptian. 6. Statues of enormous size, sphinxes carved in stone, and sculptures in outline of fabulous deities and animals, with innumerable hieroglyphics, are the decorative objects which belong to this style of architecture. The architecture of the ancient Hindoos appears to have been derived from the same original ideas as the Egyptian. The most remarkable relics of this people are their subterraneous temples, of vast size and elaborate workmanship, carved out of the solid rock, at Elephanta, Ellora, and Salsette.

The Chinese style.—The ancient Tartars and wandering shepherds of Asia appear to have lived from time immemorial in tents, a kind of habitation adapted to their erratic life. The Chinese have made the tent the elementary feature of their architecture; and of their style any one may form an idea, by inspecting the figures which are depicted upon common China ware. Chinese roofs are concave on the upper side, as if made of canvass, instead of wood. A Chinese portico is not unlike the awnings spread over shop windows in summer time. The verandah, sometimes copied in dwelling-houses, is a structure of this sort. The Chinese towers and pagodas have concave roofs, like awnings, projecting over their several stories. The lightness of the style used by the Chinese leads them to build with wood, sometimes with brick, and seldom with stone.

The Grecian style.—Grecian architecture, from which have been derived the most splendid structures of later ages, had its origin in the wooden hut or cabin, formed of posts set in the earth, and covered with transverse poles and rafters. Its beginnings were very simple, being little more than imitations in stone of the original posts and beams. By degrees, these were modified and decorated, so as to give rise to the distinction of what are now called the orders of architecture.

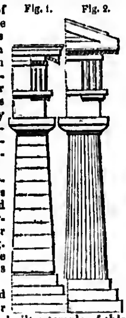
By the architectural orders are understood certain modes of proportioning and decorating the column and its entablature. They were in use during the best days of Greece and Rome, for a period of six or seven centuries. They were lost sight of in the dark ages, and again revived by the Italians, at the time of the restoration of letters. The Greeks had three orders, called the Doric, Ionic, and Corinthian. These were adopted and modified by the Romans, who also added two others, called the Tuscan and Composite.

The *Tuscan order*, as an antique, exists only in the works of Vitruvius, the description in which, being very obscure, has left a wide field for the ingenuity of modern architects. Among these, Palladio composed two profiles; one from the description of the ancient master, and the other, according to his own idea of a simplification of the Doric. That of Vignola, however, has been most generally approved and adopted.

The base of this order consists of a simple torus, with its fillet; it is, as are in general all the Roman orders, accompanied by a plinth. The proportions, from Sir W. Chambers, are as follow: The column, fourteen modules; the entablature, three modules fifteen minutes. Of the former, the base occupies one module; the shaft (including the astragal, which divides it from the capital), twelve modules, and the capital one. Of the latter, the architrave (including the fillet), thirty-one minutes and a half; the frieze, the same; and the cornice, forty-two minutes.

The intercolumniations, in all the orders except the Doric, are the same; viz. the eustyle, which is most common and beautiful, four modules twenty minutes; the diastyle, six modules; and the aræostyle, seven modules.

Fig. 1. Fig. 2.



The Tuscan order admits of no ornaments, nor flutes in the columns; but rustic cinctures are sometimes represented on the shaft, an example of which occurs in the accompanying illustration, fig. 1. This order may be employed in most cases where strength and simplicity are required, rather than magnificence; such as prisons, market-places, arsenals, and the inferior parts of large buildings.

We now come to the *Doric order*, of which numerous ancient examples exist, and which will in consequence furnish us with more materials for description than the preceding. It is represented at fig. 2. The origin of the Doric order is thus described by Vitruvius:—

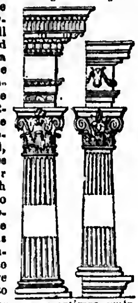
"Dorus, son of Hellen and the nymph Orises, reigned over Achaia and Peloponnesus. He built a temple of this order, on a spot sacred to Juno, at Argos, an ancient city. Many temples similar to it were afterwards raised in the other parts of Achaia, though at that time its proportions were not precisely established." This account, as well as those of the orders which we shall presently examine, is very incredible, and is now generally rejected.

The Doric is the earliest and most massive order of the Greeks. It is known by its large columns with plain capitals; its triglyphs resembling the ends of beams, and its mutules corresponding to those of rafters. The column, in the examples at Athens, is about six diameters in height. In the older examples, as those at Pæstum, it is but four or five. The shaft had no base, but stood directly on the stylobate. It had twenty flutings, which were superficial, and separated by angular edges. The perpendicular outline was nearly straight. The Doric capital was plain, being formed of a few annulets or rings, a large echinus, and a flat stone at top called the abacus. The architrave was plain; the frieze was intersected by oblong projections called triglyphs, divided into three parts by vertical furrows, and ornamented beneath by guttæ, or drops. The spaces between the triglyphs were called metopes, and commonly contained sculptures. The sculptures representing Centaurs and Lapithæ, carried by Lord Elgin to London, were metopes of the Parthenon, or temple of Minerva at Athens. The cornice of the Doric order consisted of a few large mouldings, having on their under side a series of square sloping projections, resembling the ends of rafters, and called mutules. These were placed over both triglyphs and metopes, and were ornamented, on their under side, with circular guttæ. The best specimens of the Doric order are found in the Parthenon, Propylæa, and the temple of Theseus, at Athens.

The *Ionic* is a lighter order than the Doric, its column being eight or nine diameters in height. It had a base often composed of a torus, a scotia and a second torus, with intervening fillets. This is called the Attic base. Others were used in different parts of Greece. The shaft had twenty-four or more flutings, which were narrow, as deep as a semicircle, and separated by a fillet or square edge. The capital of this order consisted of two parallel double scrolls, called volutes, occupying opposite sides, and supporting an abacus, which was nearly square, but moulded at its edges. These volutes have been considered as copied from ringlets of hair, or perhaps from the horns of Jupiter Ammon. When a column made the angle of an edifice, its volutes were placed, not upon opposite, but on contiguous sides, each fronting outwards. In this case the volutes interfered with each other at the corner, and were obliged to assume a diagonal direction. The Ionic entablature consisted of an architrave and frieze, which were continuous or unbroken, and a cornice of various successive mouldings, at the lower part of which was often a row of dentels, or square teeth. The examples at Athens, of the Ionic order, are the temple of Erectheus, and the temple on the Ilissus, which was standing in Stuart's time, seventy years since, but is now extinct.

The *Corinthian* was the lightest and most decorated of the Grecian orders. Its base resembled that of the Ionic, but was more complicated. The shaft was often ten diameters in height, and was fluted like the Ionic. The capital was shaped like an inverted bell, and covered on the outside with two rows of leaves of the plant acanthus, above which were eight pairs of small volutes. Its abacus was moulded and concave on its sides, and truncated at the corners, with a flower on the centre of each side. The entablature of the Corinthian order resembled that of the Ionic, but was more complicated and ornamented, and had, under the cornice, a row of large oblong projections, bearing a leaf or scroll on their under side, and called modillions. No vestiges of this order are now found in the remains of Corinth, and the most legitimate example at Athens is in the choragic monument of Lysicrates. The Corinthian order was much employed in the subsequent structures of Rome and its colonies. The finest Roman example of this order is that of three columns in the Campo Vaccino at Rome, which are commonly considered as the remains of the temple of Jupiter Stator. This example has received the commendation of all modern artists, yet has seldom been executed in its original form. This is probably owing to the excessive richness and delicacy of it, which renders its adoption very expensive, and perhaps the modification of it by Vignola is preferable to the original, possessing a sufficient enrichment without the excessive refinement of the other. In this order (which has been adopted by Sir William Chambers) the base is one module in height; the shaft, sixteen modules twenty minutes; and the capital, two modules ten minutes; thus giving ten diameters to the whole column. The architrave and frieze are each one module fifteen minutes in height, and the cornice, two modules. The cornice is distinguished by modillions interposing between the head-mouldings and corona;

Fig. 1. Fig. 2.



the latter is formed by a square member surmounted by a cymatium, supported by a small ogee: the former is composed of dentils, supported by a cyma reversa, and covered by the ovolo. When the order is enriched, which is usually the case, these mouldings, excepting the cymatium and square of the corona, are all sculptured: the column is also fluted, and the channels are sometimes filled to about a third of their height with cablings, which are cylindrical pieces let into the channels. When the column is large, and near the eye, these are recommended as strengthening them, and rendering the fillets less liable to fracture; but when they are not approached, it is better to leave the flutes plain. They are sometimes sculptured, but this should be only in highly enriched orders. An example is given in fig. 1.

The flutes are twenty-four in number, and commonly semicircular in their plan. The Corinthian base is similar to that of the Composite order, excepting that two astragals are employed between the scotiæ instead of one; but the Attic is usually employed for the reasons before assigned.

"The Corinthian order," says Sir William Chambers, "is proper for all buildings where elegance, gaiety, and magnificence, are required. The ancients employed it in temples dedicated to Venus, to Flora, Proserpine, and the nymphs of fountains, because the flowers, foliage, and volutes with which it is adorned, seemed well adapted to the delicacy and elegance of such deities. Being the most splendid of all the orders, it is extremely proper for the decoration of palaces, public squares, or galleries and arcades surrounding them; for churches dedicated to the Virgin Mary, or to other virgin saints, and on account of its rich, gay, and graceful appearance, it may with propriety be used in theatres, in ball or banquetting rooms, and in all places consecrated to festive mirth or convivial recreation."

Caryatides.—The Greeks sometimes departed so far from the strict use of the orders, as to introduce statues, in the place of columns, to support the entablature. Statues of slaves, heroes, and gods, appear to have been employed, occasionally, for this purpose. The principal specimen of this kind of architecture which remains, is in a portico called Pandroseum, attached to the temple of Erectheus at Athens, in which statues of Carian females, called Caryatides, are substituted for columns. One of these statues has been carried to London.

Grecian temple.—The most remarkable public edifices of the Greeks were their temples. These being intended as places of resort for the priests, rather than for the convening of assemblies within, were in general obscurely lighted. Their form was commonly that of an oblong square, having a colonnade without, and a walled cell within. The cell was usually without windows, receiving its light only from a door at the end, and sometimes from an opening in the roof. The part of the colonnade which formed the front portico was called the pronaos, and that which formed the back part, the posticus. The colonnade was subject to great variety in the number and disposition of its columns, from which Vitruvius has described seven different species of temples. These were, 1. The temple with antæ. In this the front was composed of pilasters, called antæ, on the sides, and two columns in the middle. 2. The prostyle. This had a row of columns at one end only. 3. The amphiprostyle, having a row of columns at each end. 4. The peripteral temple. This was surrounded by a single row of columns, having six in front and in rear, and eleven, counting the angular columns, on each side. 5. The dipteral, with a double row of columns all round the cell, the front consisting of eight. 6. The pseudo-dipteral differs from the dipteral, in having a single row of columns on the sides, at the same distance from the cell as if the temple had been dipteral. 7. The hypæthral temple had the centre of its roof open to the sky. It was colonnaded without, like the dipteral, but had ten columns in front. It had also an internal colonnade, called peristyle, on both sides of the open space, and composed of two stories or colonnades, one above the other. Temples, especially small ones, were sometimes made of a circular form. When these were wholly open, or without a cell, they were called monopteral temples. When there was a circular cell within the colonnade, they were called peripteral.

The theatre of the Greeks, which was afterwards copied by the Romans, was built in the form of a horse-shoe, being semicircular on one side, and square on the other. The semicircular part, which contained the audience, was filled with concentric seats, ascending from the centre to the outside. In the middle, or bottom, was a semicircular floor, called the orchestra. The opposite, or square part, contained the actors. Within this was erected, in front of the audience, a wall, ornamented with columns and sculpture, called the scene. The stage or floor between this part and the orchestra was called the proscenium. Upon this floor was often erected a moveable wooden stage, called by the Romans pulpitum. The ancient theatre was open to the sky, but a temporary awning was erected to shelter the audience from the sun and rain.

Grecian architecture is considered to have been in its greatest perfection in the age of Pericles and Phidias. The sculpture of this period is admitted to have been superior to that of any other age; and although architecture is a more arbitrary art than sculpture, yet it is natural to conclude that the state of things which gave birth to excellence in the one, must have produced a corresponding power of conceiving sublimity and beauty in the other. Grecian architecture was in general distinguished by simplicity of structure, fewness of parts, absence of arches, lowness of pediments and roofs, and by decorative curves, the outline of which was a spiral line or conic section, and not a circular arc, as afterwards adopted by the Romans.

Roman style.—Roman architecture had its origin in copies of the Greek models. All the Grecian orders were introduced into Rome, and variously modified. Their number was augmented by the addition of two new orders—the Tuscan and the Composite. The order derived from the ancient Etruscans is not unlike the Doric deprived of its triglyphs and mutules. It had a simple base, containing one torus. Its column was seven diameters in height, with an astragal below the capital. Its entablature, somewhat like the Ionic, consisted of plain running surfaces. There is no vestige of this order among ancient ruins, and the modern examples of it are taken from the descriptions of Vitruvius.

The Romans modified the Doric order by increasing the height of its column to eight diameters. Instead of the echinus, which formed the Grecian capital, they employed the ovolo, with an astragal and neck below it. They placed triglyphs over the centre of columns, not at the corners, and used horizontal mutules, or introduced foreign ornaments in their stead. The theatre of Marcellus has examples of the Roman Doric. The Romans diminished the size of the volutes in the Ionic order. They also introduced a kind of Ionic capital, in which there were four pairs of diagonal volutes, instead of two pairs of parallel ones. This they usually added to parts of some other capital; but at the present day it is often used alone, under the name of modern Ionic. The Composite order was made by the Romans out of the Corinthian, simply by combining its capital with that of the diagonal, or modern Ionic. Its best example is found in the arch of Titus. The favourite order, however, in Rome and its colonies, was the Corinthian, and it is this order which prevails among the ruins, not only of Rome, but of Nismes, Pola, Palmyra, and Balbec.

The temples of the Romans sometimes resembled those of the Greeks, but often differed from them. The Pantheon, which is the most perfectly preserved temple of the Augustan age, is a circular building, lighted only from an aperture in the dome, and having a Corinthian portico in front. The amphitheatre differed from the theatre, in being a completely circular or rather elliptical building, filled on all sides with ascending seats for spectators, and leaving only the central space, called the arena, for the combatants and public shows. The Coliseum is a stupendous structure of this kind. The aqueducts were stone canals, supported on massive arcades, and conveying large streams of water for the supply of cities. The triumphal arches were commonly solid oblong structures, ornamented with sculptures, and open with lofty arches for passengers below. The basilica of the Romans was a hall of justice, used also as an exchange or place of meeting for merchants. It was lined on the inside with colonnades of two stories, or with two tiers of columns, one over the other. The earliest Christian churches at Rome were sometimes called basilicæ, from their possessing an internal colonnade. The monumental pillars were towers in the shape of a column on a pedestal, bearing a statue on the summit, which was approached by a spiral staircase within. Sometimes, however, the column was solid. The thermæ, or baths, were vast structures, in which multitudes of people could bathe at once. They were supplied with warm and cold water, and fitted up with numerous rooms for purposes of exercise and recreation. In several particulars, the Roman copies differed from the Greek models on which they were founded. The stylobate or substructure, among the Greeks, was usually a plain succession of platforms, constituting an equal access of steps to all sides of the building. Among the Romans it became an elevated structure, like a continued pedestal, accessible by steps only at one end. The spiral curve of the Greeks was exchanged for the geometrical circular arc, as exemplified in the substitution of the ovolo for the echinus in the Doric capital. The changes in the orders have been already mentioned. After the period of Adrian, Roman architecture is considered to have been on the decline. Among the marks of a deteriorated style, introduced in the later periods, were columns with pedestals, columns supporting arches, convex friezes, entablatures squared so as to represent the continuation of the columns, pedestals for statues projecting from the sides of columns, niches covered with little pediments, &c.

Greco-Gothic style.—After the dismemberment of the Roman empire, the arts degenerated so far, that a custom became prevalent of erecting new buildings with the fragments of old ones, which were dilapidated and torn down for the purpose. This gave rise to an irregular style of building, which continued to be imitated, especially in Italy, during the dark ages. It consisted of Grecian and Roman details, combined under new forms, and piled up into structures wholly unlike the antique originals. Hence the names Greco-Gothic and Romanesque architecture have been given to it. It frequently contained arches upon columns, forming successive arcades, which were accumulated above each other to a great height. The effect was sometimes imposing. The cathedral and leaning tower at Pisa, and the church of St Mark at Venice, are cited as the best specimens of this style. The Saxon architecture, used anciently in England, has some things in common with this style.

MODERN TASTE.

So much for the varieties of the Greek and Roman styles of building, which have properly enough formed models for the erection of public edifices in every nation of modern times. But, as we have already hinted, the adoption of these models has not been always successful. It would seem as if the architects of ancient times had exhausted human ingenuity, and left nothing to be invented in the construction of ornamental and tasteful edifices; at least the architects of modern ages have not had the hardihood to attempt, or the genius to be successful in, original composition. They have copied Greek temples, porches, pillars, pediments, and cornices, without regard either to climate or situation, and also without bearing in mind that they lack the marble, and cannot afford the expensive sculpture which lent so much beauty and grace to the forms of Athenian architecture. Magnificent temples which crowned the summits of rising grounds in Greece, we find imitated in hollows; and the eye of the spectator, instead of taking in a bold and lofty outline of pillars relieved against the clear blue sky, is offended by looking down upon clusters of chimney pots. Thus innumerable public buildings in England and Scotland, possessing intrinsically good architecture, are completely lost by the want of taste in those who have placed them in unseemly awkward situations. It appears to us, likewise, that far too little attention is usually paid by architects to the nature of our climate. We cannot recal to remembrance one public edifice in the Grecian style in this country which does not possess a dingy damp look. At every projecting point, and particularly over the pediments, pillars, and flat cornices of doorways, there is generally an ugly spot covered with moisture, and exhibiting the early rudiments of vegetation on the walls. All this offends the eye of the spectator, and excites universal notice, except among those who can see nothing but beauty in Grecian architecture, however clumsy it may be, and however much out of place.

Transcendant as were the efforts of the Grecian architects, one cannot believe that they exhausted their art. Grecian literature has not prevented the rise of a literature in England suitable to its genius, so neither ought the existence of a Grecian style of architecture to be for ever an obstacle to the rise and progress of a pure modern style of building. Hitherto there has been too great a disposition to cavil at the efforts of modern artists, as if it were beyond the bounds of possibility to discover and establish new and really beautiful styles in painting, sculpture, or architecture. We are most anxious, for our national credit, to see an end put to this severity of criticism. We hope that our young architects, while studying the chaste models of antiquity, will persevere in endeavouring to elaborate something *still better*, at least some species of architecture which will be in better accordance with our climate, as well as the national genius and habits. As powerfully tending to produce so beneficial a result, we hail the appearance of such works as the ARCHITECTURAL MAGAZINE, conducted by Mr Loudon, which is designed to improve the national taste in architecture, building, furnishing, and the various trades connected therewith; and which, from its cheapness, may become popular among all those classes of artisans whose genius it is intended to cultivate. We cannot but deem it a matter of astonishment that so little has, up till a very recent period, been done to improve the style of housebuilding. It is certain that bad taste is not necessarily cheap. Under proper management, a tastefully constructed domicile is not more expensive than one the reverse—most likely it is less expensive; and there can be no question as to its superiority, and the greater degree of pleasure it yields to those who contemplate its aspect. Utility may thus be found associated with the beautiful and the economical to an extent which many will imagine to be hardly possible.

OLD ENGLISH STYLE OF ARCHITECTURE.

The style of architecture used in the erection of gentleman's country residences is at present undergoing a most wonderful improvement all over Britain. The clumsy square domiciles, oftener resembling cotton mills than gentlemen's seats, and which were brought into fashion in the reigns of George the Second and Third, are giving way to more tasteful erections in alliance with the character of rural scenery amidst which they are placed. The square chest-like houses are in the course of alteration into edifices constructed in the styles which prevailed in the days of Elizabeth and James, technically called the old English style of architecture. The origin and nature of this ornamental style are thus described by a writer in the Quarterly Review for July 1831:—

"Every country has an architecture more or less peculiarly its own, formed, like the character and language of its inhabitants, by the blending of various foreign ingredients which have at different periods introduced and naturalised themselves, but which have been also in turn modified by the original stocks, as well as by the local peculiarities of climate, soil, social condition, and political history. The national character attaches itself far more to domestic architecture than to that which is displayed in public buildings, ecclesiastical or civil. In the erection of these, the architect, often himself a stranger, or taught abroad, has sometimes wholly copied a foreign model, and merely transferred the entire cathedral or palace from the banks of the Rhine or the Po, to those of the Thames and Isis. But in designing the residences of the opulent classes of any country, it became necessary to consult the manners, habits, and wants of the future occupants, the character of the climate, and the nature of the ordinary materials within reach. And in whatever degree the architect has neglected to adapt his design to the type required by these local circumstances, to that extent has he sinned against taste and propriety, and failed in producing that harmony of ideas, that association of ornament and purpose, which, as an essential element in the quality of beauty, it is the object of his art to create.

In the erection of a country residence where the choice of a style is not fettered by the proximity of other buildings, associations of a general and imaginative nature come into play, and dictate the adoption of the national and indigenous architecture. In this country, which is still rich in the possession of numerous specimens of buildings, both ecclesiastical and domestic, belonging to the earlier ages of its history, the old English style, in some of its varieties, is that which we consider specially appropriate to a country residence. The natural scenery around presents congenial images in the venerable grove, and the ancient oaks spreading their broad arms over the lawns and glades of the park. The local annals of the estate, of the site itself, or of the proprietor's family, combine to call for the employment of a style which is connected with so many of the most pleasing recollections of our national history. The irregularity of outline which it admits, and, indeed, almost requires, allows of an arrangement of the apartments which comfort or fancy may suggest, and accommodates it to all the varied wants of modern life. However, it is equally appropriate to every rank of habitation, from the princely palace down to the snug parsonage or humble cottage. To us the Grecian temple is completely out of place in an English landscape, as would a cloistered abbey or feudal castle in the prairies of Kentucky or the Illinois.

Our Saxon ancestors reared few places of strength. Their habits were peaceful and agricultural, rather than warlike; and they lived in low and mean houses, having no pretensions either to splendour or strength. It was indeed the defenceless condition of the island which rendered it so easy a prey to the Norman conqueror; and it was to remedy this defect, and secure his newly acquired dominions, as well against invasions from without as rebellions within, that William lost no time in erecting strong castles in all the principal towns of his kingdom. His followers, among whom he had parcelled out the lands of the English, had likewise to protect themselves against the resentment of those they had despoiled, and imitated their masters' example, by building castles on their estates. 'The whole kingdom,' says the author of the Saxon Chronicle, 'was covered with them, and the poor people worn out with the forced labour of their erection.' Many of the castles of this age were of great size, and possessed a certain rude grandeur of design. After the age of Edward III., who both ameliorated the institutions of the country, and introduced into it a certain degree of elegance and refinement, we find a considerable improvement in the character of the habitations which remain to us. By degrees, it was found possible to associate much convenience and magnificence with the strength requisite for defence; and the confined plan of the close fortress expanded into a mixture of the castle and the mansion. At a later period, a still farther change took place. The reign of law had gradually succeeded to that of the strong hand. The peaceable were able to trust to the executive for the defence of their persons and property, rather than to the strength of their own walls, and roof-trees, or the falchions and iron mails of their friends and retainers. The residences of the nobility and rich landed proprietors again assumed, though by degrees, and with the exception of some districts like the borders of England and Scotland, a civil, in place of a military appearance. Beauty and ornament were consulted by the builders instead of strength, and the convenient accommodation of the ordinary indwellers, in lieu of the means for disposing of a crowded garrison, and its necessary provision in time of siege. The mansions erected under these circumstances partook but slightly of the castellated character. They usually retained the moat and battlemented gateway, and one or two strong turrets, to build which a royal licence was necessary; but their defensive strength could only have availed against a sudden and momentary attack. They were generally quadrangular in form; the larger class enclosing two open courts, of which one contained the stables, offices, and lodgings of the household; the second, the principal or state chambers, with the hall and chapel. Such buildings differed but little from the monastic residences of the same, or of an earlier date. Of the minor country residences of that and the earlier reigns, many interesting examples remain scattered through the island, sometimes fulfilling their original destination, but far more frequently employed only as farm-houses, and going fast to decay.

In a few of the houses built during the reign of Henry the Eighth, we may observe some slight traces of the Italian architecture, which in the next reign was more liberally introduced, and mixed up with the original Tudor, or early English, into an irregular, certainly, but in most instances an exceedingly rich and effective composition. Whilst in England, and the north of Europe generally, the debased Roman architecture of the lower empire, which forms the foundation of the Saxon, Norman, or Lombard style, had been successively improved into those several beautiful modifications which are now classed indiscriminately under the term Gothic, the architects of Italy had never stepped out of their ancient track. With the seat of empire, the arts had migrated to Constantinople; and when the towns of Venice and Pisa were desirous of exhibiting their newly-born opulence in the erection of splendid cathedrals, it was in Constantinople, the capital of the lower empire, where St Sophia had already risen to astonish the eastern world, that they were compelled to seek a fitting artist. But on the revival of learning, the ancient Roman edifices were disinterred, and admired, and measured; and the eastern, or, as it is called in Italy, Lombard architecture, was in turn corrected, by reference to its classical original. The architects of Italy soon rose to eminence, and their fame was a subject of deep interest in this country, where the rage for building was no less strong and general than in Italy. In the brilliant reign of Elizabeth, the English nobles and princely proprietors vied more than ever with each other in the magnificence of their mansions. It might have been supposed that the noble Tudor houses, with their panelled walls, buttresses, and battlements, traceried windows, sculptured dripstones, florid pinnacles, and embossed chimney-shafts, were sufficiently rich and gorgeous to satisfy the prevailing taste for splendour; but in their anxiety to strike and surprise the admiration of their countrymen, many deserted the native styles, and sought for designs, and even artists, from abroad. Italian architecture became, by degrees, the mode; and even where the indigenous style was adhered to in the general design, many of the enrichments and ornamental features were borrowed from the Italian. First of all, the porch or gateway, as the most conspicuous points on which to exhibit these exotic novelties, were decorated on either side the entrance, and, perhaps, a second and third story above with pilasters, belonging to the different Greek orders; the doorway itself exchanged the low-pointed or Tudor, for the circular arch; the deep, elegant, and sweeping Gothic mouldings, for the Vitruvian architecture, cut across by the awkward projecting imposts. Next was introduced the cupola, whose invention in Italy had made so much noise, that it appears our country squires were anxious to have miniature specimens of it at home. It was applied as a covering to the high turrets, round, square, or polygonal, which flanked the entrance or terminated the angles of the building, and, surmounted with gilded vanes, certainly produced a rich and imposing effect. Then followed the removal of the panelled battlements, and the substitution of a parapet, carved into fantastic notches or scrolls, or perforated with oval openings and ornamented with obelisks, balls, busts, statues, and other singular decorations. These ran up the gables, which were often twisted into strange shapes, and sometimes wholly replaced by the level balustrade. And thus the most characteristic features of the old style, its numerous steep gables and spiry pinnacles, were succeeded by the uniform horizontal straight lines of the new. At length the whole building was surrounded by columns or pilasters, rising, tier above tier, to the exhaustion sometimes of the five orders; open arcades took the place of the entrance porch, and nothing remained of the Tudor style but the mullioned window, which, however, was of itself sufficient to give a peculiarly picturesque and old-fashioned aspect to the whole building.

To us it has always appeared that this architecture of the Elizabethan age constitutes a style of its own—a compound of two extremely different modes, the Italian and the Tudor Gothic. It is evident that the Italian design was always greatly altered to suit the climate and the taste of England. Indeed, were we not afraid the comparison might be considered profane, we should say there is something in the rich irregularity of the Elizabethan architecture, its imposing dignity, gorgeous magnificence, and quaint and occasionally fantastic decoration, reminding us of the glorious visions that flitted across the imagination of Shakspeare, the immortal bard of the same age. He, like the architects of his day, borrowed largely from the foreigner, but made his importations appear exclusively his own. The architectural garden, which always accompanied this style of mansion, is not the least pleasing part of it. We delight in its wide and level terraces, decorated with rich stone balustrades, and these again with vases and statues, and connected by broad flights of stone steps—its clipped evergreen hedges—its embowered alleys—its formal yet intricate parterres, full of curious knots of flowers—its lively and musical fountains—its steep slopes of velvet turf—its trim bowling-green—and the labyrinth and wildness which form its appropriate termination, and connect it with the ruder scenary without. This kind of ornamental garden came from Italy, with the change we have been discussing, in domestic architecture.

The quadrangular embattled mansion of the last Henries affords scope for the display of much grandeur and magnificence, and adapts itself more conveniently to the plan of a modern house. The carved oriel, and deep many-lighted bay window, often projecting in a multitude of capricious angles and curves, besides the regular octagon, the panelled angle-turrets, with richly embossed finials, and the wreathed chimney-shafts, are characteristic beauties of this class of building. The gabled manor-house, together with these ornamental features, admits at the same time of a much greater irregularity of form and outline, so as to accommodate itself to every variety of disposition, and to buildings of every size, from the baronial residence to the parsonage and grange. All the forms which particularly mark the Elizabethan style may be wrought in the cheapest materials with comparatively little labour; and a small portion of ornamental work, tastefully disposed, is capable of producing very considerable effect. Lastly, the Elizabethan house is distinguished by the number and size of its rectangular and many-mullioned windows, which gave a peculiar lightness and elegance to its several parts. The roof-line may be either horizontal or broken with gables, turrets, and cupolas. In either case, it is enriched with perforated parapets, balustrades, or other architectural devices, while similar embellishments ornament the entrance, and the terraces which connect the building with the garden."

Fortunately, as we have said, this light and elegant style of domestic architecture is gradually superseding the clumsy style of the eighteenth century. A better taste is evidently extending itself, particularly as regards the erection of villas, cottages, hunting-seats, gate-lodges, and other rural residences. To these the old English style is peculiarly well adapted. The leading feature of this style applied to cottages is the doing away with unbroken lines. The house is composed of different parts projecting at right angles from each other, with also a projecting porch, and the outshot octagonal windows commanding views in three different points. It also sometimes possesses an open rustic arcade along a portion of the front or back, which will be found useful and agreeable both in sultry and cold broken weather. A usual plan with a cottage of this kind is to have on the ground-floor two parlours, communicating by folding doors, fourt[illegible] feet by twelve each, and ten feet in height; a kitchen and scullery, with a porch seven feet by five feet six inches, opening to a staircase seventeen feet six inches by eight feet, with three rooms above. The gables are enriched with pendants and ornamental dressings to the doorways and windows, and handsome octagonal chimney-stacks. In erecting ornamental cottages of this kind, there ought to be a lightness in the pointing of the upper projecting windows, with a sharp angularity in the roof; and the chimney-stacks ought to stand well out, in order to create effect in different points of view. When the little gardens adjacent are well trimmed and blooming, and the woodbine and ivy trained round the porch or mullioned window, the prospect exhibited is such as it would be impossible to surpass in rural elegance. We have not here room to enlarge on this interesting topic, and we can only conclude by recommending, that, in applying cottage architecture to a residence, much care ought to be taken to preserve the simplicity of the component parts, or the idea of the cottage will be lost in the magnitude of the dwelling. London's Encyclopædia of Architecture should certainly be consulted by gentlemen and others in the country before fixing on the style or mode of construction of their residences—that is to say, when skilful architects are not employed.

While the architectural character of gentlemen's seats and other rural residences is at present improving in its tone, so also is there now a better kind of taste exerted in the erection of ecclesiastical structures, particularly in the northern part of the United Kingdom. Throughout the greater part of last century and part of the present, the style of church architecture which prevailed in Scotland was what is now called the *barn order*, from the buildings resembling barns, and seldom possessing any kind of ornament or work to distinguish them as ecclesiastical structures, except a tall pointed steeple at one of the extremities. Within the last twenty years, however, this grovelling and unsightly style of architecture has merged in favour of a very superior taste. A class of architects or planners has arisen (chiefly in Edinburgh), who, by the encouragement given them by the heritors, or those on whom is imposed the burden of building parish churches, have erected a considerable number of ecclesiastical structures in a neat and simple Gothic style, charming to the eye in the midst of rural scenery, and strikingly picturesque when viewed in connection with the grey hills and ruined baronial castles which usually characterise Scottish landscapes. In general, these handsome Gothic churches are calculated to accommodate from a thousand to twelve or fourteen hundred sitters, are neatly fitted up with pews and galleries, and cost from three to four thousand pounds. It is but justice to the heritors to say that they rarely grudge the erection of these edifices, and to them will Scotland stand indebted for the possession of many tastefully erected country churches, highly decorative of its romantic scenery.

CITY ARCHITECTURE.

The style of architecture in cities differs very materially in different countries. The houses of Paris, London, and Edinburgh, are respectively constructed and ornamented in a style conformable to the genius of the French, English, and Scotch. Architecture is susceptible of far greater improvement in Paris than in the other two cities mentioned. The stone which is used is a whitish sandstone, not very fine in the grain, but able to preserve a purity of colour from the absence of coal smoke. Marble likewise preserves its clear white appearance in Paris, and is never seen loaded with that encrustation of culm or black dust which disfigures every public edifice and piece of ornamental sculpture in London. The French, besides, possess a much more refined architectural taste than the English. They spare no trouble or cost in the erection of splendid public structures, which, when at length erected, are not so liable to be defaced as in this country. The Parisian architects, or those who employ them, are at the same time more careful than we are in choosing good situations for their public buildings. They do not seem to grudge room, in order that a building may have a striking effect. This will be observable by all strangers in Paris. In London, space is so exceedingly valuable, that few of the public buildings are allowed a proper proportion of room around them for purposes of effect. A bad choice of situation, and the want of space around, form the prevailing characteristics of public edifices in all the large towns in Britain. In Edinburgh, which abounds in fine commanding rising grounds, some of the most splendid public buildings are erected in hollows, where they are seen to great disadvantage. From a pretty close examination, we consider that the modern French Grecian style of architecture is a great deal lighter, as regards the fabric, and more pleasing in outline, than that at work in Britain. The Bourse, or Exchange, at Paris, surrounded on all sides with Corinthian pillars, and exalted above the street line, so as to meet the eye of the spectator in a proper point of view, has not, as far as we know, an equal in Britain.

The domestic architecture of these cities, to which we would here confine our remarks, is, as above noticed, different in the different places. The Parisian, however, bears a resemblance to that of the Scottish metropolis. The houses in Paris are very lofty, and contain a number of families, living on separate floors, and entering by one common stair. The houses in London, as in mostly every other English town, are built of brick, and of a size sufficient to contain only one family each. Little or no ornament is displayed in English domestic architecture, the comfort of the interior compensating the want of external decoration. The houses of Edinburgh are of two kinds—those of the Old Town, which are generally six and seven stories in height, and those of the New Town, which are commonly three, or at most four stories high, and built on a regular uniform plan. All the modern portion of the town is constructed of sandstone, similar to that employed in Paris. In the more newly erected streets, ornaments in the Grecian style, such as well-formed pillars, pediments, and cornices, at the doorways, are common, but serve to enhance greatly the cost of erection, and, consequently, to raise the rents of the householders. In nearly all parts of the town, the division of houses into separate dwellings on the different floors is too common, and proves a source of endless disquietude to families. The style of house-building in Edinburgh seems to be yearly improving, so far as external appearance is concerned; and the extent of work done of this kind for a number of years has tended, among other circumstances, to cultivate the science of architecture and the practice of stone-masonry.

The peculiarities of taste of the English and Scotch in the erection of their domestic dwellings, form certainly a fair subject for remark in the present sketch. The English build their houses of brick, and the Scotch of stone. This decided peculiarity of taste and habit is so strongly associated with the character of the two nations, that it may be frequently observed wherever the English and Scotch are planted, especially in foreign countries. When a Scotchman crosses the Border, at almost any point, he wonders how the people come to have such a predominating taste for brick. Every house he sees seems to be built with no other material, and all the towns and villages he travels through seem but piles of so many brick-kilns set in rows. As he proceeds, he gets accustomed to this, as it appears to him, very strange fancy; but he always feels a certain degree of pity for those who are doomed to inhabit houses with walls so very thin, and so little able to keep out the cold. When an Englishman, in the same manner, enters Scotland, he is apt to be as much surprised at finding that the houses are all reared of solid stone, like so many castles or public edifices; and he is led to imagine that the Scotch are really an extravagant people, in building their dwellings with a material so dear and difficult to be wrought.

Some persons might be led to suppose that these diversities of taste in the architecture of dwelling-houses are the result of necessity; but they are by no means entirely so. In many parts of England which are covered with brick houses, the district abounds in excellent stone; while in Scotland, in places where clay is plentiful and stone is scarce, the latter material is transported by land carriage, at a heavy charge, in preference to brick, which could be easily and cheaply made. In erecting a brick house, the Englishman makes a point of consulting his own comfort and that of his family. He rears his dwelling with every imaginable convenience; sections it off into neat snug apartments, almost calculating where his own easy chair is to stand by the fireside; surrounds the house with a pretty kitchen and flower garden; encloses the whole with a smart green railing; and finishes his goodly work by attaching to the wicket a clear-burnished fanciful brass knocker. Now, the Scotchman's taste runs in an entirely different channel. He sets about his work by going through certain toilsome preliminaries, which are considered of paramount importance. His first object of search is a quarry whence he may have his stones dug, and transported to the spot where they are to be used; his second point of inquiry is for a place to which he may convey the rubbish excavated from the foundation. When he has satisfied himself in these particulars, he commences operations on a scale of wonderful magnitude, generally contriving to commence his labours with the first appearance of fine weather at the close of winter, so as to make sure of having the roof on and the walls plastered before Christmas. The Englishman erects his house for the comfort of those who are immediately to inhabit it; but the Scotchman invariably calculates on its uses to his posterity, or how "the property" will serve as a legacy to his descendants. He appears to take a delight in building for future ages; and in order to make up a good rent-roll for his grandson, or that he may enjoy the dignity of being a *laird*, he will put himself to great inconvenience.

These different processes of house-building are partly the result of the English and Scotch modes of letting land for long periods. In England it is the common practice to take leases of ground for building for a period of ninety-nine years, or perhaps less, and for this piece of ground a certain rent is charged annually, with the arrangement that the houses on the property shall fall into the hands of the lord of the manor at the expiry of the lease; and hence, in a great measure, the plan of building houses which will not last in good repair for more than a hundred years. The Scotch, being in every respect a more calculating people, despise the prospect of only a hundred years' possession—"what! some day to be turned out of our own house!" They therefore take leases of ground which shall endure till the end of the world, and think themselves very badly off, indeed, when they are restricted to the brief period of nine hundred and ninety-nine years! These perpetual leases they term *feus*, an expression importing that the lessee becomes *feudal* vassal of the ground landlord. "*Ground to Feu*" is therefore to be found on hundreds of sign-boards north of the Tweed, and to English visitants appears quite an incomprehensible announcement. In Edinburgh and its vicinity, the annual feu-duty is enormous, amounting sometimes to a charge of a guinea for every foot of ground in front; and this has to be paid as a chief rent for ever, under the penalty of loss of the property.

One good results from this peculiar conduct on the part of the Scotch; it tends, as already mentioned, to encourage a superior kind of architectural taste, and greatly improves the general aspect of the country. There can be no proper comparison of the beauty of stone and brick, and the Scotch act very wisely in building stone houses, if they can afford the cost; but the general exercise of this refined taste has an injurious effect on society, and is spoiling the large towns in the north. It limits the proprietary to a mere unit; raises up a body of large capitalists over the people, who are reduced to the character of yearly tenants; and prolongs the very absurd custom of dividing houses into separate dwellings on the different floors. For example, there are few merchants, tradesmen, or shopkeepers in the large towns in Scotland, who live in what are termed self-contained houses; for the simple reason, that they cannot afford to build, or even rent a complete stone mansion. Yet they can frequently purchase a *flat*; that is, a house up two, three, or four stairs; whereas, for the sum they thus expend for a confined lodging, they could erect a sufficient brick house from top to bottom, calculated to last during the whole period of their own lives, and those of their immediate descendants. But the prejudices of society would seem to forbid that any such course should be pursued.

MONUMENTAL COLUMNS.

The erection of triumphal or monumental columns was a favourite idea of the Romans. Augustus erected a column of white marble near the temple of Saturn, in the forum at Rome, as a centre whence the account of the miles began in the calculation of distances from the city. This celebrated column, which is still in existence, is however not of great altitude. Among the principal triumphal columns of antiquity now remaining, is what is called the column of Pompey, constructed of red granite, and situated on a rock, about a mile without the walls of Alexandria in Egypt. The total height of this column is variously mentioned as being ninety-two feet and one hundred and fourteen feet. The spectator can never be tired with admiring the beauty of its Corinthian capital, the length of the shaft, nor the extraordinary simplicity of the pedestal. To whom this famous pillar was erected is now unknown. It acquired the name of Pompey's pillar so late as the fifteenth century. The following cut will convey a correct idea of its outlines.

The Trajan column, which falls next to be mentioned, is one of the most celebrated monuments of antiquity. Its height, including the pedestal and statue, is one hundred and thirty-two feet. This monumental column was erected in the centre of the forum Trajani, and dedicated to the Emperor Trajan for his decisive victory over the Dacians, as is testified by the inscription on the pedestal. It is of the Doric order, and its shaft is constructed of thirty-four pieces of Greek marble, joined with cramps of bronze. For elegance of proportion, beauty of style, and for simplicity and dexterity of sculpture, it is the finest in the world. The figures on the pedestal are masterpieces of Roman art. It was formerly surmounted by a statue of Trajan, which has been succeeded by a statue of St Peter.

There are other columnar erections in Rome. The column of the Emperor Phocas is near the temple of Concord. It is of Greek marble, fluted, and of the Corinthian order, four feet diameter, and fifty-four feet high, including the pedestal. The Antonine column was erected by the Roman senate to the glory of Marcus Aurelius, for his victories over the Marcomanni, in the reign of Commodus. Aurelius afterwards dedicated it to his father-in-law, Antoninus Pius. According to a rigid admeasurement, made by M. de la Condamine, this column is one hundred and sixteen French feet in height, and eleven in diameter. It is built entirely of marble, and encircled with bas-reliefs, which form twenty spirals around its shaft. It has been well illustrated by engravings and descriptions by Pietro Santi Bartoli. It is in every respect inferior to that of Trajan as a work of art, particularly in the style and execution of the sculptures. There is also in Rome another column bearing the same name, situated on the Monte Cittorio. Its shaft is of a single piece of Egyptian granite, forty-five feet in height, and five feet eight inches in diameter. Its pedestal is ornamented with bas-reliefs, representing the apotheosis of Antoninus and Faustina, and other events relating to the history of Rome.

The column which ornaments the British metropolis, better known as the Monument, was designed by Sir Christopher Wren, and erected by order of parliament, in memory of the burning of the city of London, anno 1666, in the very place where the fire began. This pillar was begun in 1671, and finished in 1677. It is of the Doric order, fluted, 202 feet high from the ground, and fifteen feet in diameter, of solid Portland stone, with a staircase in the middle, of black marble, containing three hundred and eighty-five steps. The lowest part of the pedestal is twenty-eight feet square, and its altitude forty feet; the front being enriched with curious bas-reliefs. It has a balcony within thirty-two feet of the top, on which is placed a blazing urn of gilt brass.

The column in Phœnix Park, Dublin, differs from any other work of this description. It was erected in 1745. It stands in the centre of an area where four great avenues meet, and from which there are entrances to the vice-regal lodge, and that of the chief secretary. The trees which shade the avenues form vistas, through which the perspective view of the column forms a picturesque object. The pillar is formed of Portland stone, and is of the Corinthian order, fluted, and highly ornamented—the base and pedestal five feet in height, the shaft and capital twenty, and the phœnix which surmounts the column five feet, so that the whole presents an object thirty feet high.

The Napoleon column has justly been considered as the greatest ornament of the Parisian capital. It stands in the Place Vendome, and was erected to commemorate the successful result of Bonaparte's arms in the German campaign of 1805. Its total elevation is one hundred and thirty-five feet, and the diameter of its shaft is twelve feet. It is in imitation of the pillar of Trajan at Rome, and is built of stone, covered with bas-reliefs (representing the various victories of the French army), composed of twelve hundred pieces of cannon taken from the Russian and Austrian armies. The bronze employed in this monument was about three hundred and sixty thousand pounds weight. The column is of the Doric order. The bas-reliefs of the pedestal represent the uniforms and weapons of the conquered legions. Above the pedestal are festoons of oak, supported at the four angles by eagles, in bronze, each weighing five hundred pounds. The bas-reliefs of the shaft pursue a spiral direction from the base to the capital, and display in chronological order the principal actions of the campaign, from the departure of the troops from Boulogne to the battle of Austerlitz. The figures are three feet high; their number is said to be two thousand, and the length of the spiral band eight hundred and forty feet. Above the capital is a gallery, which is approached by a winding staircase within, of one hundred and seventy-six steps. The capital of the column is surmounted by an acroterium, upon which stands the statue of Napoleon, measuring eleven feet in height, and weighing five thousand and twelve pounds. The total expense of this sumptuous monument was 1,500,000 livres.

There are also several smaller columns, but of beautiful proportions, in various parts of England, in imitation of the above, but mostly of the Grecian or pure Doric order, as the Anglesea column, erected in commemoration of the battle of Waterloo, and the noble earl of that name, in the island of Anglesea; the column at Shrewsbury, erected in commemoration of the same event, and of another noble general, Lord Hill; the Nelson columns, at Yarmouth and in Dublin; the Wellington column, at Trim, in the county of Meath, Ireland; the monument commemorative of Lord Melville, at Edinburgh; and a similar one at St James's Park, of the Duke of York, &c. A very common error is committed in the erection of monumental columns, by loading their summit with a clumsy mass of masonry, on which the statue is placed, and technically called an acroterium. The Melville monument at Edinburgh presents the most notable instance of this kind of defect. If there must be an acroterium, it cannot be too modest in its proportions, or too little seen by the spectator.

To the above list we may add the Washington monument, at Baltimore, on which a colossal statue of Washington has been placed. The pillar is of the Grecian Doric order, and of very massive proportions. It stands on a grand base or zocle, and is surmounted by a circular pedestal, on which the statue rests. This base or zocle of the monument is 50 feet square, and 25 feet high; the column is 20 feet in diameter, and with its sub-base, 130 feet high; the capital is 20 feet square. The statue is 15 feet high, and the whole height of the monument, from the pavement, including the statue, will be 176 feet. As it stands on a hill 100 feet high, this structure rises 276 feet above tide. It is constructed of white marble, which is slightly variegated, and is a very conspicuous object to every one approaching the city, whether by land or water. The statue greatly increases its effect, and gives finish and beauty to the whole structure. The attitude given to the statue represents the great man to whom the monument is dedicated in the act of resigning his commission, and the authority with which he had been invested by his country, again into the hands of the people, having accomplished the great object of his appointment—the freedom and independence of the union. The statue is the work of Mr Causici.

BRIDGES.

The art of bridge-building is traced to the Romans. In the brightest days of the Grecians, when their fine style of architecture was complete, when their porticoes were crowded with paintings, and their streets with statues, the people of Athens waded or ferried over the Cephisus for want of a bridge. The Greeks do not seem to have valued the construction of the arch sufficiently to excel in bridge-building. No people of the ancient world carried the power of rearing the stupendous arch and the magnificent dome to such an extent as the Romans. After the construction of their great sewers, the aqueducts, and the cupola over the Pantheon of M. Agrippa, a bridge over the Tiber was of easy execution; and the invention of the architecture of stone bridges, as practised in its best and most effectual manner, must be conceded to this great and indefatigable people. The most celebrated bridges of ancient Rome were not distinguished by the extraordinary size of their arches, nor the peculiar lightness of their piers, but, like the rest of the magnificent works of this city, as far as construction is concerned, they are worthy of study from their excellence and durability. The span or chord of their arches seldom exceeded seventy or eighty feet, and the versed sine or height was nearly half of the chord, so that they were mostly semicircular, or constituted a segment nearly of that form.

Among the most celebrated bridges in modern times, or those built subsequently to the destruction of the Roman empire, are those of the Moors in Spain, who imitated and rivalled the best constructions of the Romans. In Great Britain, the art of building bridges appears to have been diligently studied from early times. The most ancient bridge in England is the Gothic triangular bridge at Croyland, in Lincolnshire, said to have been built in 860. The ascent is so steep that none but foot passengers can go over it, a common peculiarity of old bridges.

The greatest improvement effected in modern times upon bridge-building consists in constructing them with so level a surface or roadway above, that they are easy of access. The most splendid work of art of this kind is Waterloo Bridge, across the Thames. Its length is 1250 feet. It consists of nine elliptical arches, each of 120 feet span, and 32 feet in height. Westminster Bridge was commenced in 1740, and completed in 1750. It is 1220 feet long, and 44 feet between the parapets, has 13 large and 2 small arches, all semicircular. The middle arch is 76 feet in span. The newly-erected London Bridge is also an elegant structure, and, excepting Waterloo Bridge, is perhaps the finest bridge in the world. At Paris there are some remarkably good stone bridges across the Seine, also an excellent suspension bridge. One of the most curious provincial bridges in Great Britain is that at Taff, in Glamorganshire. It is of one arch, and its space is rather more than 140 feet. The architect of this bridge was a poor uneducated man, and the persevering courage with which he pursued his object till the completion of the edifice, is worthy of record. His first attempts failed in consequence of the enormous pressure of the haunches or sides of the bridge, which forced up the key-stone; and to obviate this, he pierced the stonework with cylindrical apertures, which remedied the defect. Prior to the erection of this bridge, that of the Rialto had the largest span of any in existence.

Metal bridges are the invention of British artists. The true elements of their construction are as yet but imperfectly understood. The Southwark Bridge over the Thames is at present the finest iron bridge in the world. It consists of three arches. The chord of the middle arch is 240 feet long, and its height 24 feet. There are several other fine bridges of this kind in England, in particular one at Sunderland, in the county of Durham.

The art of making suspension bridges is not new, but it is only in recent times that it has been brought to perfection. In this kind of erection the flooring or main body of the bridge is supported on strong iron chains or rods, hanging in the form of an inverted arch, from one point of support to another. The points of support are the tops of strong pillars or small towers, erected for the purpose. Over these pillars the chain passes, and is attached at each extremity of the bridge to rocks, or massive frames of iron firmly secured under ground. The great advantage of suspension bridges consists in their stability of equilibrium; in consequence of which, a smaller amount of materials is necessary for their construction than for that of any other bridge. If a suspension bridge be shaken, or thrown out of equilibrium, it returns by its weight to its proper place, whereas the reverse happens in bridges which are built above the level of their supporters.

The most remarkable suspension bridge in existence is that constructed by Mr Telford over the Menai Strait, between the Isle of Anglesea and Caernarvonshire in North Wales. It was finished in 1825. The roadway was 100 feet above the surface of the water at high tide. The opening between the points of suspension is 560 feet. The platform is about 30 feet in breadth. The whole is suspended from four lines of strong cables, by perpendicular iron rods, five feet apart. The cables pass over rollers on the tops of pillars, and are fixed to iron frames under ground, which are kept down by masonry. The weight of the whole bridge between the points of suspension is 489 tons. There is but one circumstance which appears at all to affect the stability of its equilibrium, and that is, the heavy and measured tread of a long line of military. The whole weight of a number of men, whose feet drop at the same instant of time, would affect any suspension bridge. The striking grandeur of this wonderful work of art cannot be described. The bridge must be visited in order to fully appreciate its beauty, its sublimity, and its other merits.

No. 48. PRICE 1½d.

CHEMISTRY APPLIED TO THE ARTS.

THERE is not an art or manufacture in which the principles of chemistry are not in one way or another employed, and practically illustrated. The applications of chemistry in the arts, manufactures, &c. are indeed so numerous, that we can scarcely do more in this paper than give a short account of the most important of them. In order to render our descriptions as intelligible as possible, we shall in the first place present a brief view of a chemical laboratory, with its various apparatus.

THE CHEMIST'S LABORATORY.

A laboratory is a chemist's workshop. It is the place where he performs his experiments, and is of course provided with all the utensils necessary for doing so. The size of an apartment of this kind necessarily varies with the purpose for which it is constructed. If it is attached to a public institution, it should be large; if for private experimentation, in a very moderately sized room the most important processes of chemical manipulation may be easily performed. It should, if possible, be upon the ground floor, and well lighted and ventilated; a skylight throws a very agreeable and convenient illumination over such an apartment. Shelving should run round the walls for the reception of vessels. The chimney should be high enough to admit of a person standing under it, and as broad as possible. Here the general working furnace, as well as others, both portable and fixed, together with an oven and a sand-bath, may be conveniently placed. It should also be provided with a pair of bellows. The other most essential fixtures are a large table in the centre of the room, on which experiments with the lamp may be performed, mixtures made, and so on. A sink having an abundant supply of water is a very important appendage; for water is continually wanted in chemical operations, both in the performance of experiments and in the cleansing of vessels. It should be placed in a corner of the room, to be out of the way. Cupboards, drawers, small portable tables or stands, blocks of wood, and boxes, are also very useful. The other small moveables, or utensils of a laboratory, are hand-mortars, of iron, glass, agate, and Wedgewood's ware, together with their pestles; earthen, stone, metal, and glass vessels of different kinds; funnels, measures, &c. These we shall describe in course. Filters and troughs are very important, and charcoal is an essential article in the replenishing of a laboratory.

BALANCES AND MEASURES.

Correct weighing is indispensable to every chemical experiment, and therefore an exact and very delicate balance is an essential requisite. There should be at least two balances; one for weighing heavy matters, and another for very minute quantities. The last instrument should be sufficiently delicate to weigh from 600 to 1000 grains, and downwards, indicating, distinctly and certainly, differences equal to the 1-50,000th or 1-60,000th part of the weight in the scale. These small weights are sometimes as low as the hundredths of a grain, and are usually made of platina, because air and moisture do not act upon that metal. As it is by carefully weighing substances, both before and after being experimented upon, that the exact constituent parts of bodies are determined, and the most important chemical truths ascertained, the balance and weights should be carefully examined at intervals, and their accuracy ascertained. The methods of determining the specific gravity of bodies by immersion in water, will be found described in our article upon Hydrostatics.

Measures are necessary for ascertaining the bulk of liquids or gases, and two integers are sufficient, the pint and the cubic inch. Measures should be made of glass, and have a graduated scale marked on both sides. They are commonly of a cylindrical shape, like a phial bottle, and possess a small spout at the orifice. The graduations on these instruments are sometimes very minute, and indicate exceedingly small quantities of matter put into them. The measures should be verified by weighing into them successively portions of mercury and water. A cubic inch of the former, at a temperature of 62°, weighs 3425.35 grains, and the same quantity of the latter at the same temperature weighs 252.458 grains. Water answers well enough for estimation down to the cubic inch, but for the tenths and the hundredths of an inch, mercury is both more exact and more expeditious.

FURNACES, LAMPS, AND BLOWPIPES.

Heat is one of the most powerful and extensively useful agents employed by the chemist for ascertaining the properties of bodies, and the methods of its production become of great moment to him. The most simple way of producing heat is by means of a common fire. Furnaces are more scientifically and elaborately constructed than our common fireplaces and stoves, and a more intense heat is accordingly generated by them. The forms of furnaces are almost innumerable, every month or even week giving birth to some new improvement upon them; but one general principle is kept in view in their construction; that is, the production of the greatest amount of heat by means of the smallest expenditure of fuel. Mr Faraday describes a very cheap and useful furnace which he is in the habit of using, made of clay and plumbago, or black lead, mixed. It is simply a vessel shaped like a common flower-pot, and having holes perforated in its sides for the admission of air. As it is liable to crack after being used, it is bound with iron or copper hoops, or wire. A small portable cast-iron grate is made to fit into it, and repose about two-thirds downwards from the top to the bottom. Charcoal, the fuel employed, is placed upon this grate, and there reposes the crucible with the substance to be experimented on. A funnel pipe may be made to fit upon this furnace, by which means the draught, and consequently the heat, is greatly augmented. This is a very simple form of such apparatus, and can be obtained for a mere trifle. Furnaces upon a larger scale are constructed in various ways of fire-brick, which resists fusion, at least until the temperature is very high. The main object is to produce an immense amount of heat, and this can be accomplished either by propelling air upon the combustible matter by means of bellows, in which case the furnace is called a *blast-furnace*, or by forming long flues and raising a high chimney, so as to produce a strong draught of air; this is termed a *wind-furnace*. The best construction of furnaces has scarcely been ascertained, certain kinds of them being best adapted for certain purposes. Upon the top of the furnace, and even upon the flues, vessels containing sand, and hence called sand-baths, are placed. In these, bodies can be raised to a high degree of temperature. Charcoal is the substance most commonly used in furnaces. It produces an intense heat without smoke, but very soon consumes. Coke or charred coal produces a strong and lasting heat.

A lamp may be considered a species of small furnace, and is a cheap and convenient source of heat. Spirit-lamps, which are trimmed with cotton-wick in the ordinary way, and fed with alcohol, or spirit of wine, are the most useful. The flame of alcohol, which is pale, produces no smoke or fuliginous matter, and the heat which it generates is very intense. Common oil-lamps, and also gaslight, are used, but the heat of such apparatus is not so great. By means of a very simple instrument, the blowpipe, all the effects of the most violent heat of furnaces can be produced. A common blowpipe is merely a glass pipe, about one-eighth of an inch in diameter at one end. The hole gradually lessens until it terminates at the opposite extremity in a very small orifice. Two or three inches of the narrow end are bent nearly at right angles to the longer part of the tube. By placing the thick end of the instrument in the mouth, and urging a stream of air upon the flame of a lamp or candle, an intense degree of heat is produced, which may be brought to bear upon any substance placed in a small spoon of pure gold or platina. If the body to be fused be not of such a nature as to sink into the pores of charcoal, that substance is commonly used. A great many important and beautiful experiments may be performed by this cheap and convenient instrument, but the proper way of blowing it requires practice. If the two gases, oxygen and hydrogen, be mixed together in the proportions which form water, and compressed to the amount of many atmospheres in a metallic box provided with a small tube, what is called an oxy-hydrogen blowpipe is formed. By this apparatus an almost incredible degree of heat can be produced, but accidents often occur in using it.

TRITURATION, FUSION, SOLUTION, DISTILLATION, &c.

As a general principle, having, however, certain limitations, it may be stated, that the more minutely matter is divided, the more rapid will be the chemical action exerted between the particles. This division of matter is effected in various ways. First, by trituration, or the reduction of substances to a state of powder, which is a mechanical action not affecting the physical state of the body, and only relating to solids. In accomplishing this, the pestle and mortar are generally used. Externally, mortars are usually shaped like a flower-pot, the inside, at the bottom, being curved like the thick end of an egg. They are made of various materials, such as metal, porphyry, agate, and so on, according to the purposes to which they are applied. The pestle is generally of the same material as the mortar, and is a solid rod having a rounded bulb at one end for pulverising the substance in the mortar. Trituration answers very well the purpose of promoting chemical action in a number of experiments, but by fusion and solution it is rendered more complete.

Bodies are said to be in a state of fusion, when, heat being applied to them, they assume the liquid form, a state in which all the particles of a substance move easily amongst themselves. When a solid body, such as a piece of sugar, is put into water, it is gradually dissolved; and when the lump of saccharine matter has disappeared, and become mixed with the water, and remain so, it is said to be held in solution by it. Heat greatly promotes the rapidity of solution; and glass vessels having a rounded bottom, such as a Florence flask, and placed upon a spirit-lamp, are very commonly employed. In processes connected with the subdivision of matter, those in which hot water is merely poured upon the substance, the process is called *infusion*; when heat is applied for some time, it is called *decoction*; and when it consists of pouring hot or cold water on the substance, and allowing it to stand for some time, it is termed *maceration*. There is a process of solution called *lixivation*, which consists in the separation of a soluble body from an insoluble one by means of washing.

Distillation and sublimation mean nearly the same thing; both consist in the conversion of a body into vapour, its transference in that state and consequent separation from other substances, and its ultimate condensation. The difference generally consists in the state assumed by the vapours when condensed; if the product be solid, the process is called sublimation; if liquid, distillation. The substance is raised to such a temperature as causes it to assume the gaseous state, in which state it is conducted into a vessel containing water of a low temperature, where it is condensed into a fluid or solid state. A common still consists of a metal boiler for containing the substance to be distilled; a head terminating in a peak is adapted to it; the latter is made to fit into the commencement of a spiral tube, called a worm, fixed in a tub; the whole of this part of the apparatus being called the refrigerator. The substance is raised into vapour in the still, and being condensed in the worm, runs out at its lower extremity. Distillations are usually effected in the laboratory by means of glass retorts and flasks; for substances, however, which require a greater degree of temperature to effect their distillation, metallic retorts are employed. Bodies which are very volatile are distilled or sublimed in an alembic, which consists of a globular bottom and conical-shaped head, whence a nose or beak passes off in a downward direction into a receiver.

FILTRATION, EVAPORATION, &c.

Filtration consists in putting mixed substances into vessels which are porous enough to admit of the passage of one substance through them, but close enough to retain another. Unsized paper, cloth, flannel, tow, sponge, sand, pulverised glass, flints, porous stones, earthenware, and many other substances, are used on different occasions; but the first is almost exclusively used in the laboratory, a few of the others now and then being resorted to only on particular occasions. Evaporation is a process so simple as scarcely to require description; it is merely the assumption of the gaseous form by bodies either at ordinary temperatures, or when heat is applied to them. In this general characteristic it resembles distillation and sublimation, but it differs from these processes in this respect, that the substance evaporated is generally allowed to pass off uncollected by a refrigerator, not being that part of the mixture which is required.

Professor Leslie invented a very ingenious method of evaporation. He placed the substance to be evaporated, along with a vessel containing sulphuric acid, under the receiver of an air-pump. When the air was withdrawn, evaporation went rapidly on; and the sulphuric acid having a strong attraction for water, absorbed the vapour as fast as it was given off, and ice was very soon formed.

The drying of substances, or *desiccation*, as it is usually called in scientific works, may be carried on without exhaustion by means of what is called desiccators or dryers. This is better effected in close vessels than in the open air, unless a current be taken advantage of. In these processes, sulphuric acid, chloride of calcium, carbonate of potash, quicklime, and similar absorbents, may be used. A basin of common quicklime, with a moist precipitate placed above it, the whole being covered with a jar or receiver, will soon dry the precipitate.

CRUCIBLES, RETORTS, TROUGHS.

Crucibles are open vessels which resist very high temperatures. They are made of various shapes, triangular or circular, and of different kinds of materials, but by far the greater number are formed of earthenware. To promote chemical action, what are called *fluxes* (which will be afterwards described) are employed. Now, it is important that the crucible be made of a substance which is not rendered more fusible by a flux. Wedgewood's crucibles are made of a close white ware; and although thin, they are not easily dissolved; and they retain fluxes at moderate temperatures longer than other crucibles. Those made of a mixture of coarse plumbago and clay are also excellent in these respects. But the most valuable in the laboratory are the Hessian and Cornish crucibles. Charcoal and metallic ones are likewise used; those formed of platina being the most generally useful, although they are at first very expensive.

Retorts are vessels employed for many distillations, and most frequently for those which require a degree of heat superior to that of boiling water. This vessel is a species of bottle with a long neck, so bent that it makes with the globular belly of the retort an angle of about sixty degrees. The most capacious part of the retort is called its belly, its upper part the arch or roof, and the bent part the neck. They are composed of different kinds of materials, those of glass being by far the most common. They answer for all operations conducted at temperatures less than that at which glass softens; and from their transparency, they admit of constant observation of the materials within: they are, besides, acted upon or injured by few substances, and may be easily cleaned. To the bent neck of the retort various tubes can be fitted, and the evaporated substance conducted into a refrigerator. For distillations or sublimations requiring great degrees of temperature, metallic retorts are had recourse to. Those made of platina are the most expensive, but by far the most valuable and useful.

A pneumatic trough is a vessel constructed so as to retain water, and large enough to admit of jars being filled in it. Shelves and supports are fixed in it beneath the surface of the water; on these, vessels may be firmly placed. If now a large open-mouthed glass jar be filled with water, inverted beneath the surface of the water in the trough, and put upon one of these stands, a tube from a retort or other distilling vessel, introduced into the inverted mouth of the jar, will bring over the vapoury matter, which displacing the water occupying the jar, can thus easily be collected in it. In this manner gases are obtained. If the jar be provided with a stopcock, they can easily be withdrawn into vessels fitted to retain them. Instead of water, mercury, which is fluid at ordinary temperatures, is used in experiments where water would absorb the gases, or where exceeding nicety is required.

A great variety of other apparatus than those enumerated are either necessary or useful in a laboratory. Electrifying machines, galvanic batteries, air-pumps, syringes, tubes bent into various forms and of different sizes for fitting into the necks of retorts, &c., dishes for holding both solids and fluids, as well as other materials which it is unnecessary to name, are frequently required; but a very convenient small laboratory, where a vast number of remarkable experiments can be performed, may be furnished at very little expense.

TESTS, FLUXES, LUTES, CEMENTS, &c.

Acids and alkalis in a free state possess the power, even in very small quantities, of effecting certain general and regular changes in the tints of some vegetable colours. Accordingly, colours of this description are used for ascertaining the presence of these bodies when in excess or uncombined, and are called *tests*. Litmus and turmeric papers are most generally used. They are prepared by dipping unsized and bibulous paper in solutions of these substances. The litmus imparts a fine blue tinge to the paper, the turmeric a yellow one. In using these test-papers with a fluid suspected to contain free acid or alkali, or knowing that one of these substances is predominant, in order to ascertain which is so, all that is necessary is to moisten the papers with the liquid, and observe the change which is effected; if the fluid be acid, the blue colour of the litmus will immediately become red; if alkaline, the yellow colour of the turmeric will be changed to brown.

A *flux* is a substance made use of to assist the fusion and union of minerals or metals. It acts by protecting the substance from the air, by dissolving impurities which would otherwise be infusible, and by conveying active agents, such as charcoal and reducing matter, into contact with the substance operated upon. Upon a large scale, limestone and fusible spar are used as fluxes; those employed in philosophical experiments are alkaline, and they render the earthy mixtures fusible by converting them into glass. What is called crude flux, is a mixture of nitre and cream of tartar, put into the vessel along with the substance to be fused. White flux consists of the same ingredients, in equal quantities, but they are first deflagrated in an earthen crucible heated red-hot at the bottom. Black flux has the same constituents as the preceding, but the weight of the tartar is double that of the nitre.

Lutes are soft adhesive mixtures, principally earthy, used either for closing apertures existing at the junction of different pieces of apparatus, or for coating the exterior of vessels which have to be subjected to very high temperatures. The lutes employed for junctions pass into the nature of cements, which are substances used for uniting or joining together things of the same or different kinds, so as to form a whole. The best lute used for coating a vessel is made of Stourbridge clay. It is formed into a paste, which should be beaten until it becomes perfectly ductile and uniform, flattened into a cake, and then applied to the vessel which it is wished to coat. The same substance also answers for joining different parts of apparatus together; but there are various other lutes and cements employed for the same purpose. What is called *fat lute* is prepared by beating dried and finely pulverised clay (pipe-clay or Cornish clay) with drying linseed oil, until the mixture be soft and ductile. Caustic lime, when mixed with various mineral and vegetable substances in solution, affords numerous cements and lutes, which become hard when dry, and are impervious to vapours. One of the best is that obtained by using white of egg diluted with its bulk of water. The fluids are to be beaten together until the mixture pours with perfect liquidity. The substance is then to be treated with dry slaked lime in powder, until the mixture assumes the consistency of thin paste. A solution of glue or the serum of blood is sometimes substituted for the white of egg. White lead ground with oil also makes a very useful lute or cement. Soft cement consists of yellow wax (which alone is sometimes used as a cement) melted with its weight of turpentine, and a little Venetian red to give it a colour. When cold, it is hard like soap; but when pressed by the hand, the warmth of the latter renders it pliant.

With these preliminary observations, we shall now proceed to give a brief outline of the principal arts and manufactures in which chemistry has been applied. We shall not treat of these in the order of their relative importance; indeed it would be a difficult matter to determine which is the most important, or most largely contributes to human comfort. But there are a few, the names of which are more familiar to us than the rest, and with these we shall commence.

BLEACHING.

Bleaching is the art by which various articles used for clothing are deprived of the dark colour which they naturally possess, and are rendered white. Bleaching, especially in Egypt, where white linen or cotton was a common article of clothing, must have been early practised by mankind. Pliny informs us that different plants, and the ashes of plants, were used in this art; and Mr Parkes says that lime was employed by the ancients; but according to Dr Thomson,* there is no foundation for this assertion. Until about eighty years ago, the art of bleaching was very little known or practised in Britain, it being customary to send goods to Holland to be purified. About the year 1750, however, a bleaching establishment was set up in the north of Scotland. The process was then long and tedious; but an important change in the method of bleaching took place in 1787, for which we are indebted to the celebrated chemist Berthollet. This was simply the employing of the substance now called chlorine, which possesses a wonderful power of destroying vegetable colours. In the old process of bleaching, the cloth was merely steeped in a potash ley, washed with water, and afterwards with sour milk; then spread out upon the grass, and exposed for months to the action of the solar rays during summer. Without adverting to the various improvements which from time to time were made upon the idea suggested and practically acted upon by Berthollet, we shall describe the process of bleaching as it is now almost universally practised. The bleaching-powder, or chloride of lime, as it is usually called, is manufactured by exposing slaked lime to the action of chlorine gas, till as much of the latter is absorbed as the lime is capable of combining with under these circumstances. Mr Tennant of Glasgow, who discovered the process, prepares it by covering the floor of a stone chamber with a layer of slaked lime, to the height of a few inches. The floor is coated with a cement which is impervious to the chlorine. Above there is an aperture by which the common air can make its escape, the door of the apartment being air-tight and closed. A mixture of native black oxide of manganese, ground to a fine powder of common salt, and of vitriol diluted with water, is put into a large leaden vessel, nearly spherical, and provided at the top with a lid, which fits so as to be air-tight. From this top a leaden pipe passes into the lime chamber, where by this means the chlorine gas is conveyed as it is formed. The leaden vessel is cased in an iron one, a space being left between the two for the purpose of introducing steam to heat the materials after the process has continued for some time. At the beginning this is not required, because the chemical action goes on rapidly; but after the process has continued for some time, in order to decompose the whole of the salt, and disengage the whole of the chlorine gas, it is at last found necessary. Before the bleaching powder is applied to the cloth, it is dissolved in water; and the quantity employed for the first process consists of a solution of twenty-four pounds of the powder to sixty gallons of water. The specific gravity of the solution is 1.02, and the quantity necessary for 700lbs. of cloth is 071 gallons.

In cotton bleaching, the cloth is first boiled in lime-water, one pound of lime being necessary for thirty-five pounds of cloth. After being thus treated, it is carefully washed to remove the lime, and then subjected to the action of the bleaching powder. It is left in this cold solution about six hours, and then taken out and washed with water. The next part of the process is called *souring*, which is immersing the cloth in a solution of sulphuric acid, so diluted that it does not injure the texture of the goods, whilst it improves their colour. The sulphuric acid dissolves and removes the oxide of iron with which the cloth is always contaminated; it also removes the lime which may have attached itself to the cloth during its previous treatment with that substance. It is again washed, boiled in an alkaline ley, and once more carefully washed in cold water. Another solution of bleaching powder, two-thirds the strength of the former, is then prepared, in which the cloth is immersed, and left for five or six hours; it finally undergoes another process of souring, by which means it is rendered perfectly white. The acid is carefully removed by washing; and after each piece of cloth has been stretched to its full length, it undergoes a process of mangling, by being passed successively between cylinders forced towards each other by levers, to which a considerable weight is attached. The cloth being thus stretched, smoothed, and wound upon a roller, is rendered fit for *starching*. The starch is that of flour, deprived of its gluten by remaining for twenty-four hours in water, and then passed through a sieve, which retains the bran, and allows the starch to pass. A little indigo is mixed with it, and sometimes porcelain clay. The starch is applied in the state of a pretty thick paste whilst the cloth is passing between a pair of rollers. The goods are then dried, and passed through a calender for the purpose of giving them a gloss and texture.

Such is the process of bleaching as practised by the great bleaching establishments. The number of processes which the cloth undergoes amounts to about twenty-five, but some of the earlier ones are occasionally omitted. The expense of bleaching and finishing a yard of cotton cloth is about one halfpenny; and with respect to the time required, we state the following circumstance on the authority of Dr Thomson:—A bleacher in Lancashire received fourteen hundred pieces of grey muslin on a Tuesday, which on the Thursday following were returned bleached to the manufacturers, at the distance of sixteen miles, and on the same day they were packed up and sent to a foreign market.

The bleaching of linen is similar to the bleaching of cotton, but more difficult; hence the boiling in an alkaline ley, and the steeping in the solution of chloride of lime, must be repeated three or four times. In general, the linen is exposed to the sun's rays for some weeks, but this part of the process is not essentially necessary. The loss of weight which linen sustains during bleaching amounts to about one-third part of the whole goods; cotton scarcely loses one-tenth—a fact which proves the difference in the difficulty between bleaching the two kinds of cloth.

In the bleaching of wool, as that substance contains an oily matter, the first process is to cleanse it of that grease, by washing the cloth in an ammoniacal ley, which operation is called *scouring*. The ley is made by mixing five parts of soft water with one part of stale purified urine, which contains a considerable quantity of ammonia. This mixture is boiled for a short time, and allowed to cool to about 56°, when the wool is immersed in it. After being stirred for some

* Article *Bleaching* in the Encyclopædia Britannica.

time, it is taken out and rinsed, by exposure in baskets to a stream of running water. After this, the wool is sometimes carried to the fulling-mill, where it acquires an additional degree of whiteness. The above is chiefly employed for the coarser wools, and wool that has yet to be carded for the making of broadcloth; but for the finer kind, it is preferable to use a bath in which soap has been dissolved. The wool is separated into small parcels, immersed in the bath, washed, and dried; it is then deprived of all its natural oily matter by another scouring, after which it is combed before it gets quite dry. After combing, the wool sometimes undergoes several other washings, when the goods are wanted of a very delicate white. For the sake of economy, fullers have long been known to use a clayey matter, well known under the name of *fullers' earth*, which combines with the greasy matter, and renders it more soluble in water. But notwithstanding all this scouring and washing, before the wool can be brought to that brilliant state of whiteness which is frequently required, it undergoes a process called sulphuring, which is simply the exposing of the goods to the fumes of burning sulphur in a close chamber. The sulphureous acid destroys any colouring matter which remains, and the vapour itself is removed by washing. Properly scoured wool has its filaments smooth, long, and slender, white, perfectly free from foreign substances, and without having lost their natural tenacity. Dutch wool is generally considered the purest; the English is next in quality, but it is foulder and harsher than the former; the German is still more so, and the French is inferior to them all.

BLEACHING OF SILK.

Silk is bleached in two ways. By the first method, it is deprived of the yellow varnish which adheres to it in a raw state. By the second, this is retained, in order to give it that stiffness which is required for gauzes, blondes, &c. In the first process, the silk undergoes a scouring similar to that described as necessary for cleansing wool. For every hundred pounds of silk, thirty pounds of soap are dissolved in water, and boiled; but before the silk is put in, the solution must be cooled down to about 90°, at which temperature it is kept during the process. The silks are suspended in the liquor by rods or frames; and after the gum is destroyed, they are taken out, wrung, put into bags containing about thirty pounds each, and again steeped in a fresh bath, and boiled for two or three hours. After this the silks are wrung as before, and washed with water. The blue tinge of silk is imparted to it by litmus and indigo dissolved in a bath at 90°. A tolerably clear white is imparted to silk by these processes; but it receives its highest degree of purity by the action of sulphureous acid, either in the state of vapour, as formerly described, or, as is usually practised, by immersion in the diluted liquid acid.

Rags for the paper-maker are bleached by means of the bleaching powder, after having been well washed in an engine for the purpose. Yellow wax is now bleached white by being subjected for an hour or two to the action of chlorine gas. Chlorine has also been applied to the whitening and cleaning of prints, maps, books, and other articles of paper. For this purpose, simple immersion in liquid chlorine, letting the article remain in it a longer or shorter period according to the strength of the liquor, will be sufficient to whiten an engraving. When bound books are required to be cleaned, the leaves must be carefully separated, so that the liquid may act upon both sides of the whole of them; and the boards may be easily made to rest upon the sides of the vessel, so that only the paper enters the liquor. The latter assumes a yellow tint, and the leaves of the book become white in proportion. In three or four hours the process of whitening is completed, and the book is then plunged in pure water, for the purpose of extracting the acid and destroying the disagreeable smell. Chaptal, a celebrated chemist, first suggested this method of cleaning books and papers, and by it several of the most valuable works of the French national library have been restored.

DYEING.

Dyeing, in the limited and more proper signification of the term, is the art of imparting colours to wool, silk, feathers, cotton, or flax, or the thread or cloth formed of any of these substances. This art was practised at a very early period, and probably originated in Egypt or in India. In the time of Moses dyeing had made great progress in the former country. At a very remote era it had arrived at a state of high perfection in Phœnicia, and the *purple* of Tyre passed into a proverb. The dye used was extracted from certain species of shell-fish. The fine colours given to cotton cloths in India are well known; the methods of doing so are not modern inventions, but were practised in that country when it was visited by Alexander the Great. That conqueror had, we are informed by Pliny, transplanted the art into Greece. But it would appear that neither amongst the Greeks nor the Romans was it carried to any great degree of perfection. Amongst the moderns, the first attempt at methodical arrangement of the different processes was made in a work published at Venice in the year 1429. The art was greatly advanced by the introduction of indigo and cochineal into Europe, although the importation of the former substance was at first prohibited in England and other countries. The reason of these restrictions was, that pastel and woad, which were European productions, being employed for dyeing blue, it was supposed that indigo would supersede their use, and destroy one branch of native industry. Under the administration of Colbert, dyeing was greatly encouraged in France; but the revocation of the edict of Nantes, in 1685, was a fatal blow to the pre-eminence of France in the arts and manufactures. The most skilful workmen were driven from the kingdom, and carried their knowledge into Britain and other countries. As chemistry began to be more generally studied, and to assume the character of a distinct science, dyeing gradually advanced towards that high state of perfection in which we now find it. Within the last thirty years, great improvements have taken place, and many new dye-stuffs have been introduced; but we can only in this place give a brief view of the best methods of dyeing the most important articles, without adverting to the period at which the discoveries of the various processes were made.

A remarkable circumstance connected with dyeing is the different degrees of facility with which animal and vegetable substances imbibe the colouring matter applied to them. Tissues composed of the former, as silk and wool, receive more brilliant colours than those composed of the latter, as cotton and linen. The cause of this is unknown; it is usually ascribed to the superior attractive power of animal bodies for tinging matter, but still the interrogatory, what is the *cause* of this, remains to be responded to.

MORDANTS.

Although in a great many cases it is easy to impart colour to various tissues, yet when these become exposed to moisture, the dye-stuff is removed. It has therefore been found necessary to employ certain chemical substances, which shall have the property of permanently fixing the colour upon the body which is dyed. These substances have obtained the name of mordants (from the Latin word *mordere*, to bite), because they were supposed at first, figuratively speaking, to bite the dye into the cloth. The same name has also been applied to those preparations which possess the property of altering the shade or of heightening the colour, as it is called. The latter, at the suggestion of Berthollet, are sometimes termed *alterants*. The principal mordants are alumina, employed universally, we believe, in the form of a salt, as that of alum; the oxides of tin, employed like the former in the shape of salts; they are prepared by dissolving tin in muriatic acid. Silk and woollen dyers, however, employ nitric acid or aqua-fortis for forming the salts of tin which they use. The salts of lead and copper are likewise had recourse to as mordants, and the nut-gall, which contains two very peculiar vegetable substances, tannin and gallic acid, is not only employed as a mordant, but also as a powerful dye-stuff.

By varying the mordant, a great variety of shades may be derived from the same colouring matter. Indeed, the mordant itself, in many instances, supplies a colour. For example, in dyeing with cochineal, when the aluminous mordant is employed, the colour produced is crimson; but when oxide of iron is substituted for the alumina, a black colour is the result. The whole phenomena are accounted for on the principle of chemical affinity or attraction. The mordant employed should have an attraction both for the stuff to be dyed and the colouring matter, and act as it were like a third party in reconciling two inimicals. The way in which it is used must depend entirely upon the degree of affinity exerted between the stuff and the colouring matter. Where that is slight, the former should be saturated with the mordant before the latter is communicated. A knowledge of the chemical affinities and habits of the substances used is necessary before mordants can be had recourse to as a medium of union in imparting colour to cloths or other stuffs which we wish to dye; for by an indiscriminate use of them, results the very opposite of those anticipated may take place. Practice, or a thorough knowledge of chemistry, is essential to success.

It were impossible in this place to present a perfect account of the various methods of dyeing different stuffs of different colours; all we can do is to mention some of the most useful and important of them.

TO DYE RED.

The principal colouring matters used in dyeing red are madder, cochineal, kermes, lac, archil, carthamus, Brazil wood, and logwood. Madder is the root of a plant; cochineal is the name given to a small insect, a native of Mexico; kermes and lac are also animal substances; the remaining four dye-stuffs belong to the vegetable kingdom.

Wool.—In the dyeing of woollen goods a mordant is necessary; that one is employed which will produce the peculiar tint required. Coarse stuffs are dyed with madder, after being boiled for two or three hours in a solution of alum and cream of tartar; five ounces of the former and one ounce of the latter to each pound of wool is recommended, but the proportions are varied according to the shade of colour wanted. The quantity of madder used varies very considerably. Some employ one-third of the weight of the wool; others use more or less, according to circumstances. In dyeing with madder, the bath should not be boiling. When it is at a temperature which the hand can bear, Hellot recommends the addition of half a pound of grape madder for every pound of wool to be dyed. It must be well stirred before the wool is introduced, and must remain an hour without boiling.

Scarlet is the finest and most splendid of all colours, and is communicated to woollen stuffs by means of cochineal. They are first boiled in the following manner:—For one hundred pounds of cloth, six pounds of pure tartar are added to the water, which is made pretty warm. After being stirred and heated a little more, half a pound of powdered cochineal is introduced, and the whole is then well mixed. As the bath begins to boil, the cloth is introduced, and boiled for two hours, when it is taken out, washed, and again put into the bath, which has in the meantime been emptied and replenished with five pounds and three quarters of cochineal. When a crust has formed upon the surface, after the stirring has ceased, a quantity of the solution of tin (some use twelve or fourteen pounds) is poured in. The cloth is boiled for an hour, then withdrawn and washed. A shorter process is, not to remove the cloth in the first instance, but merely to refresh the bath with a new supply of ingredients. To impart to scarlet a bright fiery red, a little turmeric may be added to the cochineal; to increase the brightness of the hue, a little common salt is used, and sometimes a small quantity of quercitron bark. Every shade of scarlet may be obtained by varying the proportions of the ingredients. To dye crimson by a single process, a solution of two and a half ounces of alum, and an ounce and a half of tartar, for every pound of stuff, is employed for the boiling; and the stuff is afterwards to be dyed by an ounce of cochineal. It is usual also to employ a solution of tin, but in smaller proportions than those required to produce scarlet. Archil and potash deepen the colour of crimson, but the bloom imparted is extremely fugacious. Different substances, such as the alkalis, alum, and earthy salts in general, convert the colour of scarlet to crimson, which is the natural colour of cochineal. For dyeing fine woollen cloth, the lac dye is commonly used. It contains less colouring matter, but it is a great deal cheaper than cochineal. The tin mordant used is made by dissolving two ounces of tin in thirty pounds of aqua-fortis, mixed with one pound of muriatic acid.

Dyeing of Silk.—Silk may be dyed red in the following manner:—Half a pound of alum is to be dissolved in each quart of hot water employed, and two ounces of potash are afterwards to be added. When the liquor has become clear, the silk is put in, and kept there for two hours; it is then taken out and put into a madder bath. By the following process, a fine crimson hue is imparted to silk:—The silk is cleaned by washing and beetling. The bath is prepared by filling a large boiler two-thirds with water, to which are added, when it boils, from half an ounce to two ounces of powdered white galls for every pound of silk. When it has boiled for a few seconds, from two to three ounces of powdered cochineal for every pound of silk are put in, and afterwards one ounce of tartar to every pound of cochineal. After the tartar is dissolved, one ounce of solution of tin is added for every ounce of tartar. For the solution of tin, Macquer (a great French chemist) recommends the following proportions:—For twelve ounces of water there should be one pound of nitric acid, two ounces of sal ammoniac, and six ounces of fine grain tin. When these ingredients are mixed together, the boiler is to be filled up with cold water; and the proportion of the bath for every pound of silk is about eight or ten quarts of water. In this the silk is immediately immersed, and turned on the winch till it appear to be of a uniform colour. The bath being kept boiling for two hours, the fire is then put out, and the silk removed to the dye-bath, where it remains a few hours longer; then it is taken out and washed. Various shades of red are produced by employing carthamus. A scarlet colour is obtained by soaking silk for two hours in a solution of murio-sulphate of tin, diluted with five times its weight of water. After being partially dried, it is immersed in a bath prepared with four parts of cochineal, and three of quercitron bark. If the latter dye-stuff is omitted, a rose-colour will be obtained.

Cotton and Linen.—The processes of dyeing these two vegetable products are the same. The brightest and most substantial red is that called Turkey red. The cloth, after having been steeped in a weak alkaline ley, is put into a liquor composed of the following ingredients:—One gallon of Gallipoli oil; one and a half gallons of soft sheep dung; four gallons of solution of carbonate of soda of the specific gravity 1.06; one gallon of solution of pearl-ash of the specific gravity 1.04; cold water being added so as to make twenty-two gallons. After the cloth is dried and steeped in a weak solution of pearl-ash, it is immersed in a ley somewhat similar to the preceding, which process is repeated thrice, then washed in a mixed ley of pearl-ash and soda. Galling is the next step. Let eighteen pounds of Aleppo galls be boiled in twenty-five gallons of water, till the whole is reduced to twenty gallons; this is sufficient to impregnate one hundred pounds of cloth; after this, it undergoes a process of aluming. To a solution of alum in water, of the specific gravity 1.04, as much pearl ash, soda, or chalk, is added as is sufficient to precipitate the alumina contained in the alum. Through this muddy liquor, which should have a temperature of from 100° to 120°, the cloth is steeped and pressed for twelve hours. By this means the cloth becomes readily impregnated with the alumina, after which it is stove-dried, and then put into the dyeing-bath. From one to three pounds of powdered madder for every pound of cloth is employed, the quantity being determined by the shade of colour wanted. The cloth is put into the boiler when cold, and boiled for two hours. For every twenty-five pounds of cloth dyed, one gallon of bullock's blood is indispensably requisite for obtaining a fine red colour. The cloth then undergoes a *clearing process*, as it is called, by being boiled for twelve hours or so in one of the saponaceous leys formerly employed. Lastly, it is boiled under a pressure of two atmospheres, in a solution consisting of six pounds of soap and about eighteen ounces of proto-chloride of tin. Such are the several processes by which this beautiful and permanent colour is fixed on cloth. The scarlet and crimson hues are imparted to cotton and linen by means of cochineal, but they are by no means permanent.

DYEING YELLOW.

The principal colouring matters used in dyeing yellow are weld, fustic, catechu, annotto, and quercitron. Weld is the dried leaves of a plant that grows wild in Britain, and different other European countries; fustic is the wood of a West India tree; catechu is obtained from certain East India plants; annotto is the product of an American berry; and quercitron is the bark of a large tree which grows spontaneously in North America.

To Dye Wool.—A pure and permanent yellow is obtained by dyeing woollen stuffs with weld, the mordants being alum and tartar. The boiling is to be conducted in the usual way, as already described under the head dyeing of red. According to Hellot, four ounces of alum [illegible] one ounce of tartar are to be employed. From [illegible] four pounds of weld may be allowed to every pound of stuff. The addition of common salt or sulphate of lime to the weld, communicates both a richer and deeper colour. By boiling the stuff two hours, with one-fourth of its weight of a solution of tin, and the same proportion of tartar, and then washing and boiling it with the same proportion of weld, a fine yellow is obtained. Different shades are produced either by the addition of other substances, or by varying the proportions of those above mentioned. Equal weights of quercitron bark and alum, boiled in a suitable proportion of water, form a cheap and excellent yellow dye. The colour may be heightened by passing the cloth through hot water impregnated with fine chalk. To obtain the most permanent colours, the stuff should be boiled for about an hour with one-seventh of its weight of alum dissolved in a proper proportion of water. The stuff is then to be immersed in the dyeing-bath, and turned through the boiling liquor until the proper colour is obtained. A little clean chalk added to the bath a short while before the operation is discontinued, will be found to improve the colour.

Orange yellow is produced in a short space of time, by making a bath of hot water, and putting in ten pounds of quercitron bark for every hundred pounds of stuff, and after a few minutes adding eight or ten pounds of murio-sulphate of tin. Golden yellow, and the various other shades of yellow, may be produced by varying the above-named substances; a greenish tinge may be imparted by the addition of a little tartar or verdigris, dissolved in vinegar. The colours produced by quercitron bark are very durable.

Dyeing Silk Yellow.—Weld was the only substance formerly employed to dye silk yellow; but Dr Bancroft informs us that all the shades of yellow may be imparted to it by means of quercitron bark. From one to two pounds of powdered bark for every twelve pounds of silk is put into the dyeing-vat while cold, and when heated to 100°, the silk, having previously undergone an aluming process, is to be immersed and dyed in the ordinary way. Pearl-ashes deepen the shade, and a little murio-sulphate of tin produces a more lively yellow. Silk is dyed of an orange shade by employing annotto; but the stuffs must be reddened with vinegar or alum. These colours, however, are not permanent.

Dyeing Cot[illegible]d Linen Yellow.—Amongst the various methods of dyeing cotton yellow, we can only afford the following one by Dr Bancroft, and it is one of the best:—One pound of sugar of lead is to be dissolved in a sufficient quantity of warm water. The cotton or linen, after being properly rinsed, is to be soaked in this mixture, heated to the temperature of 100°, for two hours. It is then taken out and moderately pressed over a vessel, to prevent the waste of the aluminous liquor. It is then dried by stove heat, and after being again soaked in the aluminous solution, it is wrung out and dried a second time. Without being rinsed, it is to be barely wetted with lime-water, and afterwards dried; and if a full, bright, and durable yellow is wanted, it may be necessary to soak the stuff in the diluted aluminous mordant, and after drying, to wet it a second time with lime-water. After it has been soaked for the last time, it should be well rinsed with clean water.

In the preparation of the dyeing-bath, from twelve to eighteen pounds of powdered quercitron bark are inclosed in a bag for every hundred pounds of the stuff, the proportions being varied according to the shade required. The bark is put into the water whilst it is cold; the stuff is then immersed, and the heat slowly increased till the bath boils, at which temperature the stuff must only remain for a few minutes. It is then taken out, rinsed, and dried.

In the East, a plan similar to that followed in dyeing Turkey red is practised. After the usual preliminary steps are taken, the cloth is dyed with quercitron bark. In this country, these processes can be superseded, and as beautiful and permanent a colour given to cotton by impregnating it with acetate or nitrate of lead, and then passing the cloth through a solution of bichromate of potash.

DYEING BLUE.

The grand dye-stuff used for imparting a blue colour to cloth is indigo, which is a vegetable product of India.

Wool.—Into a vat put four hundred pounds of pastel or woad (which, before the introduction of indigo, was the substance used in dyeing blue), and let thirty pounds of weld be boiled in a copper vessel for three hours, in a sufficient quantity of water to fill the vat. Add to the decoction twenty pounds of madder and a basketful of bran. Continue the boiling for half an hour longer, then cool the copper with water, take out the weld, and after the liquid has settled, pour it into the vat, which is stirred for half an hour, and then covered up in a hot state, and allowed to remain so for six hours. It is then uncovered, stirred again for thirty minutes, which process is repeated every three hours until blue streaks appear on the surface, when eight or nine pounds of quicklime are added, and from ten to thirty pounds of indigo, according to the intensity of the hue required. The vat stands several days, and great care must [illegible] taken to cover it closely up, and to put in a proper [illegible]antity of lime; if too much lime be added, the necessary fermentation is retarded; and if there be too little, the putrifactive process commences.

Into a dyeing solution prepared as above described, the stuff to be coloured is put after having been wetted with pure water a little heated; there it is moved about until the proper tinge required is imparted to it.

To produce a Saxon blue colour on woollen stuffs, they are prepared with alum and tartar, and in proportion to the shade required the quantity of solution of indigo put into the bath must be regulated.

Silk.—Silk is dyed blue with indigo alone, without any woad. It is first boiled with soap, and well cleaned with repeated beetlings in a stream of water. Only small portions should be immersed in the bath at a time, and the silk, when taken out, should be put upon a frame kept constantly in motion. To produce Turkey blue, a strong bath of archil or cochineal is prepared, and the cloth passed through it. A blue is given to silk by means of verdigris and logwood, but it possesses little durability.

Cotton and Linen.—Of the various processes of dyeing these stuffs, the following simple one is followed at Rouen in France. The vats, which are constructed of a kind of flint, are coated within and without with fine cement, and are arranged in one or more parallel lines. Each vat contains four hogsheads of water. The indigo, to the amount of eighteen or twenty pounds, being macerated for a week in a caustic ley strong enough to bear an egg, is ground in a mill; three hogsheads and a half of water are put into the vat, and afterwards twenty pounds of lime. The lime being thoroughly slaked, the vat is raked, and thirty-six pounds of copperas are added; and when the solution is complete, the ground indigo is poured in through a sieve. It is raked seven or eight times the same day; and after being left at rest for thirty-six hours, it is in a state fit for dyeing. The colour denominated English blue is produced by the solution of indigo in sulphuric acid. This compound, improperly called sulphate of indigo, has hitherto only been used in dyeing wool and silk, and cannot advantageously be applied to cotton or linen.

DYEING BLACK.

The principal substances which are employed to give a black colour are gall-nuts, which contain tan, and the red oxide of iron. Oak bark, which contains the same astringent principle, has been used, especially in dyeing hats. Logwood is employed to give a lustre to black colours. The black colour is produced by the combination of the astringent principle with the oxide of iron held in solution by an acid, and fixed on the stuff.

Wool.—English dyers use the following proportions of ingredients in dyeing wool black:—For every hundred pounds of cloth previously dyed a deep blue, about five pounds of sulphate of iron, five pounds of galls, and thirty of logwood, are necessary. The first step in the process is to boil the cloth in galls, after which it is passed through the decoction of logwood, to which the sulphate of iron has been added. It is then washed in a river, fulled, and dried.

Silk.—In dyeing silk black, it is first boiled with soap; then with three-fourths of its own weight of galls for three or four hours; after this the liquor remains at rest for two hours; the silk is then put into the bath, where it lies from twelve to thirty-six hours, and is then taken out and washed. To communicate what is called heavy black, silk is allowed to remain longer in the gall liquor. The bath should al[illegible]ays be kept below the boiling point; and the gum and solution of iron are added to it in proportions varying, according to the different processes. To remove the harshness which attaches to silk after it has been dyed, it is washed in a soapy solution. Velvet is dyed black in much the same manner.

Cotton and Linen.—After undergoing galling, these stuffs are put into a bath containing iron liquor, which is a solution of iron in acetic acid. Five quarts of this liquor for every pound of stuff is requisite. The cotton is wrought with the hand, pound by pound, for fifteen minutes, and then taken out, wrung, and aired. The operation is repeated, a fresh supply of liquor having been put in, after which the stuffs are taken out. In the next operation, a pound of alder bark for every pound of stuff is boiled in a sufficient quantity of water for an hour. One-half of the bath which was employed in the galling, and about one-half the quantity of sumach as of alder bark, are then added. The whole is boiled together for two hours, and strained through a sieve. When this liquid is cold, the stuffs are immersed, wrought pound by pound, and occasionally aired. They are afterwards put into the bath, and after remaining for twenty-four hours, are wrung out and dried. The above is a process, which, according to D'Apligny, is followed at Rouen for dyeing cotton and linen. The process followed at Manchester, though it differs from the above in some respects, is upon the whole so nearly similar to it that we need not detail it in this place.

DYEING BROWN.

A great number of vegetable substances are capable of producing a fawn or brown colour on different stuffs, but those mostly used are walnut peels and sumach. The peels constitute the green covering of the nut; they are internally of a white colour, which is converted into brown or black by exposure to the air. Sumach is a shrub produced naturally in several parts of Asia and Europe. Bark of birch, sandalwood, or soot, are likewise capable of producing a fawn or brown colour.

Berthollet made a number of experiments to ascertain the difference of colour obtained from the simple decoction of walnut peels and the addition of metallic oxides as mordants. The oxide of tin, he found, yielded a clearer and brighter fawn colour than that of the simple decoction. The oxide of zinc produced a still clearer colour, inclining to ash or grey. The colour from oxide of lead had an orange cast, while that from oxide of iron was of a greenish brown.

A fawn colour which has a shade of green is obtained from sumach alone; but to cotton stuffs which have been impregnated with printers' mordant or acetate of alumina, sumach communicates a good and durable yellow.

Such is a view of the most approved methods of dyeing the simple colours, and compound ones are formed by mixtures of them, and different shades are obtained by different proportions. Mixtures of blue and yellow form green; and to dye green, the stuff is first immersed in one of these colours, and then in the other. By the mixture of red and blue, there are obtained violet, purple, dove-colour, lilac, and a great variety of other shades. Yellow and red form orange, and by the mixture of black with other colours, brown, grey, hazel, puce colour, marone, and other dyes, are produced.

CALICO PRINTING.

Calico printing is the art of impressing different colours to particular parts of the surface of cloth, chiefly cotton and linen, whilst the rest of the fabric is allowed to retain its white colour, or any other colour which may have been communicated to it, as blue or yellow. There are two methods of doing this; first, by block printing; and, secondly, by cylinder printing. The former is a very ancient invention. The figure which we wish to communicate to the cloth is cut upon a block of sycamore; thus making in fact a large woodcut. For fine lines, pieces of copper are ingeniously indented in the block. The cylinder is a large circular copper plate, being a circular ruler several feet long, and several inches in diameter, upon which the different figures to be given to the cloth are engraved. A circular motion is given to it, by which means the whole of these figures are impressed upon the cloth as it moves under the cylinder. In every case the treatment of the goods is nearly the same.

In general, the printing process is applied to fixing mordants on the cloth, which is afterwards dyed in the usual way, those parts which have received the mordant only retaining the colour, the other remaining white. In some cases the colour is removed from certain portions of cloth already dyed, so that they may either remain white, or receive some new colour afterwards. Sometimes it is applied to cloth before it is dyed blue, in order to prevent the indigo from being fixed on those parts to which it is applied, that they may remain white, or receive other colours afterwards. Substances possessed of this property are called resist-pastes. Lastly, it is frequently employed to communicate mordants and colouring matter at once to cloth. As the mordants employed for different dye-stuffs, and the substances which are had recourse to for producing the different colours, have already been amply detailed under bleaching, it is unnecessary to recapitulate what has been already stated, or enter further into detail in this place.

SOAP-MAKING.

The well-known and useful article soap is a compound of certain principles in oils, fats, or resin, with a salifiable base. If this base be potash or soda, the compound is used as a detergent in washing clothes. When an alkaline earth, or oxide of a common metal, such as lead, which forms litharge, &c. is the base, the compound is insoluble in water. The insoluble compounds, however, are very little used, except in some few cases of surgery. Dr Ure thus writes of soaps and saponification:—

"Fats are compounds of a solid and a liquid substance, the former called *stearine*, the latter resembling vegetable oil, and therefore called *elain*. When fat is treated with a hot ley of potash or soda, the constituents react on one another, so as to generate the solid pearly matter, *margaric acid*, and the fluid matter, *oleic acid*, both of which enter into a species of saline combination with the alkali; while the third matter that is produced, the *sweet principle*, remains free. We must therefore regard our common soap as a mixture of an alkaline margarate and oleate, in proportions determined by the relative proportions of the two acids producible from the peculiar species of fat. It is probable, on the other hand, that the soap formed from vegetable oil is chiefly an oleate. No chemical researches have hitherto been made known on the compounds of resin with alkalis, though these constitute the brown soaps so extensively manufactured in this country. All oils or fats do not possess in an equal degree the property of saponification." In general, the only soaps employed in commerce are those of olive oil, tallow, lard, palm oil, and rosin.

Olive Oil Soap is thus manufactured:—To one hundred parts of olive oil, twenty parts of that of rape-seed are added. These require about fifty-four parts of the soda (barilla) of commerce, and three parts of barilla require one of quicklime. After bruising the soda and slaking the lime, they are mingled, and cold water is poured upon the mixture. This is run off at the end of twelve hours, and is called the first ley. Two other leys of a weaker description are successively obtained from it. After a sufficient quantity of ley is made, the soap-boiling commences. Large boilers are used, which have in all cases a pipe at the bottom, two inches and two-thirds in diameter, called the thorn (*epine*, French). Weak ley is first put into the boiler, then the oil is gradually added, and the mixture boiled. After the combination is effected, which is in a short while, the fire is tempered, and weak ley and oil successively added, taking care to keep the mass in a state of equal consistency throughout. When all the oil which we wish to saponify has been poured in, some strong ley is slowly added, which completes the saturation of the oil, converting the emulsion with an oily excess into a perfect soap, which separates from the ley and floats upon the surface. The ley is withdrawn by the pipe; fresh leys are added, and the fire rekindled, by which means the perfect saturation of the oil with alkali is effected. The soap is of a blue colour, and is converted into white, by mingling it gradually with dilute leys, and applying a gentle heat, allowing deposition to take place with a covered boiler. It is now taken out and run into wooden frames, where it hardens in cooling. From these it is finally removed and cut into bars. This soap is known in France under the name of soap in tables (*savon en table*), and, according to M. Thenard, it consists of soda 4.6 fat matter 50.2, water 45.2 in 100 parts.

Hard Soap is made in Scotland chiefly with kelp and tallow That crude alkali rarely contains more than from one to five per cent. of free soda, mixed with some sulphate and hydrosulphate, and nearly thirty-three per Cent of muriate of soda. To every ton of kelp broken into small fragments, about one-sixth of new-slaked lime is added. The whole after mixture is put into a large tub called a cave, having a perforation at the bottom, shut with a wooden plug. Upon the materials water is very slowly poured. The liquid, after digestion, is suffered to run slowly off into a reservoir sunk in the ground. The first portion, or ley No. 1, is of course the strongest, and is reserved for the last operation in soap-boiling. Six days are required to make one boiling of soap, in which two tons or upwards of tallow may be employed. The leys 2 and 3, mixed, are used at the beginning diluted with water, on account of the excess of sea-salt in the kelp. A quantity of ley, not well defined, is poured on the melted tallow, and the mixture is boiled, a workman agitating the materials to facilitate the combination. The fire being withdrawn, and the aqueous liquid having subsided, it is pumped off, and a new portion is thrown in. A second boil is given, and so on in succession. Two or three boils are performed every twelve hours, for six days, constituting twelve or eighteen operations in the whole. Towards the last, the stronger ley is brought into play. Whenever the workman perceives the saponification perfect, the process is stopped, and the soap is lifted out and poured into the moulds.

Soft Soaps.—The compounds of fats or oils with potash, remain soft, or at least of a pasty consistency. There are three kinds known in commerce—the soaps from rape-seed and other oleaginous seeds, called green soaps; those made with hogs' lard, called toilette soaps; and the common soft soaps made with fish oils. We can only afford space for an account of the method of manufacturing the latter, as practised by an eminent soap-boiler near Glasgow. Whale or cod oil to the amount of two hundred and seventy-three gallons is put into a boiler alongst with four hundred-weight of tallow, and two hundred and fifty-two gallons of potash ley. On heat being applied, the mixture froths up very much, but means are adopted to prevent its boiling over. There are then added at intervals fourteen measures of stronger ley, each measure holding twenty-one gallons. After suitable boiling without agitation, the soap is formed, amounting in all to one hundred firkins of sixty-four pounds each, from the above quantity of materials.

TANNING.

Tanning is the art by which the hides and skins of animals are converted into leather, by being macerated with lime and water, to promote the separation of the hair and wool, and of the fat and fleshy parts, and then saturated with certain astringent principles, particularly the bark of the oak-tree, which contains the vegetable principle called tannin. The process, though it may be shortly described, is long and laborious. The hide, which consists for the most part of gelatin, is deprived of its hair, fat, &c. by being soaked in water, handled and trodden, and then immersed in milk of lime. Some use an acescent infusion of barley or rye meal, or spent tan, instead of lime, and others recommend the application of sulphuric acid in a very dilute state. Similar acidulous waters are made use of to raise or swell the hide when this is required. The hides are then put into a cistern made in the ground, alongst with ground oak-bark, the whole being disposed in regular layers, covered with half a foot of tan, and well trodden down. A little water is found to accelerate the tanning. Sir H. Davy recommends the slow tanning of leather, and the application of weak infusions of bark. By this treatment it appears that the leather is softer and stronger than when it is tanned by strong infusions.

POTTERY.

Pottery is intimately connected with chemistry, not only on account of the nature and preparation of the materials of which vessels are formed, but also from the way in which they are fired and glazed, and colours and engravings applied to them. The art, as may be inferred from its close connection with the most common processes of domestic economy, is of the very highest antiquity; but instead of describing either the bricks of Babylon, or the exquisitely fashioned vases of Greece or Egypt, and tracing from age to age, and from clime to clime, the various steps of improvement by which it has arrived at its present state, we prefer giving a brief view of the methods of manufacture as now practised in Britain. The chief ingredients used in the composition of all kinds of pottery are alumina and silica, or clay and flint. The clay principally used in the potteries of Staffordshire, an English county famous for its manufactures of this description, is brought from Dorsetshire and Devonshire, the former being considered as the best for the potter's use. These clays are each of two kinds: that of Dorsetshire is distinguished into brown clay and blue clay; that of Devonshire into black clay and cracking clay. The good qualities of brown clay are, that it burns of an excellent white, and is not liable to crack during the process of burning. It is subject, however, to an imperfection, technically called crazing; that is, cracking of the glaze. Blue clay is incomparably the best of them all. It burns very white, forms a solid species of ware, and combines with the greatest quantity of siliceous earth, for upon this depends the whiteness of the ware; the limit to the use of flint being the inability of the clay to bear it in combination beyond a certain proportion without cracking. Black clay owes its distinctive character to the presence of coaly matter, which, however, dissipates during the firing, and leaves the articles of which it is composed of a good white. Cracking clay is so called, because it is liable to crack during the first application of fire; but the goods made of it are of an extreme whiteness. A species of clay found in Cornwall, and denominated China clay, is much prized for the manufacture of the finer kinds of earthenware and porcelain; and steatite, or soapstone, has of late years been much used for the same purpose.

The first operation is to mix the clay in the purest water to the consistence of cream. In large establishments this is done in the most effectual manner by means of machinery. The pulp is then run through a series of sieves of increasing degrees of fineness, which are worked to and fro by machinery; thus the clay is refined as well as more thoroughly mixed. Flint is first burnt, and then pounded to small pieces, and ground fine in a mill with water. The dilution of clay is considered of the proper consistency for mixing when a quantity that will fill a pint measure weighs twenty-four ounces; and that of the flint is held equally suitable for use when the same bulk of it weighs thirty-two ounces. It is by a comparison of their relative densities that the manufacturer is enabled to ascertain the real proportions of the materials, and to combine them in the degrees which his experience leads him to employ for the composition of various kinds of pottery; and too much nicety can hardly be given to this important part of his labours. After this the mixture is passed through sieves, deprived of its impurities, and brought to a state of uniformity and homogeneousness throughout. It is then slowly dried on flues to the consistency of paste, cut into pieces of a moderate size for lifting, and well incorporated together or tempered, as well as deprived of its air-bubbles, by being beat with wooden mallets, and otherwise wrought. It should then be allowed to remain in a mass for a considerable time. What the relative proportions of clay and flint in pottery are, it is scarcely possible to state. Each manufacturer has his own, which he considers the best, and accordingly keeps a profound secret from every body. Vauquelin informs us that silex forms at least two-thirds of all kinds of pottery; alumine from one-fifth to one-third; lime from 1-500th to 1-2000th part; and iron from the smallest quantity up to twelve and even fifteen per cent.

After the clay has been brought to a proper state of consistency, it undergoes the operation of throwing; that is, it is shaped into vessels of a circular form by a machine called a potter's lathe. The piece of clay is placed upon a piece of wood, which is made to wheel round by a simple piece of machinery driven with the hand; and as it revolves, the potter forms it into a vessel of the proper shape wanted. The article is then partially dried for a day or two, and receives a further smoothing and polishing on the turning-lathe of the potter, which is exactly similar to that used by the turner of wood. Knives and other instruments are employed for paring and smoothing the vessel; and at this stage of the process it is furnished with handles, spouts, and other requisite appendages. For making circular dishes, plates, saucers, or shallow bowls, a plaster mould is placed upon the first lathe, and the articles are formed upon it. Ornamented spouts and handles are formed by being cast in two moulds of plaster of Paris, one-half of the figure being impressed in each of the moulds, which must fit exactly. Small ornaments in relief, which project on the sides of vessels, are first cast in moulds, and then fixed on by the parts which are to be united being moistened. The moulds used for plates, and various other kinds of dishes which are formed by pressing, are simple in their construction; but others which are used for the third department, that of casting, require much skill for their invention and execution. Casting is performed by pouring the mixture into the mould, whilst the former possesses the consistency of cream. The plaster of Paris, which has a remarkable affinity for water, quickly absorbs the liquid, and a coating of clay remains in the mould; another portion of dilute clay, but of a firmer consistency than the former, is poured in after the first has been allowed to dry; and the mould is then set in a stone, and the article removed from it when sufficiently dry to admit of separation.

Firing and Glazing.—After the vessels are brought to a state when they can undergo the first process of firing, they are placed in circular boxes made of fire-clay, called *seggars*, and which are capable of standing the most intense degree of heat without being fused. Their office is to protect the ware from the direct application of flame, and from smoke; by this means, also, the heat is more uniformly applied. Methods are adopted to keep the articles in the seggars separate from each other. A great number of these are arranged together in a cylindrical oven; and here they are baked for about fifty hours, then gradually cooled. From the similarity of its appearance to well-baked ship bread, the ware is now called *biscuit*, in which state the substance which is to impart the glaze is applied to it. It is then put into what is called the glass oven, disposed in seggars in the same way as formerly, and fired, till, by the fusion of the substance with which the vessels have been covered, they acquire a glazed surface. The glaze usually employed for common kinds of earthenware is compounded of litharge of lead and ground flints, in the proportion of ten parts by weight of the former to four parts of the latter. This mixture is called the raw glaze, and is given to vessels by their being dipped in a solution of it, of the consistency of cream, and then sent to the oven, as already described. The glazes are varied to suit the different materials of which the ware is formed, and every manufacturer has his own. Those for porcelain and the finer kinds of earthenware are generally made with white lead, ground flints, ground flint-glass, and common salt; Lynn sand, combined with soda as a flux, being frequently added. The different colours observable on the outer surface of drinking-jugs and other articles, is owing to the partial use of a glaze, the part to which this is applied becoming dark in the heat of the kiln, whilst the glazing of the light-coloured portion is caused by the introduction of salt. This acts in a similar manner to a mordant, as described under dyeing.

Painting and Engraving.—So refined and philosophical is now the process by which painting on earthenware is effected, that in some measure it deserves the name of a science. Metallic oxides form the bases of all vitrifiable colours; but they must be combined with a flux to promote their fusion, and the composition of the flux varies according to the means employed for diluting the colours at the time they are used. Where a volatile oil is chosen for this dilution, a flux composed of glass, nitre, and borax, is most proper; but when gum-water is substituted for this oil, a compound of glass, lead, and silex, is preferable. The former menstruum consists of powdered glass, forty parts; calcined borax, twenty-two parts; and refined nitre, forty-four parts. These ingredients are pounded in a mortar, and then fused into a mass in a crucible. By this flux the colours are fixed upon the porcelain, and made to assume a resplendent appearance; the metallic oxides being enveloped by the flux, are preserved from all contact with the air, and their colour is rendered permanent; the fusion taking place at a temperature too low for their destruction. Metallic oxides which would have their colours altered by a strong or often repeated heat, are employed after being mixed with their flux, but without having been previously fused with it. In many cases metallic oxides are first fused with the requisite proportion of their flux, and are then ground for use.

Enamel is glass made opaque by the oxide of tin, and made fusible by the oxide of lead. All glasses that contain lead participate in the properties of enamel. Raw glasses used for covering tender porcelain are of this nature. The colours employed in painting this porcelain are those which serve for painting in enamel; they require less flux than others, because the surface to which they are applied becomes soft enough to be penetrated by them. Hard porcelain, whose nature is identical with those of China and Saxony, has two kinds of colours applied to it. Those of the first kind, which are used in the representation of different objects, are baked by a heat much below that necessary for porcelain; whilst the other colours, which are few in number, must be exposed to the highest degree of temperature required by the porcelain itself. The glaze used for hard porcelain has little lead in its composition. In some manufactories feldspar instead of lead is employed. We may now shortly describe how the different colours are produced. Purple and violet colour are obtained by dissolving gold in aqua regia, and immersing a bar of pure tin in the solution. Violet colour is likewise made with the purple oxide of gold, requiring the presence of some portion of lead in the flux, for the developement of this shade. Red oxide of iron, prepared by the united action of fire and nitric acid, yields a red colour, which, although beautiful, is less so than that produced from gold. A very permanent red colour is obtained by calcining the oxide of iron with double its own weight of common salt. To obtain a *yellow* colour, white oxide of antimony, mixed with sand and oxide of lead, are employed, the latter substance serving as a flux to the others. Blue colours are obtained from cobalt; green from copper; black from iron; straw colour from chromium; Naples yellow from antimony and lead. By a mixture of the different kinds of oxides, a great variety of shades may be obtained.

The process of transferring printed designs to earthenware, may be shortly described. The landscape or pattern is engraved on copper, and the colour, which is mixed with boiled linseed oil, is laid on the plate in the same manner as ink is applied by copperplate printers. To increase the fluidity of the oil, the plate is then temporarily placed in a stove, a sheet of damped tissue paper is laid on it, and both are passed in the ordinary manner through the press. The paper wet with the colour is then reduced in size, by cutting away the blank part surrounding the pattern, and applied to the ware when in the state of *biscuit*. The paper after being well rubbed, so as to press the colouring matter into the article, is removed after having been dipped in a cistern of water. It comes easily off, leaving the impression entire. The ware is then placed in an oven for the purpose of dissipating the oil, preparatory to its receiving the glaze.

The great excellence of the porcelain manufactured in China is proverbially well known. The inhabitants of that country employ in the composition of this article two kinds of earths, and two oils or varnishes. Of the earths, one, which is called kao-lin, is found intermixed with particles of a shining substance resembling mica; the other is known by the name of pe-tun-tse, and is of a brilliant white, exceedingly fine in its grain, and soft to the touch. The two substances described as oil or varnish are procured, one from a combination of pe-tun-tse with another mineral substance, and the other from lime. It is the kao-lin which gives strength and body to the porcelain. Its constituents are found to be, silica, 52.; alumina, 42.; oxide of iron, 0.33. It would be useless to detail the processes by which the Chinese manufacture their ware, as they are nearly similar to our own. For the finest porcelain, equal quantities of the two minerals are intimately mixed in the usual way; and kao-lin is diminished, to form a coarser description of ware. The manufactories are of great extent, and the heat employed in baking and glazing the articles is immense. The designing of the Chinese is most execrable. Any blind asylum in Europe could produce better artists than they appear to possess.

GLASS-MAKING.

Glass is a substance too well known to require definition. Many authorities concur in assigning the merit of the invention to the Phœnicians, and the discovery, as indeed is very likely, has been attributed by Pliny to accident. The ancient Egyptians were well acquainted with the manufacture of this substance; and the glasshouses of Alexandria were long famed for the skill and ingenuity displayed by their workmen. Some are of opinion that glass-making was known to the *Druids of Britain*, but it would appear that our regular instructors in this art came from beyond seas in the seventh century, for the purpose of glazing the windows of the church and monastery of Weremouth in Durham. But the art made only slow progress amongst us; it has now, however, been brought to a high state of perfection, and is a source of considerable national revenue.

The glass of commerce is always composed of some silicious earth, the fusion and vitrification of which has been occasioned by certain alkaline earths or salts, and sometimes by the aid of metallic oxides. There are five qualities of glass:—*First*, flint-glass or crystal; second, crown or German sheet glass; third, broad or common window-glass; fourth, bottle or common green glass; and fifth, plate-glass. In giving an account of the methods of manufacturing these several compounds, one remark we shall make, which applies to the whole of them. Whilst the general processes may be depended upon as pretty nearly the same for each, the proportions of the ingredients used by different manufacturers for forming the same kind of glass vary very considerably. As we observed with respect to earthenware, each has his own recipes, and considers them as infinitely superior to those of other brethren of the trade. One fact, however, may be relied upon as essential to every kind of glass, the presence of silica and an alkali. The latter is used in the form of a carbonate, the carbonic acid flying off during the manufacture, and the result being a compound of the two substances mentioned. The variations of quality and distinctive differences observable in glass, principally result from the kind of alkali employed, and its degree of purity, as well as from the addition of other necessary ingredients, such as nitre, oxide of lead or of manganese, white oxide of arsenic, borax or chalk. Nitre, which is used in small proportions, is employed for the purpose of destroying any carbonaceous matter which may be present in the other materials. This salt is added previous to the fusion of the glass. At a degree of heat much below that of the furnace, nitre decomposes, giving out a great quantity of oxygen, which maintains the metallic oxides in their highest states of oxygenation. It is thus of use in fixing arsenic, the volatile property of which increases as it approaches the metallic state. Oxide of lead, either in the form of litharge or red lead, enters largely into the composition of flint-glass. This metal acts, in the first place, as a most powerful flux; and it also imparts valuable properties to the glass, of which it forms a part, rendering it more dense, more tenacious when red-hot, more capable of bearing uninjured sudden changes of temperature, and more efficacious in refracting the rays of light. The black oxide of manganese has a singular effect upon glass. When added in a moderate proportion to any simple glass, it imparts a purple colour; if the quantity be increased, the glass will acquire a hue nearly black. If, whilst the mass thus coloured is still in fusion, either white arsenic, or charcoal, or other carbonaceous matter, be added, an effervescence follows, the colour disappears, and the glass gradually becomes clear and transparent. Manganese is employed to counteract the green hue of glass, and the moment that the proportion put in is more than sufficient, the purple colour appears, and is corrected by thrusting a piece of wood into the melted glass, which causes the purple to vanish. If nitre be added, the purple hue is restored. Manganese and arsenic are both also used as powerful fluxes; and arsenic, like nitre, destroys any carbonaceous matter present. Borax is principally used in preparing the finest kinds of plate-glass. Lime in the form of chalk is used as a very cheap flux.

Flint-Glass or Crystal.—Messrs Aikin state that a very excellent article may be made from one hundred and twenty parts of fine clean white sand, forty of well-purified pearl-ash, thirty-five of litharge or red lead, thirteen of nitre, and a small quantity, to suit the tinge wanted, of the black oxide of manganese. These, after having been mixed together, are put into pots made of Stourbridge clay, which have previously been brought to a white heat. After vitrification has been effected, and the glass has cooled down to a proper state of consistency, a hollow tube about three feet long, called the *punty*, is dipped into it, upon which the proper quantity of material wanted for the article to be manufactured is collected. It is rolled upon a square mass of cast metal, the tube is blown into, and the fluid mass expands to the dimensions required, when by various means it is fashioned into different shapes. Glass does not suddenly assume the solid state, but remains some time in a condition fit for working, affording ample opportunities for giving to it every shape which fancy or taste may suggest. After the vessel is formed, it is put into an oven, where it is annealed, a process of very great importance, as without it glass would be liable to fly to pieces with the smallest change of temperature, or shiver with the slightest scratch. Annealing is simply a very gradual cooling, by which it would appear that the whole of the particles of the glass had an opportunity of arranging themselves at equal distances from each other. By sudden cooling, the external particles would be forcibly contracted, whilst the inner substance would remain soft and expanded. Some crystal vessels are afterwards ground into various tasteful shapes.

Crown-Glass.—The name of crown-glass is given to the best kind of glass commonly used in making windows, and for similar purposes. It has no metallic flux in its composition but manganese, and cobalt in small quantities is frequently used for correcting the colour. The following mixture is stated as forming a very superior quality of crown-glass:—White sand, one hundred and twenty parts; purified pearl-ash, sixty; saltpetre, thirty; borax, two; and arsenic, one. If the colour is yellow, it may be corrected by adding a little manganese. When these ingredients are fritted, that is, calcined in a furnace previous to vitrification, they are put into a crucible and melted. As in the case of flint-glass, a punty is dipped in and collects a quantity of glass. This dipping is repeated until nine or ten pounds of metal are attached to the end of the hollow tube, which is now blown into, and expanded into a globular form. The side opposite to the end of the tube is then flattened upon a plane surface, a small portion of glass is collected upon the end of another punty, and is applied to the centre of this flattened side, forming an union with it exactly opposite to the hollow tube, which is then removed by wetting the glass near to their points of union, leaving a circular hole in the glass about two inches in diameter. At this period the glass must be again held to one of the openings of the furnace until it has become sufficiently hot and ductile for the further alteration of its shape. The workman then dexterously twirls the punty in his hand, slowly at first, and then more and more quickly, when the glass yields to the centrifugal impulse; its diameter becomes greater and greater; the hole just mentioned expands proportionally; and when in this continued progression, the doubled portion opposite to the iron rod, and between the periphery of the glass and the orifice, is diminished to a ring only a few inches wide; this instantly flies completely open, and the glass is converted into a plane disc of fifty to sixty inches diameter, having a uniform thickness throughout the entire plate, with the exception of the spot where it is attached to the iron rod, and where there is a knot or lump, which is called a bull's eye. Twelve of these plates make up what is called a crate or [illegible] of glass.

The effect of this operation upon persons who witness it for the first time, is both pleasing and surprising in a high degree. The force wherewith the glass flies open at the close of the process would be sufficient, if its brittleness were not removed by heat, to break it into innumerable fragments. The plate, when thus finished, is detached from the rod in the usual manner, and placed, resting on its edge, in the annealing oven.

Broad-Glass is a coarse description of the article, which it is unnecessary to describe.

Bottle-Glass.—More than one-half of the entire manufacture of glass in Great Britain is composed of common green bottle-glass. The composition of the article is not at all uniform, but varies almost with every different manufactory. Loysel gives the following proportions, as those usually employed in France for the production of the material:—Common white or yellow sand, 100 parts; coarse kelp, 30 to 40; lixiviated earth of ashes, 160 to 170; fresh wood or other ashes, 30 to 40; yellow clay, or brick earth, 80 to 100; broken glass *ad libitum*, usually 100; which composition does not produce what is called glass gall.

At Newcastle-upon-Tyne, where the manufacture of bottle-glass is much encouraged by the excessive cheapness of small coal, or slack, the manufacturers employ a mixture of lime and sea-sand. This must be frequently wetted with sea-water, which, on evaporating, deposits its salt; the soda contained in this being the only alkali employed. When combined with silica, and exposed to a high degree of heat, lime appears to be endued with the property of decomposing common salt; its presence is therefore essential to the success of this operation.

Articles made of bottle-glass are fashioned by the same process as those made of flint, with the exception of wine and beer bottles, the containing parts of which are blown in metallic moulds, in order to keep them nearly of an uniform size. The green colour of this glass is owing to the presence of a portion of iron in the sea-sand, and probably, also, in the vegetable ashes of which it is composed.

Plate-Glass.—There are two kinds of plate-glass. One is made by blowing, the other by casting the melted materials upon a plane metallic surface, somewhat in the method followed in making sheet-lead. Plates of glass which are blown are necessarily limited in their size, although some of considerable dimensions are produced in this way. When cast, the extent of the plates may be much greater, and, indeed, is limited only by the very heavy expense attending the erection of machinery, and the prosecution of the manufacture in its various parts.

The well-known property of borax as a powerful flux has occasioned the suggestion that by its means glass made with potash might be caused to flow in fusion as freely as that wherein soda is employed. It has been asserted that small quantities of borax have always been used in the works at St Gobain; but the secrecy observed in regard to all the operations carried on in that establishment, renders it impossible to say what degree of truth there is in the assertion. Great care is required in mixing the materials, much more indeed than is called for in regard to other kinds of glass. The sand, lime, soda, and manganese, being properly intermingled, are fritted in small furnaces, where the temperature is gradually raised to a full red or even to a white heat, at which point it is maintained; and the materials are carefully stirred until vapour is no longer given off, and no further change is undergone by the substances. This process of fritting lasts about six hours; and when it is nearly completed, the remaining part of the ingredients, consisting of the cobalt and broken glass, are added.

When the melted glass which has been taken from the furnace and put into the cuvette (a vessel for holding it) is found to be in the exact state that experience has pointed out as being most favourable for it flowing readily and equally, this vessel is withdrawn from the furnace by means of a crane, and is placed upon a low carriage, in order to its removal to the casting-table. Measures are then taken for cleaning the exterior of the crucible, and for carefully removing with a broad copper sabre any scum that may have formed upon the surface of the glass, as the mixture of any of these foreign matters would infallibly spoil the beauty of the plate. These done, the cuvette is wound up to a sufficient height by the crane; and then, by means of another simple piece of mechanism, is swung over the upper end of the casting-table; and being thrown into an inclined position, a torrent of melted glass is suddenly poured out on the surface of the table, which must previously have been heated, and wiped perfectly clean. When the plate of glass thus formed has been sufficiently fixed by cooling, it is slipped from the table gradually and carefully into one of the annealing-ovens, where it remains in a horizontal position. The plates have then to undergo all the operations of squaring, grinding, polishing, and silvering, in order to fit them for sale.

MANUFACTURES IN METALS.

Amongst the manufactures in metals, by far the most important are those of iron and steel. Iron is rarely found in a native state, but generally in combination with combustible bodies, particularly sulphur, or as an oxide or salt. Of all the iron ores, iron pyrites is the most universally distributed; but other three kinds of the metal are likewise brought back to the metallic state by certain chemical processes. They are first roasted in large heaps in the open air, for the purpose of expelling the sulphur and arsenic with which they are commonly combined, and also to facilitate their reduction. The roasting is assisted by the combustion of coal or charcoal. The ore is then transported to the smelting furnace, where it is converted into iron by the application of a powerful heat. That form of the metal called cast or pig-iron, is obtained by exposing the ore, mixed if necessary with limestone as a flux, to the action of carbon at an elevated temperature in a furnace urged by bellows. The metal is reduced to a metallic state by being fused in a furnace, in which coke is the fuel employed. These furnaces are called *puddling furnaces*. The operation commences with melting down the cast-iron in refining furnaces. When it is properly fused, a tap-hole is opened in the crucible, and the metal flows out into a fosse bedewed with water mixed with clay, which forms a coating to prevent the metal from sticking to the ground. After being cooled with water to make it brittle, and also to oxidise it slightly, it is broken into pieces, piled up in a reverberatory furnace; it is again melted, and cooled more than once, formed into balls, and condensed under rolling cylinders.

Steel.—The following method of making steel was communicated to Dr Ure by an extensive manufacturer of Monkland.—"The chests or troughs in which the iron bars are stratified are nine feet long, and composed of an open-grained silicious freestone unalterable by the fire. The Dannemora or Oregrounds iron is alone employed for conversion into steel at Monkland. The increase of weight is from four to twelve ounces per hundredweight. The average is therefore one in two hundred and twenty-four parts. The first proportion constitutes mild, and the second very hard steel. Should the process be pushed much farther, the steel would then melt, and in the act of fusion would take a dose of charcoal sufficient to bring it to the state of No. 1 cast-iron. The charcoal used in stratifying with the bar-iron is raised, so as to pass through a quarter-inch riddle. Whenever the interior of the troughs arrives at 70° Wedgewood, the carbon begins to be absorbed by the iron. There is no farther diminution of the weight of the charcoal than what is due to this combination. What remains is employed at another charge. Great differences are found between the different kinds of bar-iron imported at the same time, which occasion unexpected differences in the resulting steel." It is further added, that cast-steel is made by being fused in a crucible *without* charcoal, which corrects a common error that carbon is indispensable in its manufacture.

The various uses to which iron and steel are adapted are too numerous to be here entered upon; indeed they scarcely lie within the limits of our subject.

Of the other metals, tin, lead, and copper are the most important in a commercial point of view. The county of Cornwall is remarkable for the variety and value of its mineralogical productions, and, amongst the rest, tin is found, and occurs in veins or fissures, locally called *lodes*, in considerable quantities. In one of the largest smelting establishments, culmcoal is used as the flux, in the proportion of about one-eighth to the ore, of which nearly six hundred hundredweight is smelted within six hours, and yields about three hundred and fifty hundredweight of tin. The tin is run like iron from the furnaces, and is shaped into blocks or pigs. The uses of tin are very numerous, and so well known that they scarcely need to be pointed out. A very important application of tin is in the coating of other metals, such as those of iron and copper, which have been formed into vessels. The silvering of looking-glasses, and the fabrication of a great variety of vessels and utensils for domestic and other uses, are among the advantages derived from this metal.

Lead.—This valuable metal is found in various parts of Great Britain, and occurs as an ore. It is first roasted to expel the sulphur, arsenic, &c.; then smelted in furnaces, and cast into long bars in iron moulds. The diversity of uses to which lead is applied in the ordinary arts and manufactures, is by far too great to admit even of enumeration.

Copper.—This metal is found, like tin, abundantly in Cornwall. Of tin ores there are hardly more than four or five, but those of copper are almost innumerable. The processes in a copper work are simple; they consist of alternate calcinations and fusions. By the former, the volatile matter is expelled, and the metals previously combined with the copper oxidised, the general fusibility of the mass being thereby increased. The furnaces in which these operations are carried on are reverberatory, and of the usual construction. This metal it is well known is applied to a great variety of uses, but it is to its combinations with other metals that we must more particularly attend.

Brass.—This is a compound metal consisting of copper and zinc, in the proportion of two of the former to one of the latter. The best brass is made by the cementation of calamine, which is the ore of zinc, with granulated copper.

Bell Metal is a compound of copper and tin, which becomes not only more sonorous, but heavier, than either of the ingredients apart. The proportions differ; in general, however, twenty-three pounds of tin are mixed with a hundred pounds of copper, the latter being somewhat increased when the bells are large. Brass, spelter, and even lead, are sometimes added, and more rarely silver, which is considered much to improve the tone of the bell.

Bronze is a mixed metal, of which copper is the principal ingredient, and a small proportion of tin. Bronze, composed of from eight to twelve parts of tin, combined with one hundred parts of copper, becomes an alloy much harder than copper, less liable to rust, and so fusible as to run thin, and be easily cast in a mould. Bronze is used for making statues, cannon, and other articles, in all of which the proportions of the ingredients vary.

Pewter.—This is a compound of tin and copper, the latter being in the proportion of about one part to twenty of the former. Other metallic ingredients are sometimes added, according to the experience of the workman, as lead, zinc, bismuth, and antimony. Dr Ure says there are three sorts of pewter, distinguished by the names of plate, trifle, and ley-pewter. The first was formerly much used for plates and dishes; of the second are made the pints, quarts, and other measures of beer, so common in London; and of the ley-pewter, wine measures and large vessels in general. The pewterers are anxious to unite in their wares the greatest degree of hardness with a white or silvery colour, and it is this which has led to such a diversified use of the above-mentioned ingredients. Various objections have, at one time or other, been raised against the large intermixture of lead or copper in the composition of culinary utensils, and not without reason, when the articles are intended to be subjected to heat. As a precaution against any poisonous properties, the more tin pewter contains, the better it is undoubtedly; on the other hand, it is worse as it contains lead in excess; not, however, that any deleterious effects are to be apprehended in the latter constitution of the alloy, as usually exhibited.

Britannia Metal is made by an alloy of $3\frac{1}{2}$ cwt. best block-tin, 28 lbs. martial regulus of antimony, 8 lbs. of copper, and 8 lbs. of brass. The amalgamation is effected by melting the tin, and raising it just to a red heat in a stout cast-iron pot or trough, and then pouring into it, first, the regulus, and afterwards the copper and brass, from the crucibles in which they have been respectively melted; the caster meanwhile stirring the mass about during the operation, in order that the mixture may be complete. The fusion of the whole being completed, by the continual application of the fire for a short time under the pot, the liquid metal is in the next place transferred therefrom, by means of large iron ladles, to the casting-boxes, which are composed of cast-iron, and give to the metal poured into them the form of a slab fifteen inches long, by six inches wide, and one inch thick. It is likewise put into other moulds, forming small ingots, for the convenience of being used in the casting of such articles as are not made out of the sheet metal.

Type Metal.—The metal used by the typefounder is a composition consisting chiefly of lead and regulus of antimony, with a little tin, and sometimes other ingredients. The chief object of mixture is to obtain perfect fluidity, so that the counterpart of the matrix shall come away sharp and perfect; moreover, that the letters shall be hard enough to wear well, and stand to their work firmly, without at the same time becoming brittle; a type, however, will break sooner than bend.

PRECIOUS METALS.

By this appellation gold and silver are commonly denoted. The simplest method of obtaining gold consists in collecting the grains or small particles from the beds of rivers, especially after rains, which bring down fresh matter from the mountains. The dust and grains of gold are smelted in Brazil with a flux of muriate of mercury; the furnaces are heated with charcoal, and the contents of the crucibles are poured into iron ingot-moulds, holding about thirty-two pounds of the metal. Gold is afterwards purified by being submitted to the processes of infiltration, parting, and quartation; by the former process the refiner gets quit of every particle of lead or other inferior metallic alloys, and by the latter, separates any portion of silver which might remain intermixed with the gold.

Silver is a much more plentiful product than gold. It is found both in a metallic state or in the shape of an ore, of which there are numerous varieties. It is extracted from these either by smelting in the usual way, or by amalgamation. The method of extracting silver from lead, with which it is often combined, is to expose the mixture to a strong heat in the open air. The lead becomes gradually oxidised, and separates from the pure silver. Native alloys of the precious metals are sometimes, but not frequently, met with. Besides their practical application in the arts and manufactures, and their use in the fabrication of goods of various kinds, silver and gold, it is well known, form the most valuable portion of the circulating medium of almost every country.

GILDING AND SILVERING.

Gilding and silvering are the arts of covering the surfaces of bodies with gold or silver; and to give an idea of the processes, we shall confine ourselves to gilding. Gold for painting must first be reduced to powder, in which state it is called shell-gold. For gilding by friction, a piece of linen rag must be steeped in a solution of gold, taken out, dried, and then burned to tinder. The article to be gilt must be well polished. A piece of cork is then dipped, first in a solution of salt water, and afterwards into the black powder. The article is then to be rubbed with it. For water-gilding, the solution of gold must first be evaporated and suffered to crystallise, and the crystals dissolved in water. This is copiously diluted with alcohol, and iron is gilded by being steeped therein. Sulphuric ether is used instead of alcohol for gilding steel. For Grecian gilding, equal parts of sal ammoniac and corrosive sublimate are dissolved in nitric acid, and a solution of gold made in this menstruum, which is concentrated. Silver becomes black when this is applied to it; but if subjected to a red heat, it assumes the appearance of gilding. Silver, brass, or copper, may be gilt by an amalgam, as follows: Eight parts of mercury and one of gold are incorporated by heat. When the gold is dissolved, the mixture is poured into cold water, when it is fit for use.

COLOUR-MAKING.

This is a subject by far too extensive to be entered upon in this paper. Colours are obtained from a variety of sources, but metallic oxides generally yield the best and most permanent. Under the heads dyeing, calico-printing, and pottery, we have mentioned what those metals are from which different colours are obtained, and also what vegetable substances yield the most beautiful descriptions of colouring matter.

GUNPOWDER.

Dr Ure thus describes the manufacture of this well-known compound:—"This explosive substance consists of an intimate mixture, in determinate proportions, of saltpetre, charcoal, and sulphur; and is better in proportion, every thing else being equal, to the quality of these ingredients. The nitre, in particular, ought to be perfectly refined, by successive crystallisations, and finally freed from adhering water, by proper drying, or by fusion in iron pots at a regulated heat. Nothing can surpass in these respects the nitre prepared in the government powder-works at Waltham Abbey. It is tested by adding to its solution in distilled water, nitrate of silver, with which it occasions no perceptible opalescence. The sulphur ought also to be of the finest quality, and purified by skimming, or even sublimation, if at all necessary. The charcoal should be newly made; it should burn without having any sensible residuum, be dry, sonorous, light, and easily pulverised. The charcoal for gunpowder is made either of alder, willow, or dogwood—the latter being preferred—which are cut into lengths, and ignited in iron cylinders. It deserves notice that the proportion of powder used for the several pieces of ordnance by the navy, &c., has been reduced one-third, in consequence of the increased strength of the composition into which this cylinder charcoal enters, compared with that manufactured formerly from charcoal made in pits. The wood, before charring, is carefully stripped of its bark.

The three ingredients being thus prepared, are ready for manufacturing into gunpowder. They are first separately ground to a fine powder, which is passed through proper sieves or bolting-machines; 2d, They are mixed together in the proper proportions. These do not seem to be definitely determined, for they differ in different establishments of great respectability, as is shown in the following table:—

	Nitre.	Charcoal.	Sulphur
Royal mills at Waltham Abbey	75	15	10
French, for war . .	75	12.5	12.5
for sportsmen .	78	12	10
for mining . .	65	15	20
Chaptal's proportions .	77	14	9
Chinese do. . . .	75.7	14.4	9.9
Mr Napier's do. . . .	80	15	5

3d, The composition is then sent to the gunpowder-mill, which consists of two edgestones of a calcareous nature, turning by means of a shaft on a bedstone of the same nature, which give no sparks, as sandstones would be apt to do. On this bedstone the composition is spread, and moistened with as small a quantity of water as will, in conjunction with the weight of the revolving stones, bring it into a proper body of *cake*, but not of *paste*. The line of contact of the edgestone is constantly preceded by a scraper, which goes round with the wheel, constantly scraping up the cake, and turning it into the track of the stone. From fifty to sixty pounds are usually worked at once in each mill-wheel. When the cake has been thoroughly incorporated, it is sent to the corning-house, where a separate mill is employed to form the cake into grains or corns. 4th, Here it is first pressed into a hard firm mass, then broken into small lumps; after which the graining is executed, by placing these lumps in sieves, on each of which is laid a disc of *lignum vitæ*. The sieves are made of parchment-skins, perforated with a multitude of round holes. Several such sieves are fixed in a frame, which by proper machinery has such a motion given to it as to make the *lignum vitæ* runner in each sieve move round with considerable velocity, so as to break the lumps of the cake, and force the substance through the sieves, forming grains of several sizes. These granular particles are afterwards separated from the finer dust, by proper sieves and reels. 5th, The corned powder is next hardened, and the rougher edges taken off, by being revolved in a close reel or cask turning rapidly on its axis. This vessel somewhat resembles a barrel-churn; it should be only half full at each operation, and has frequently square bars inside, parallel to its axis, to aid the polish by attrition. 6th, The gunpowder is now dried, which is done generally by a steam-heat, or by transmitting a body of air, slightly heated in another chamber over canvass shelves covered with the damp gunpowder.

GLUE.

Glue is an inspissated jelly, made from the parings of hides and other offals, by boiling them in water, straining through a wicker basket, suffering the impurities to subside, and then boiling it a second time. The articles should first be digested in lime-water, to cleanse them from grease and dirt; then steeped in water, stirring them well from time to time; and lastly, laid in a heap, to have the water pressed out before they are put into the boiler. Some recommend that the water should be kept as nearly as possible to a boiling heat, without suffering it to enter into ebullition. In this state it is poured into flat frames or moulds, then cut into square pieces when congealed, and afterwards dried in a coarse net. It is said to improve by age; and that glue is reckoned the best which swells considerably without dissolving by three or four days' infusion in cold water, and recovers its former dimensions and properties by drying. Shreds or parings of vellum, parchment, or white leather, make a clear and almost colourless glue.

INK.

Although ink may be obtained of almost any colour, yet we are only familiar with two kinds, black and red. Of black ink there are three principal kinds, Indian ink, printers' ink, and writing ink.

Indian Ink.—This article is used in China for writing with a brush, and for painting upon the soft flexible paper of Chinese manufacture. It is ascertained, as well from experiment as from information, that the cakes of this ink are made of lampblack and size, or animal glue, with the addition of perfumes or other substances not essential to its quality as an ink. The fine soot from the flame of a lamp or candle, received by holding a plate over it, mixed with clean size from shreds of parchment or glove-leather not dyed, will make an ink equal to that imported.

Printers' Ink.—This is a black paint, smooth, uniform in its composition, and very tenacious. Linseed or nut oil are employed in its manufacture, and lampblack is the common material used for giving the black colour, of which two ounces and a half are sufficient for sixteen ounces of the oil, which must first be boiled down to the consistency of varnish. Vermilion gives a red colour. Ten or twelve gallons of the oil are set over the fire in an iron pot, capable of holding at least half as much more; for the oil swells up greatly, and its boiling over into the fire would be very dangerous. When it boils, it is kept stirring with an iron ladle; and if it do not itself take fire, it is kindled with a piece of flaming paper or wood; for simple boiling, without the actual accension of the oil, does not communicate a sufficient degree of the drying quality required. The oil is suffered to burn for half an hour or more, and the flame being then extinguished by covering the vessel close, the boiling is afterwards continued with a gentle heat, till the oil appears of a proper consistence; in which state it is called varnish. It is necessary to have two kinds of this varnish, a thicker and a thinner, from the greater or less boiling, to be occasionally mixed together as different purposes may require; that which answers well in hot weather being too thick in cold, and large characters not requiring so stiff an ink as small ones. The thickest varnish, when cold, may be drawn into threads like weak glue; by which criterion the workmen judge of the due boiling, small quantities being from time to time taken out and dropped upon a tile for this purpose. It is very viscid and tenacious, like the soft resinous juices, or thick turpentine. Neither water nor alcohol dissolve it; but it readily enough mingles with fresh oil, and unites with mucilages into a mass diffusible in water in an emulsive form. Boiling with caustic alkali produces a soapy compound. It is by washing with hot soap-leys and a brush that the printers clean their types. The oil loses from one-tenth to one-eighth of its weight by the boiling into the thick varnish. It is affirmed that varnish containing either turpentine or litharge, particularly the latter, is more adhesive than other varnish, and presents a great difficulty in cleaning the types, which soon become clogged. Very old oil requires neither of these additions. New oil can hardly be brought into a proper state for drying, so as not to set off, without the use of turpentine.

Writing Ink.—The following is considered an excellent recipe for the manufacture of this useful liquid:—Take eight ounces of Aleppo galls (in coarse powder); four ounces of logwood (in thin chips); four ounces of sulphate of iron; three ounces of gum-arabic (in powder); one ounce of sulphate of copper; and one ounce of sugar-candy. Boil the galls and logwood together in twelve pounds of water for one hour, or till half the liquid has evaporated. Strain the decoction through a hair sieve or linen cloth, and then add the other ingredients. Stir the mixture till the whole is dissolved, more especially the gum; after which, leave it to subside for twenty-four hours; then decant the ink, and preserve it in bottles of glass or stoneware, well corked. Inks of other colours may be made from a strong decoction of the ingredients used in dyeing, mixed with a little alum and gum-arabic. For example, a strong decoction of Brazil wood, with as much alum as it can dissolve, and a little gum, forms a good red ink. These processes consist in forming a lake, and retarding its precipitation by the gum.

Sympathetic Inks.—These are inks by which any thing written with them may be invisible when first traced upon the paper, but can be rendered visible at will by certain means, such as the application of heat. By these inks the most amusing experiments may be performed. Dr Ure mentions the following as amongst the number of those which a slight knowledge of chemistry may suggest to the student:—

"1. If a weak infusion of galls be used, the writing will be invisible till the paper be moistened with a weak solution of sulphate of iron; it then becomes black, because these ingredients form ink. 2. If paper be soaked in a weak infusion of galls, and dried, a pen dipped in the solution of sulphate of iron will write black on that paper, but colourless on any other paper. 3. The diluted solutions of gold and silver remain colourless upon the paper, till exposed to the sun's light, which gives a dark colour to the oxides, and renders them visible. 4. Most of the acids or saline solutions being diluted, and used to write with, become visible by heating before the fire, which concentrates them, and assists their action on the paper. 5. Diluted prussiate of potash affords blue letters when wetted with the solution of sulphate of iron. 6. The solution of cobalt in aqua regia, when diluted, affords an ink which becomes green when held to the fire, but disappears again when suffered to cool. This has been used in fanciful drawings of trees, the green leaves of which appear when warm, and vanish again by cold. If the heat be continued too long after the letters appear, it renders them permanent. 7. If oxide of cobalt be dissolved in acetic acid, and a little nitre added, the solution will exhibit a pale rose colour when heated, which disappears on cooling. 8. A solution of equal parts of sulphate of copper and muriate of ammonia, gives a yellow colour when heated, that disappears when cold. Sympathetic inks have been proposed as the instruments of secret correspondence; but they are of little use in this respect, because the properties change by a few days remaining on the paper; most of them have more or less of a tinge when thoroughly dry; and none of them resist the test of heating the paper till it begins to be scorched. Nitrate of silver for a surface impregnated with carbonate of soda, and muriate of gold for one impregnated with proto-muriate of tin, form good indelible inks."

FERMENTATION.

The word fermentation expresses the changes which animal and vegetable matter undergoes spontaneously when the principle of life has departed from it, or when its powers are suspended in individual parts. This is at once a process of destruction and of reproduction; for although there is not produced again a regularly organised structure, there is the production of new substance, different from that which characterised the organic body previous to the change taking place. The following case will serve to illustrate the nature of fermentation and its various stages:—If a quantity of grape juice be put into a vessel, and allowed to stand for some time, only exposed to the ordinary temperature of summer, the following phenomena will be observed: the liquor becomes muddy; an internal motion is observable, and sometimes the temperature may be found to rise; air bubbles rise to the surface, occasioning a bubbling noise when they break; and the bulk of the liquid being increased, it has a tendency to boil over. From this circumstance, the process is called fermentation, from the Latin word *fervere*, to boil. The bubbles created rise to the surface involved in a viscid matter, the whole resembling froth, which, parting with the air, subsides to the bottom, and the liquor becomes tranquil and transparent. This viscid matter is well known under the name of *yeast* or *barm*, and it has the property of exciting fermentation in bodies not otherwise at the moment predisposed to it. The reason of this has not been properly explained.

The grape juice has now been entirely changed into an intoxicating liquor, the base of which is alcohol, and this process is termed *vinous fermentation*. If this liquor be kept for some time at about 75°, a new series of phenomena will take place. Providing there be a large quantity of it, the temperature may perhaps rise fifteen degrees. A slight motion takes place, accompanied with the disengagement of a small quantity of gas; and floating filaments or shreds begin to thicken in the liquid, collecting into a gelatinous cake. This is indicative of another change. The vinous flavour and the alcoholic or intoxicating quality has disappeared, whilst the liquid has become at once sour and transparent. In short, the wine has become vinegar, called in Latin *acetum*; and the process is called the *acetous* fermentation.

Let this vinegar be kept for a length of time, and another, and from the previous quality of the liquor, unexpected, change takes place. It becomes mantled with a green mould; the acidity and pungent acid smell disappear, and a fœtid odour becomes perceptible. This proceeds from the rottenness of the vegetable matter present, and the change is called the *putrifactive* fermentation, from the Latin word *putrescere*, to rot. There are thus three different kinds of fermentation, which it may be necessary more fully to explain.

The question arises, What is the nature of the different ferments which produce these changes? The attention of chemists has as yet been particularly directed only to that one called *yeast*, and even our knowledge of it is extremely imperfect. Fabroni, a celebrated chemist, considered yeast as identical with *gluten*, a substance which imparts to wheaten flour the property of forming a tough paste with water, and separable from flour by kneading under water. This gluten, or some modification of it, the above-named chemist considered as the real *vinous* ferment. It is most probably an approximation to it; and it has been conjectured that *ferment* may be as much a proximate principle of vegetables, as sugar or starch, and as extensively diffused throughout nature. A great quantity of carbonic acid is given out during fermentation, and the various changes which take place during the vinous fermentation have been thus briefly described —Some of the carbon and some of the oxygen combine to form carbonic acid; while the remainder of the carbon, the remainder of the oxygen, and the whole of the hydrogen, combine to form alcohol; and we may totally neglect the decomposition of the yeast, it amounting to almost nothing. Thus is this inert, solid, fixed, sweet matter, resolved by a new arrangement of its principles into substances which possess none of these properties, and one of which exerts a control of so singular a nature over the animal economy.

The phenomena attendant upon acetous fermentation we have already alluded to, and the question occurs, What becomes of the alcohol, the most remarkable ingredient of the original vinous liquor, when the latter is changed into vinegar? In answer to this, all that can be said is, that it has been decomposed; its elemental particles, which, united in certain determinate or definite proportions, formed one particular kind of substance, have separated, and combined again in certain other definite proportions, by this means forming an entirely new substance. It is to be observed, that in every case where vinegar is formed, whether it be from solutions of sugar, infusions of malt, or from wines, the greater the quantity of alcohol which existed in the liquor, the stronger will be the vinegar obtained, and the more difficult and slow will be its formation. All vinegars prepared by fermentation contain the following ingredients:—A considerable quantity of water, a little alcohol, some malic acid, a small proportion of sugar, some glutinous and mucilaginous matter, with what is vaguely called extractive matter, besides acetic acid.

The last stage of spontaneous decomposition is the putrifactive fermentation. It is that final change which animal and vegetable life undergoes, the resolution of organic structures into the inanimate materials of which they had been originally composed. The cause of the remarkable fœtor which accompanies it is not well understood, but it in part would appear to arise from the hydrogen gas given out, holding phosphorus and sulphur dissolved, which compounds are remarkably fœtid. It seems also partly to arise from some animal or vegetable matter, or some other substance being held in solution besides.

Upon the other and less important branches of practical chemistry, our limits prevent us from entering; but we have studied to give an account of such processes as can be easily comprehended by those who have carefully perused the number of this work upon Chemistry, and which are calculated to be most extensively useful.

THE END.
